## Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

# Foreword

Sidney Hurwitz, MD

After 15 years of practicing pediatrics and at 40 years of age, Dr. Sidney Hurwitz returned to Yale University School of Medicine to pursue a residency in dermatology and, subsequently, to embark on a career dedicated to the advancement of research, knowledge, and treatment of skin disorders in the young. During the next 25 years, Dr. Hurwitz became a legend in pediatric dermatology as Clinical Professor of Pediatrics and Dermatology at Yale University School of Medicine. He was a founder and President of both the Society for Pediatric Dermatology (U.S.) and the International Society of Pediatric Dermatology, and an author of more than 100 articles on childhood skin diseases and two single-authored textbooks, *The Skin and Systemic Disease in Children* and *Clinical Pediatric Dermatology*, first published in 1981. The first edition took 6 years of nights, weekends, and holidays, and the second edition 4 years. He dedicated the texts to his family: his wife, Teddy, and three daughters, Wendy, Laurie, and Alison. Dr.

Hurwitz died of overwhelming viral pneumonia at the age of 67 in November 1995, during his tenure as Honorary President of the International Society of Pediatric Dermatology. At the International Congress, Dr. Hurwitz's many contributions were recognized, including his textbook *Clinical Pediatric Dermatology*, recognized throughout the world as "the classic" in our field. He embraced us all with his ready smile, warmth, affection, and friendship. Sidney Hurwitz was a role model for all of us.

Drs. Amy S. Paller and Anthony J. Mancini share and embrace Dr. Hurwitz's vision of their specialty. As he did, they revel in providing clinical care to children of all ages, in the mentoring of future pediatric dermatologists, and in their love of learning, teaching, and collaborating with colleagues. True to the example set by Dr. Hurwitz, both Drs. Paller and Mancini have served the Society for Pediatric Dermatology in leadership roles.

Dr. Paller has contributed to the specialty as a National Institutes of Health-funded bench scientist and leading clinical investigator, in addition to her 30 years of practice in pediatric dermatology. She has a busy international and national lectureship schedule and has published more than 400 peer-reviewed papers and chapters, as well as four textbooks, among them *Clinical Pediatric Dermatology*. In common with Dr. Hurwitz, Dr. Paller relishes her years of working with young pediatric dermatologists. Dr. Paller served for 16 years as Head of the Division of Pediatric Dermatology at the former Children's Memorial Hospital in Chicago, following in the footsteps of her teacher and mentor, Dr. Nancy B. Esterly. She currently serves as the Walter J. Hamlin Professor and Chair of Dermatology and Professor of Pediatrics at Northwestern University. Dr. Paller has received several national and local awards for her mentorship and scholarship.

Dr. Mancini became Head of the Division of Pediatric Dermatology at Northwestern University and Children's Memorial Hospital (now Ann and Robert H. Lurie Children's Hospital of Chicago) in 2004 and is Professor of Pediatrics and Dermatology. Following in the footsteps of his mentors, he has dedicated his career to pediatric and dermatology education, as well as patient care and clinical research. He directs the pediatric dermatology fellowship program, established in 1983 as the first fellowship program in the country, and has published numerous scientific papers, chapters, and three textbooks. One of his greatest senses of accomplishment is that of mentoring his U.S.-trained and international pediatric dermatology fellows, as well as the pediatric residents at Children's Memorial Hospital, who have recognized Dr. Mancini with the Faculty Excellence in Education award for 13 years.

It is fitting that Drs. Paller and Mancini, authors of the third, fourth, and now fifth edition of *Clinical Pediatric Dermatology*, continue to immortalize Dr. Hurwitz's legacy.

# Preface

Amy S. Paller, MD

Anthony J. Mancini, MD

We were truly honored when initially asked to consider updating *Hurwitz Clinical Pediatric Dermatology*. Dr. Hurwitz was a true icon of our specialty and one of its founding fathers. Thanks to Dr. Hurwitz, the widely recognizable book sits on many a shelf and has educated and enlightened pediatricians, dermatologists, family practitioners, medical students, residents, nurses, and other allied pediatric care providers for decades. It is our hope that this tradition will continue, and we have made every effort to maintain the practicality, relevance, and usability of the text.

What lies between these covers will be familiar, but with many additions. The field of pediatric dermatology has continued to expand since our last edition. The molecular bases for many established skin diseases, as well as syndromes with cutaneous features, continue to be elucidated. Several new disease and syndrome associations have been recognized and described. The therapeutic armamentarium for cutaneous disease has broadened, with further elucidation of mechanisms of disease and, as a result, several newer classes of drugs available to the clinician. We have strived to maintain a text that is a marriage between cutting-edge review and practical clinical application, while maintaining the flavor of Dr. Hurwitz's first two editions and our third and fourth editions, each of them a balance between narrative text, useful tables, and vivid clinical photographs.

Several new features have been added to this fifth edition, including a downloadable ebook with the printed edition and over 350 new clinical images. We have updated the section on atopic dermatitis to reflect our growing understanding of underlying barrier defects and immune activation, which is starting to impact pediatric management. The numerous recent discoveries about the genetic basis underlying the ichthyoses, ectodermal defects, and mosaic gene disorders, many based on studies with whole exome sequencing, are now included. New directions, such as the use of stem cell and cell therapy, as well as recombinant protein, for treating epidermolysis bullosa are also touched on. Our discussion of treatment for pediatric head lice reflects the multitude of new therapy options, and we have expanded the discussion of viral exanthematous diseases, including the resurgence in measles infections and the broadened scope of manifestations related to enteroviral illnesses. The section on Epstein–Barr virus infections has been expanded, including an added section on acute

genital ulceration related to this and other organisms. In alignment with the explosive gains in knowledge about pediatric vascular lesions, there are expanded sections on oral and topical beta blocker therapy for infantile hemangioma and hemangioma syndrome associations, and an updated discussion of vascular malformations and several more recently elucidated syndrome associations. There is an updated discussion of the contemporary pediatric acne classification, acne presenting at various ages in childhood, and available acne therapies. Finally, our discussion of systemic disorders reflects the growing number of effective anti-inflammatory medications. The references have been extensively updated in our companion online edition, leaving only some excellent reviews and landmark articles to allow for more complete textual content for our readers of the print version.

We continue to be indebted to several individuals, without whom this work would not have been possible. First and foremost, we thank Dr. Sidney Hurwitz, whose vision, dedication, and enthusiasm for the specialty of pediatric dermatology lives on as a legacy in this text, initially published in 1981. We are indebted to Teddy Hurwitz, his wife, who entrusted to us the ongoing tradition of this awesome project; to Dr. Alvin Jacobs, a “father” of pediatric dermatology who kindled the flame of the specialty in both of us through his teaching at Stanford; to Dr. Nancy B. Esterly, the “mother” of pediatric dermatology, whose superb clinical acumen and patient care made her the perfect role model for another female physician who yearned to follow in her footsteps; and to Dr. Alfred T. Lane, who believed in a young pediatric intern and mentored him through the process of becoming a mentor himself.

We are also indebted to the staff at Elsevier, most notably Russell Gabbedy and Alex Mortimer, who worked tirelessly through this edition to again meet the many demands of two finicky academicians; to our patients, who continue to educate us on a daily basis and place their trust in us to provide them care; to the clinicians who referred many of the patients seen in these pages; to our pediatric dermatology fellows and nurses, who contribute enormously through assistance with taking and archiving our many clinical photographs; and to our families, whose understanding, sacrifice, support, and unconditional love made this entire endeavor possible.

# *Dedication*

Our Families:

Etahn	Nicki
Josh	Mallory
Max	Chris
&	Mack
Ben	&
	Alex

whose ongoing patience, understanding, support and  
personal sacrifice enabled us to  
complete this project.

And to the memory of

Sidney Hurwitz, MD,  
a role model par excellence

# An Overview of Dermatologic Diagnosis and Procedures

Accurate diagnosis of cutaneous disease in infants and children is a systematic process that requires careful inspection, evaluation, and some knowledge of dermatologic terminology and morphology to develop a prioritized differential diagnosis. The manifestations of skin disorders in infants and young children often vary from those of the same diseases in older children and adults. The diagnosis may be obscured, for example, by different reaction patterns or a tendency toward easier blister formation. In addition, therapeutic dosages and regimens often differ from those of adults, with medications prescribed on a “per kilogram” (/kg) basis and with liquid formulations.

Nevertheless, the same basic principles that are used to detect disorders affecting viscera apply to the detection of skin disorders. An adequate history should be obtained, a thorough physical examination performed, and, whenever possible the clinical impression verified by appropriate laboratory studies. The easy visibility of skin lesions all too often results in a cursory examination and hasty diagnosis. Instead, the entire skin should be examined routinely and carefully, including the hair, scalp, nails, oral mucosa, anogenital regions, palms, and soles, because visible findings often hold clues to the final diagnosis.

The examination should be conducted in a well-lit room. Initial viewing of the patient at a distance establishes the overall status of the patient and allows recognition of distribution patterns and clues to the appropriate final diagnosis. This initial evaluation is followed by careful scrutiny of primary and subsequent secondary lesions in an effort to discern the characteristic features of the disorder.

Although not always diagnostic, the morphology and configuration of cutaneous lesions are of considerable importance to the classification and diagnosis of cutaneous disease. A lack of understanding of dermatologic terminology commonly poses a barrier to the description of cutaneous disorders by clinicians who are not dermatologists. Accordingly, a review of dermatologic terms is included here (**Table 1-1**). The many examples to show primary and secondary skin lesions refer to specific figures in the text that follows.

## Configuration of Lesions

A number of dermatologic entities assume annular, circinate, or ring shapes and are interpreted as ringworm or superficial fungal infections. Although tinea is a common annular dermatosis of childhood, there are multiple other disorders that must be included in the differential diagnosis of ringed lesions including pityriasis rosea, seborrheic dermatitis, nummular eczema, lupus erythematosus, granuloma annulare, psoriasis, erythema multiforme, erythema annulare centrifugum, erythema migrans, secondary syphilis, sarcoidosis, urticaria, pityriasis alba, tinea versicolor, lupus vulgaris, drug eruptions, and cutaneous T-cell lymphoma.

The terms *arciform* and *arcuate* refer to lesions that assume arc-like configurations. Arciform lesions may be seen in erythema multiforme, urticaria, pityriasis rosea, and bullous dermatosis of childhood.

Lesions that tend to merge are said to be *confluent*. Confluence of lesions is seen, for example, in childhood exanthems, *Rhus* dermatitis, erythema multiforme, tinea versicolor and urticaria.

Lesions localized to a dermatome supplied by one or more dorsal ganglia are referred to as *dermatomal*. Herpes zoster classically occurs in a dermatomal distribution.

*Discoid* is used to describe lesions that are solid, moderately raised, and disc-shaped. The term has largely been applied to discoid lupus erythematosus, in which the discoid lesions usually show atrophy and dyspigmentation.

Discrete lesions are individual lesions that tend to remain separated and distinct. *Eczematoid* and *eczematous* are adjectives relating to eczema and suggest inflammation with a tendency to thickening, oozing, vesication, and/or crusting.

Grouping and clustering are characteristic of vesicles of herpes simplex or herpes zoster, insect bites, lymphangioma circumscriptum, contact dermatitis, and bullous dermatosis of childhood.

Guttate or drop-like lesions are characteristic of flares of psoriasis in children and adolescents that follow an acute upper respiratory tract infection, usually streptococcal.

*Gyrate* refers to twisted, coiled, or spiral-like lesions, as may be seen in patients with urticaria and erythema annulare centrifugum.

*Iris* or target-like lesions are concentric ringed lesions characteristic of erythema multiforme. The classic “targets” in this condition are composed of a central dusky erythematous papule or vesicle, a peripheral ring of pallor, and then an outer bright red ring.

*Keratosis* refers to circumscribed patches of horny thickening, as seen in seborrheic or actinic keratoses, keratosis pilaris, and keratosis follicularis (Darier disease). *Keratotic* is an adjective pertaining to keratosis and commonly refers to the epidermal thickening seen in chronic dermatitis and callus formation.

The *Koebner phenomenon* or *isomorphic response* refers to the appearance of lesions along a site of injury. The linear lesions of warts and molluscum contagiosum, for example, occur from autoinoculation of virus from scratching; those of *Rhus* dermatitis (poison ivy) result from the spread of the plant's oleoresin. Other examples of disorders that show a Koebner phenomenon are psoriasis, lichen planus, lichen nitidus, pityriasis rubra pilaris, and keratosis follicularis (Darier disease).

Lesions in a linear or band-like configuration appear in the form of a line or stripe and may be seen in epidermal nevi, Conradi syndrome, linear morphea, lichen striatus, striae, *Rhus* dermatitis, deep mycoses (sporotrichosis or coccidioidomycosis), incontinentia pigmenti, pigment mosaicism, porokeratosis of Mibelli, or factitial dermatitis. In certain genetic and inflammatory disorders, such linear configurations represent the lines of Blaschko, which trace various clones of embryonic cells and, as such, represent a form of cutaneous mosaicism. This configuration presents as a linear pattern on the extremities, wavy or S-shaped on the lateral trunk, V-shaped on the central trunk, and varied patterns on the face and scalp.

*Moniliform* refers to a banded or necklace-like appearance. This is seen in monilethrix, a hair deformity characterized by beaded nodularities along the hair shaft.

*Multiform* refers to disorders in which more than one variety or shape of cutaneous lesions occurs. This configuration is seen in patients with erythema multiforme, early Henoch–Schönlein purpura, and polymorphous light eruption.

*Nummular* means coin-shaped and is usually used to describe nummular dermatitis.

*Polyyclic* refers to oval lesions containing more than one ring, as commonly is seen in patients with urticaria.

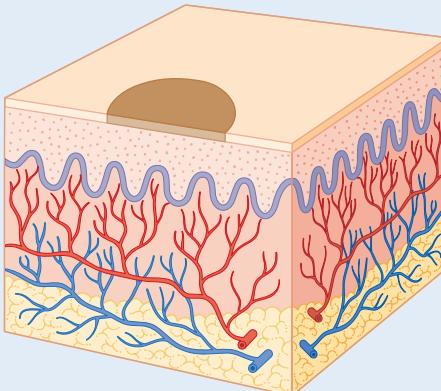

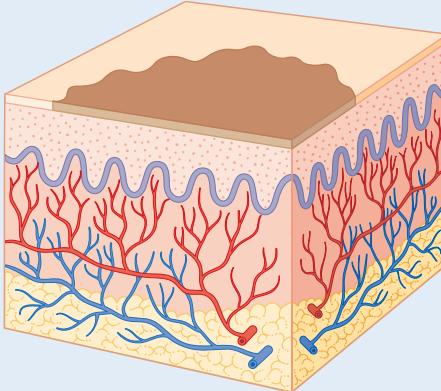

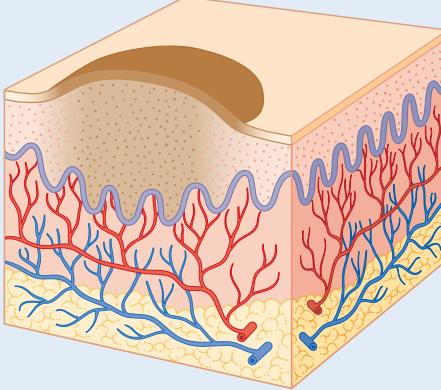

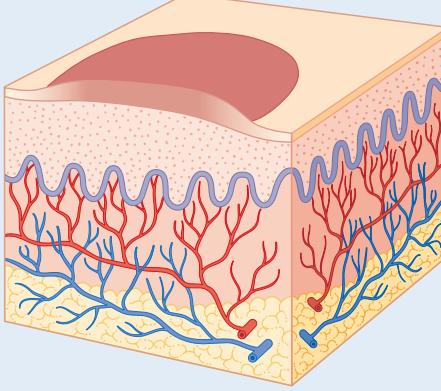

A reticulated or net-like pattern may be seen in erythema ab igne, livedo reticularis, cutis marmorata, cutis marmorata telangiectatica congenita, and lesions of confluent and reticularized papillomatosis.

*Serpiginous* describes the shape or spread of lesions in a serpentine or snake-like configuration, particularly those of cutaneous larva migrans (creeping eruption) and elastosis perforans serpiginosa.

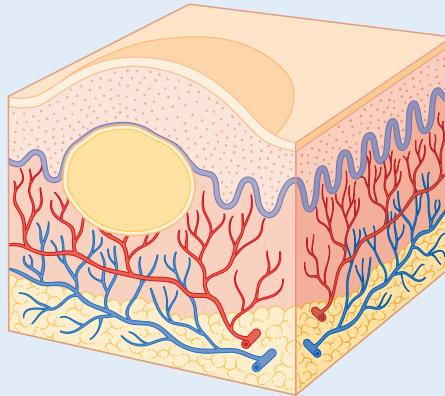

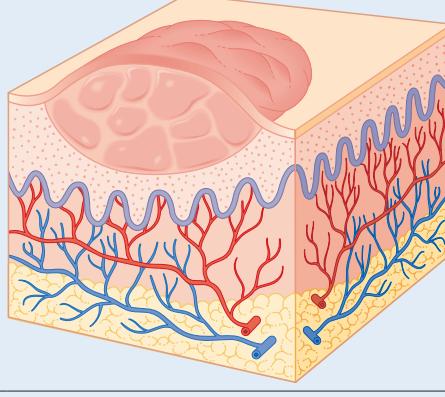

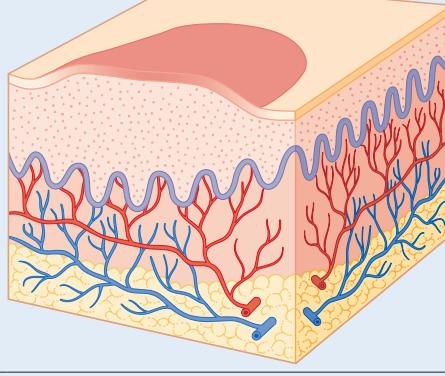

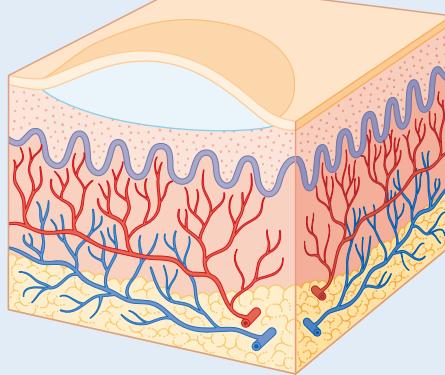

Umbilicated lesions are centrally depressed or shaped like an umbilicus or navel. Examples include lesions of molluscum contagiosum, varicella, vaccinia, variola, herpes zoster, and Kaposi varicelliform eruption.

*Text continued on p. 7*

**Table 1-1** Glossary of Dermatologic Terms

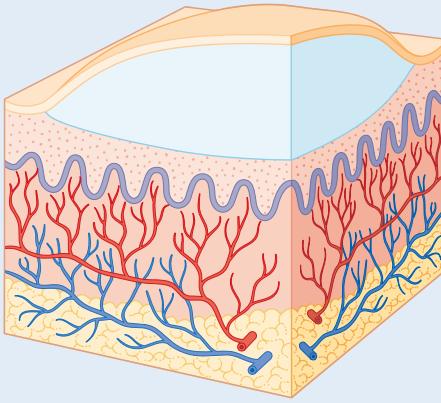

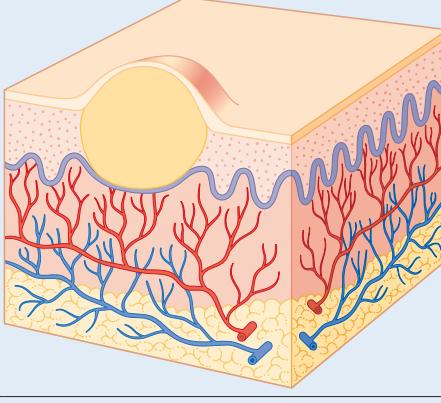

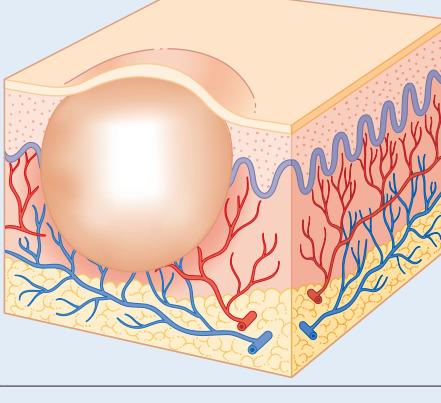

Lesion	Description	Illustration	Examples
<b>PRIMARY LESIONS</b>			
Macule	Flat, circumscribed change of the skin. It may be of any size, although this term is often used for lesions <1 cm. A macule may appear as an area of hypopigmentation or as an area of increased coloration, most commonly brown (hyperpigmented) or red (usually a vascular abnormality). It is usually round but may be oval or irregular; it may be distinct or may fade into the surrounding area.		Ephelides; lentigo (see Fig. 11-41); flat nevus (see Fig. 9-1); and tinea versicolor (see Fig. 17-35).
Patch	Flat, circumscribed lesion with color change that is >1 cm in size.		Mongolian spot (see Fig. 11-57); port wine stain (see Fig. 12-57); nevus depigmentosus (see Fig. 11-22); larger café-au-lait spot (see Fig. 11-43); and areas of vitiligo (see Figs. 11-1 through 11-10).
Papule	Circumscribed, nonvesicular, nonpustular, elevated lesion that measures <1 cm in diameter. The greatest mass is above the surface of the skin. When viewed in profile it may be flat-topped, dome-shaped, acuminate (tapering to a point), digitate (finger-like), smooth, eroded, or ulcerated. It may be covered by scales, crusts, or a combination of secondary features.		Elevated nevus (see Fig. 9-4); verruca (see Fig. 15-17); molluscum contagiosum (see Fig. 15-40); perioral dermatitis (see Fig. 8-20); and individual lesions of lichen planus (see Fig. 4-43).
Plaque	Broad, elevated, disk-shaped lesion that occupies an area of >1 cm. It is commonly formed by a confluence of papules.		Psoriasis (see Fig. 4-4); lichen simplex chronicus (neurodermatitis) (see Fig. 3-37); granuloma annulare (see Fig. 9-58); nevus sebaceus (see Figs. 9-41 through 9-44); and lesions of lichen planus (see Fig. 4-45).

**Table 1-1** Glossary of Dermatologic Terms (Continued)

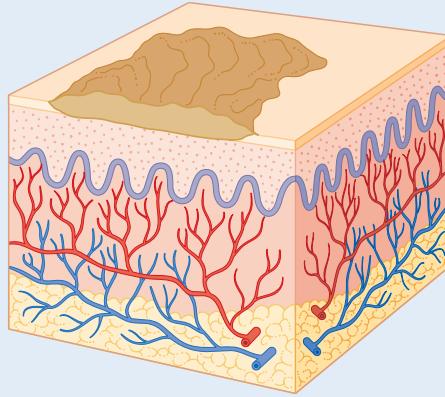

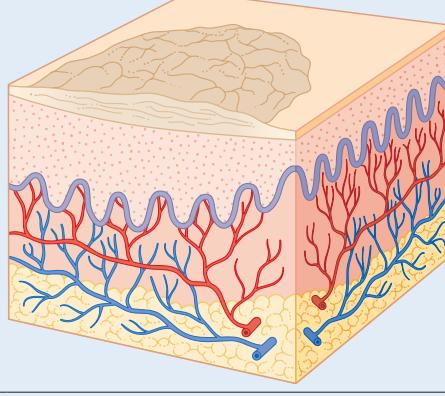

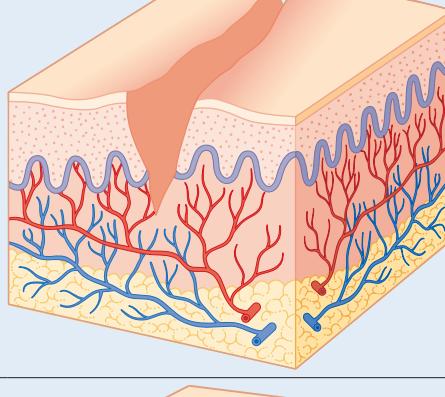

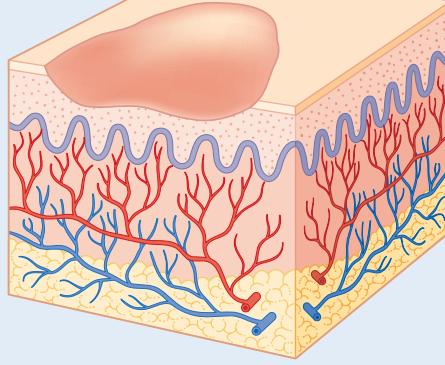

Lesion	Description	Illustration	Examples
Nodule	Circumscribed, elevated, usually solid lesion that measures 0.5 to 2 cm in diameter. It involves the dermis and may extend into the subcutaneous tissue with its greatest mass below the surface of the skin.		Erythema nodosum (see Figs. 20-44 and 20-45); pilomatrixoma (see Fig. 9-48); subcutaneous granuloma annulare (see Fig. 9-60); and nodular scabies (see Fig. 18-9).
Tumor	Deeper circumscribed solid lesion of the skin or subcutaneous tissue that measures >2 cm in diameter. It may be benign or malignant.		Deep hemangioma (see Fig. 12-7) and plexiform neurofibroma (Fig. 11-50).
Wheal	Distinctive type of elevated lesion characterized by local, superficial, transient edema. White to pink or pale red, compressible, and evanescent, they often disappear within a period of hours. They vary in size and shape.		Darier sign of mastocytosis (see Fig. 9-52); urticarial vasculitis (see Fig. 21-14); and various forms of urticaria (see Fig. 20-2).
Vesicle	Sharply circumscribed, elevated, fluid-containing lesion that measures ≤1 cm in diameter.		Herpes simplex (see Figs. 2-47, 15-10 and 15-11); hand-foot-and-mouth disease (see Fig. 16-30); pompholyx (see Fig. 3-41); varicella (see Fig. 16-1); and contact dermatitis (see Fig. 3-57).

Continued on following page

**Table 1-1** Glossary of Dermatologic Terms (Continued)

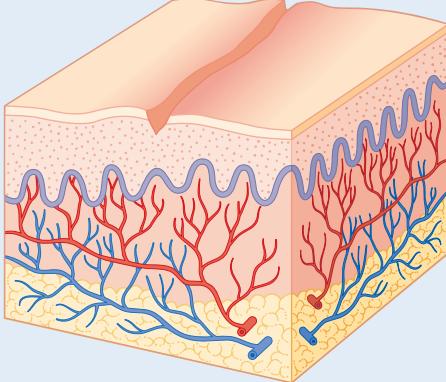

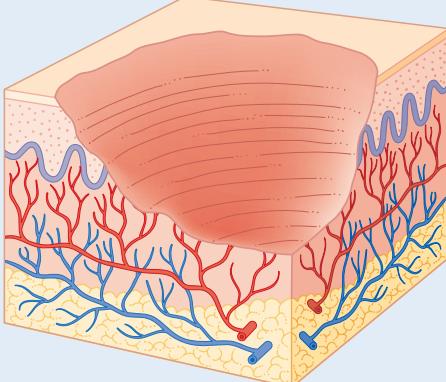

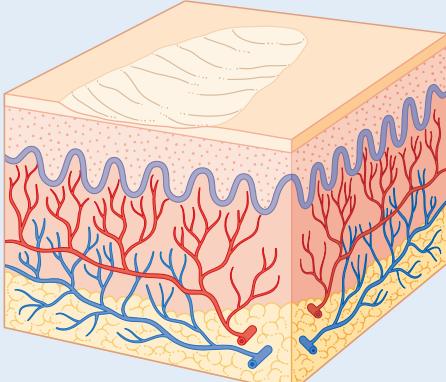

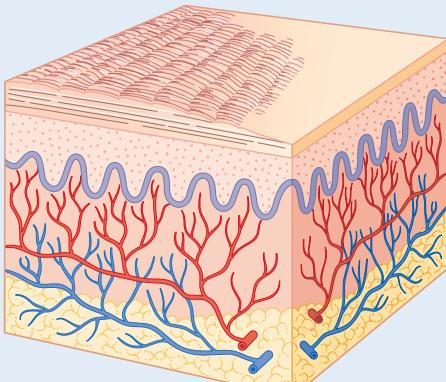

Lesion	Description	Illustration	Examples
Bulla	Larger, circumscribed, elevated, fluid-containing lesion that measures >1 cm in diameter.		Blistering distal dactylitis (see Fig. 14-21); bullous pemphigoid (see Fig. 13-26); chronic bullous disease of childhood (see Fig. 13-29); bullous systemic lupus erythematosus (see Fig. 13-32); and epidermolysis bullosa (see Fig. 13-4).
Pustule	Circumscribed elevation <1 cm in diameter that contains a purulent exudate. It may be infectious or sterile.		Folliculitis (see Fig. 14-11); transient neonatal pustular melanosis (see Fig. 2-17); pustular psoriasis (see Fig. 4-22); and infantile acropustulosis (see Fig. 2-19).
Abscess	Circumscribed, elevated lesion >1 cm in diameter, often with a deeper component and filled with purulent material.		Staphylococcal abscess (in a neonate, see Fig. 2-5; in a patient with hyperimmunoglobulinemia E, see Fig. 3-35).
<b>OTHER PRIMARY LESIONS</b>			
Comedone	Plugged secretion of horny material retained within a pilosebaceous follicle. It may be flesh colored (as in closed comedone or whitehead) or slightly raised brown or black (as in open comedone or blackhead). Closed comedones, in contrast to open comedones, may be difficult to visualize. They appear as pale, slightly elevated, small papules without a clinically visible orifice.		Acne comedones (see Figs. 8-3 and 8-4) and nevus comedonicus (see Fig. 9-45).
Burrow	Linear lesion produced by tunneling of an animal parasite in the stratum corneum.		Scabies (see Fig. 18-3) and cutaneous larva migrans (creeping eruption, see Fig. 18-39).
Telangiectasia	Persistent dilation of superficial venules, capillaries, or arterioles of the skin.		Spider angioma (see Fig. 12-86); periungual lesion of dermatomyositis (see Fig. 22-25); and Goltz syndrome (see Fig. 6-15).

**Table 1-1** Glossary of Dermatologic Terms (Continued)

Lesion	Description	Illustration	Examples
<b>SECONDARY LESIONS</b>			
Crust	Dried remains of serum, blood, pus, or exudate overlying areas of lost or damaged epidermis. Crust is yellow when formed by dried serum, green or yellowish-green when formed by purulent exudate, and dark red or brown when formed by bloody exudative serum.		Herpes simplex (see Fig. 15-4); weeping eczematous dermatitis (see Fig. 3-1); and dried honey-colored lesions of impetigo (see Fig. 14-2).
Scale	Formed by an accumulation of compact desquamating layers of stratum corneum as a result of abnormal keratinization and exfoliation of cornified keratinocytes.		Seborrheic dermatitis (greasy and yellowish, see Figs. 3-2 and 3-39); psoriasis (silvery and mica-like, see Fig. 4-1); pityriasis alba (fine and barely visible, see Fig. 3-33); and lamellar ichthyosis (large and adherent, see Fig. 5-10).
Fissure	Dry or moist, linear, often painful cleavage in the cutaneous surface that results from marked drying and long-standing inflammation, thickening, and loss of elasticity of the integument.		Angular cheilitis (see Fig. 17-40) and dermatitis on the plantar aspect of the foot (see Fig. 3-61).
Erosion	Moist, slightly depressed vesicular or bullous lesions in which part or all of the epidermis has been lost. Because erosions do not extend into the underlying dermis or subcutaneous tissue, healing occurs without subsequent scar formation.		Herpes simplex (see Figs. 3-28 and 15-1); epidermolytic ichthyosis in a neonate (see Fig. 5-4); and superficial forms of epidermolysis bullosa (see Fig. 13-7).

*Continued on following page*

**Table 1-1** Glossary of Dermatologic Terms (Continued)

Lesion	Description	Illustration	Examples
Excoriation	Traumatized or abraded (usually self-induced) superficial loss of skin caused by scratching, rubbing, or scrubbing of the cutaneous surface.		Atopic dermatitis (see Fig. 3-9) and acne excoriée (see Fig. 8-19).
Ulcer	Necrosis of the epidermis and part or all of the dermis and/or the underlying subcutaneous tissue.		Pyoderma gangrenosum (see Fig. 25-27) and ulcerated hemangioma of infancy (see Figs. 12-15 and 12-26).
Atrophy	Cutaneous changes that result in depression of the epidermis, dermis, or both. Epidermal atrophy is characterized by thin, almost translucent epidermis, a loss of the normal skin markings, and wrinkling when subjected to lateral pressure or pinching of the affected area. In dermal atrophy the skin is depressed.		Anetoderma (see Fig. 22-53); morphea (see Figs. 22-42 through 22-49); steroid-induced atrophy (see Fig. 3-32); and Goltz syndrome (see Fig. 6-17).
Lichenification	Thickening of the epidermis with associated exaggeration of skin markings. Lichenification results from chronic scratching or rubbing of a pruritic lesion.		Atopic dermatitis (see Fig. 3-8); chronic contact dermatitis (see Fig. 3-53); and lichen simplex chronicus (see Fig. 3-37).

**Table 1-1** Glossary of Dermatologic Terms (Continued)

Lesion	Description	Illustration	Examples
Scar	A permanent fibrotic skin change that develops after damage to the dermis. Initially pink or violaceous, scars are permanent, white, shiny, and sclerotic as the color fades. Although fresh scars often are hypertrophic, they usually contract during the subsequent 6 to 12 months and become less apparent. Hypertrophic scars must be differentiated from keloids, which represent an exaggerated response to skin injury. Keloids are pink, smooth, and rubbery and are often traversed by telangiectatic vessels. They tend to increase in size long after healing has taken place and can be differentiated from hypertrophic scars by the fact that the surface of a keloidal scar tends to extend beyond the area of the original wound.		Keloid (see Fig. 9-83); healed areas of recessive dystrophic epidermolysis bullosa (see Fig. 13-17); acne scarring (see Fig. 8-8), congenital erosive and vesicular dermatosis with reticulated supple scarring (see Fig. 2-21); and amniocentesis scars (see Fig. 2-4).

*Universal (universalis)* implies widespread disorders affecting the entire skin, as in alopecia universalis.

*Zosteriform* describes a linear arrangement along a nerve, as typified by lesions of herpes zoster, although herpes simplex infection can also manifest in a zosteriform distribution.

## Distribution and Morphologic Patterns of Common Skin Disorders

The regional distribution and morphologic configuration of cutaneous lesions are often helpful in dermatologic diagnosis.

Acneiform lesions are those having the form of acne, and *an acneiform distribution* refers to lesions primarily seen on the face, neck, chest, upper arms, shoulders, and back (see Figs. 8-3 through 8-13).

Sites of predilection of atopic dermatitis include the face, trunk, and extremities in young children; the antecubital and popliteal fossae are the most common sites in older children and adolescents (see Figs. 3-1 through 3-12).

The lesions of erythema multiforme may be widespread but have a distinct predilection for the hands and feet (particularly the palms and soles) (see Figs. 20-33 through 20-37).

Lesions of herpes simplex may appear anywhere on the body but have a distinct predisposition for the areas about the lips, face, and genitalia (see Figs. 15-1 through 15-12). Herpes zoster generally has a dermatomal or nerve-like distribution and is usually but not necessarily unilateral (see Figs. 15-13 and 15-14). More than 75% of cases occur between the second thoracic and second lumbar vertebrae. The fifth cranial nerve commonly is involved, and only rarely are lesions seen below the elbows or knees.

Lichen planus often affects the limbs (see Figs. 4-43 through 4-51). Favorite sites include the lower extremities, the flexor surface of the wrists, the buccal mucosa, the trunk, and the genitalia.

The lesions of lupus erythematosus most commonly localize to the bridge of the nose, malar eminences, scalp, and ears, although they may be widespread (see Figs. 22-3 and 22-6). Patches tend to spread at the border and clear in the center with atrophy, scarring, dyspigmentation, and telangiectases. The malar or butterfly rash is neither specific for nor the most common sign of lupus erythematosus; telangiectasia without the accompanying features of erythema, scaling, or atrophy is never a marker of this disorder other than in neonatal lupus.

Molluscum contagiosum is a common viral disorder characterized by dome-shaped skin-colored to erythematous papules, often with a central white core or umbilication (see Figs. 15-35 through 15-45). These papules most often localize to the trunk and axillary areas.

Although molluscum lesions can be found anywhere, the scalp, palms, and soles are rare sites of involvement.

Photodermatoses are cutaneous disorders caused or precipitated by exposure to light. Areas of predilection include the face, ears, anterior "V" of the neck and upper chest, the dorsal aspect of the forearms and hands, and exposed areas of the legs. The shaded regions of the upper eyelids, subnasal, and submental regions tend to be spared. The major photosensitivity disorders are lupus erythematosus, dermatomyositis, polymorphous light eruption, drug photosensitization, and porphyria (see Chapter 19).

Photosensitive reactions cannot be distinguished on a clinical basis from lesions of photocontact allergic conditions. They may reflect internal as well as external photoallergens and may simulate contact dermatitis from airborne sensitizers. Lupus erythematosus can be differentiated by the presence of atrophy, scarring, hyperpigmentation or hypopigmentation, and the presence of periungual telangiectases. Dermatomyositis with swelling and erythema of the cheeks and eyelids should be differentiated from allergic contact dermatitis by the heliotrope hue and other associated changes, particularly those of the fingers (periungual telangiectases and Gottron papules).

Pityriasis rosea begins as a solitary round or oval scaling lesion known as the *herald patch* in 70% to 80% of cases, which may be annular and is often misdiagnosed as tinea corporis (see Figs. 4-38 through 4-41). After an interval of days to 2 weeks, affected individuals develop a generalized symmetrical eruption that involves mainly the trunk and proximal limbs. The clue to diagnosis is the distribution of lesions, with the long axis of these oval lesions parallel to the lines of cleavage in what has been termed a *Christmas-tree pattern*. A common variant, inverse pityriasis rosea, often localizes in the inguinal region, but the parallel nature of the long axis of lesions remains characteristic.

Psoriasis classically consists of round, erythematous, well-margined plaques with a rich red hue covered by a characteristic grayish or silvery-white mica-like (micaceous) scale that on removal may result in pinpoint bleeding (Auspitz sign) (see Figs. 4-1 through 4-10). Although exceptions occur, lesions generally are seen in a bilaterally symmetric pattern with a predilection for the elbows, knees, scalp, and lumbosacral, perianal, and genital regions. Nail involvement, a valuable diagnostic sign, is characterized by pitting of the nail plate, discoloration, separation of the nail from the nailbed (onycholysis), and an accumulation of subungual scale (subungual hyperkeratosis). A characteristic feature of this disorder is the Koebner or isomorphic response in which new lesions appear at sites of local injury.

Scabies is an itchy disorder in which lesions are characteristically distributed on the wrists and hands (particularly the interdigital webs), forearms, genitalia, areolae, and buttocks in older children and

adolescents (see Figs. 18-1 through 18-11). Other family members may be similarly affected or complain of itching. In infants and young children, the diagnosis is often overlooked because the distribution typically involves the palms, soles, and often the head and neck. Obliteration of demonstrable primary lesions (burrows) because of vigorous hygienic measures, excoriation, crusting, eczematization, and secondary infection is particularly common in infants.

Seborrheic dermatitis is an erythematous, scaly or crusting eruption that characteristically occurs on the scalp, face, and postauricular, presternal, and intertriginous areas (see Figs. 3-38 and 3-39). The classic lesions are dull, pinkish-yellow, or salmon colored with fairly sharp borders and overlying yellowish greasy scale. Morphologic and topographic variants occur in many combinations and with varying degrees of severity from mild involvement of the scalp with occasional blepharitis to generalized, occasionally severe erythematous scaling eruptions. The differential diagnosis may include atopic dermatitis, psoriasis, various forms of diaper dermatitis, Langerhans cell histiocytosis, scabies, tinea corporis or capitis, pityriasis alba, contact dermatitis, Darier disease, and lupus erythematosus.

Warts are common viral cutaneous lesions characterized by the appearance of skin-colored small papules of several morphologic types (see Figs. 15-16 through 15-33). They may be elevated or flat lesions and tend to appear in areas of trauma, particularly the dorsal surface of the face, hands, periungual areas, elbows, knees, feet, and genital or perianal areas. Close examination may reveal capillaries appearing as punctate dots scattered on the surface.

## Changes in Skin Color

The color of skin lesions commonly assists in making the diagnosis. Common disorders of brown hyperpigmentation include postinflammatory hyperpigmentation, pigmented and epidermal nevi, café-au-lait spots, lentigines, incontinentia pigmenti, fixed drug eruption, photodermatitis and phytophotodermatitis, melasma, acanthosis nigricans, and Addison disease. Blue coloration is seen in mongolian spots, blue nevi, nevus of Ito and nevus of Ota, and cutaneous neuroblastomas. Cysts, deep hemangiomas, and pilomatricomas often show a subtle blue color, whereas the blue of venous malformations and glomuvenous malformations is often a more intense, dark blue. Yellowish discoloration of the skin is common in infants, related to the presence of carotene derived from excessive ingestion of foods, particularly yellow vegetables containing carotenoid pigments. Jaundice may be distinguished from carotenemia by scleral icterus. Localized yellow lesions may represent juvenile xanthogranulomas, nevus sebaceous, xanthomas, or mastocytomas. Red lesions are usually vascular in origin, such as superficial hemangiomas, spider telangiectases, and nevus flammeus (capillary malformations), or inflammatory, such as the scaling lesions of atopic dermatitis or psoriasis.

Localized lesions with decreased pigmentation may be hypopigmented (decreased pigmentation) or depigmented (totally devoid of pigmentation); Wood lamp examination may help to differentiate depigmented lesions, which fluoresce a bright white, from hypopigmented lesions. Localized depigmented lesions may be seen in vitiligo, Vogt-Koyanagi syndrome, halo nevi, chemical depigmentation, piebaldism, and Waardenburg syndrome. Hypopigmented lesions are more typical of postinflammatory hypopigmentation, pityriasis alba, tinea versicolor, leprosy, nevus achromicus, tuberous sclerosis, and the hypopigmented streaks of pigment mosaicism. A generalized decrease in pigmentation can be seen in patients with albinism, untreated phenylketonuria, and Menkes syndrome. The skin of patients with Chédiak-Higashi and Griscelli syndromes takes on a dull silvery sheen and may show decreased pigmentation.

## Racial Variations in the Skin and Hair

The skin of African-American and other darker-skinned children varies in several ways from that of lighter-skinned children based on genetic background and customs.<sup>1,2</sup> The erythema of inflamed black skin may be difficult to see and likely accounts for the purportedly decreased incidence of macular viral exanthems such as erythema

infectiosum. Erythema in African-American children commonly has a purplish tinge that can be confusing to unwary observers. The skin lesions in several inflammatory disorders such as atopic dermatitis, pityriasis rosea, and syphilis commonly show a follicular pattern in African-American children.

Postinflammatory hypopigmentation and hyperpigmentation occur readily and are more obvious in darker-skinned persons, regardless of racial origin. Pityriasis alba and tinea versicolor are more commonly reported in darker skin types, perhaps because of the easy visibility of the hypopigmented lesions in marked contrast to uninvolved surrounding skin. Lichen nitidus is more apparent and reportedly more common in African-American individuals; lichen planus is reported to be more severe, leaving dark postinflammatory hyperpigmentation. Vitiligo is particularly distressing to patients with darker skin types, whether African-American or Asian, because of the easy visibility in contrast with surrounding skin.

Although darker skin may burn, in general sunburn and chronic sun-induced diseases of adults such as actinic keratosis and carcinomas of the skin induced by ultraviolet light exposure (e.g., squamous cell carcinoma, keratoacanthoma, basal cell carcinoma, and melanoma) have an extremely low incidence in African-Americans and Hispanics. Congenital melanocytic nevi also tend to have a lower tendency to transform to malignancy in darker-skinned individuals. Café-au-lait spots are more numerous and seen more often in African-Americans, although the presence of six or more should still raise suspicion about neurofibromatosis. Dermatoses papulosa nigra commonly develop in adolescents, especially female, of African descent. Mongolian spots occur more often in persons of African or Asian descent. Physiologic variants in children with darker skin include increased pigmentation of the gums and tongue, pigmented streaks in the nails, and Voight-Futcher lines, lines of pigmentary demarcation between the posterolateral and lighter anteromedial skin on the extremities.

Qualities of hair may also differ among individuals of different races. African-American hair tends to tangle when dry and becomes matted when wet. As a result of its naturally curly or spiral nature, pseudofolliculitis barbae is more common in African-Americans than in other groups. Tinea capitis is particularly common in prepubertal African-Americans; the tendency to use oils because of hair dryness and poor manageability may obscure the scaling of tinea capitis. Pediculosis capitis, in contrast, is relatively uncommon in this population, possibly related to the diameter and shape of the hair shaft. Prolonged continuous traction on hairs may result in traction alopecia, particularly with the common practice of making tight corn row braids. The use of other hair grooming techniques such as chemical straighteners, application of hot oils, and use of hot combs increases the risk of hair breakage and permanent alopecia. Frequent and liberal use of greasy lubricants and pomades produces a comedonal and sometimes papulopustular form of acne (pomade acne).

Keloids form more often in individuals of African descent, often as a complication of a form of inflammatory acne, including nodulocystic acne and acne keloidalis nuchae. Other skin disorders reportedly seen more commonly are transient neonatal pustular melanosis, infantile acropustulosis, impetigo, papular urticaria, sickle-cell ulcers, sarcoidosis, and dissecting cellulitis of the scalp. Atopic dermatitis and Kawasaki disease have both been reported most often in children of Asian descent.

## Procedures to Aid in Diagnosis

### BETTER VISUALIZATION

Although most lesions are diagnosed by clinical inspection, several techniques are used to aid in diagnosis. The Wood lamp (black light) is an ultraviolet A (UVA)-emitting device with a peak emission of 365 nm. With the room completely dark and the light held approximately 10 cm from the skin, the examiner can see: (1) more subtle differences in pigmentation and the bright whiteness of vitiligo lesions based on the strong absorbance of the light by melanin; and (2) characteristic fluorescence of organisms such as the pink-orange fluorescence of urine in porphyria (see Chapter 19), the coral red fluorescence of erythrasma, the yellow-orange fluorescence of tinea versicolor, the

green fluorescence of ectothrix types of tinea capitis (e.g., *Microsporum*) (see Chapter 17), and sometimes pseudomonas infection. False-positive assessments can result from detection of other fluorescent objects such as lint, threads, scales, and ointments.

Magnification using a lens or lighted devices such as the otoscope or ophthalmoscope can be used to more easily visualize lesions such as nailfold capillaries, especially after swabbing the skin with alcohol or applying a drop of oil. *Dermoscopy* (also known as *dermatoscopy* or *epiluminescence microscopy*) refers to examination of the skin with a dermatoscope, a handheld magnifier with an embedded light source. Dermoscopy provides more than just magnification, because it allows the viewer to visualize dermal diagnostic clues. In pediatric patients dermoscopy can be particularly useful for reassurance regarding the benign nature of pigmented nevi, visualization of vascular lesions, and hair disorders ranging from shaft defects to alopecia areata.<sup>1–3</sup> Finally, diascopy involves pressing a glass microscope slide firmly over a lesion and watching for changes in appearance. Purpura, which does not blanch with diascopy because the erythrocytes have leaked into tissue, can be distinguished from erythema from vasodilation, which blanches because the pressure from the slides forces the erythrocytes to move out of the compressed vessels. The yellow-brown (“apple jelly”) color of granulomatous lesions (e.g., granuloma annulare, sarcoidosis) persists during diascopy, and the constricted blood vessels of nevus anemicus do not refill when the slides are lifted after diascopy (as do the surrounding normal areas).

Several diagnostic techniques involve procedures to obtain scales or discharge (by scraping or swabbing) for analysis. Scraping can be performed with a sterile surgical or Fomon blade. A Cytobrush<sup>4</sup> or moistened swab<sup>5</sup> can be used for obtaining scales and broken hairs for fungal cultures and may be less frightening for young children (see Chapter 17). Vesicular lesions can be scraped for Tzanck smears and obtaining epidermal material for direct fluorescent analysis and viral (primarily herpes) cultures or to show the cellular content such as eosinophils in the vesicular lesions of incontinentia pigmenti. Potential scabies lesions, especially burrows, can be dotted with mineral oil and scraped vigorously for microscopic analysis, which may reveal live mites, eggs, or feces (see Chapter 18). When looking for superficial fungi, both potassium hydroxide (KOH) wet-mount preparations and cultures are often performed, although KOH examination should be performed in a Clinical Laboratory Improvement Amendments (CLIA)-approved setting (see Chapter 17). For skin lesions the blade or Cytobrush should scrape the active lesional border. For possible tinea capitis it is important to obtain broken (infected) hairs and scales. The Cytobrush technique has been shown to be more effective than scraping,<sup>3</sup> and vigorously rubbing with a moistened cotton swab (either with tap water or the Culturette transport medium) before inoculation into fungal culture medium is well-tolerated, easy, and reliable.<sup>4</sup> Nail scrapings and subungual debris can also be obtained for evaluation; nail clippings can be sent for histopathologic evaluation with special stains to demonstrate fungal elements.

Hair plucks tend to be traumatic for children and often cause hair shaft distortion, but gentle-traction hair pulling yields hair that is appropriate for determining whether alopecia areata is still active (hair-pull test) and for microscopic evaluation of the telogen bulbs of telogen effluvium and the distorted bulb and ruffled cuticle of loose anagen syndrome (see Chapter 7). Cutting the hair shafts may suffice for seeking hair shaft abnormalities via a microscopic trichogram (which may require polarizing light such as to detect trichothiodystrophy) and detecting nits of pediculosis versus hair casts (see Chapter 18).

Patch testing is key to determining or confirming triggers of delayed-type hypersensitivity reactions in children with allergic contact dermatitis (see Chapter 3). Round aluminum (Finn) chambers are taped to the back for 48 hours, and reactions are detected immediately after removal and generally twice thereafter to capture late reactivity. Although a ready-to-apply system is available (TRUE test), expanded testing is often necessary to comprehensively evaluate possible triggers and is usually best performed by dermatologists who have expertise in patch testing more comprehensively.

Although swabs of mucosae and of purulent skin material are appropriate for microbial cultures, obtaining biopsy material for special stains and cultures of suspected deep fungal or mycobacterial

infections is better for pathogen detection (see Therapeutic Procedures section). Biopsies are also important for making a diagnosis based on routine histopathologic, immunofluorescent, and/or immunohistochemical evaluation. For example, immunofluorescent testing is used to delineate the level of cleavage and absent skin proteins in epidermolysis bullosa (see Chapter 13), as well as to define the immune deposits and patterning in immunobullous disorders (see Chapter 13) and Henoch–Schönlein purpura (see Chapter 21); in contrast, immunohistochemistry is important for confirming the diagnosis of Langhans cells in histiocytosis (see Chapter 10) and a variety of cutaneous lymphoproliferative disorders. Clinicopathologic correlation is important, however, and the pathologic result should be questioned (or repeated) if not consistent with clinical findings.

## Therapeutic Procedures

The most common therapeutic procedures in pediatric dermatology are: (1) treatment of warts with cryotherapy; (2) treatment of molluscum with cantharidin or curettage; (3) lesional biopsy or excision; and (4) laser therapy. These techniques should only be performed by trained, experienced practitioners. Phototherapy with ultraviolet B (UVB) light, narrow-band UVB, and UVA light is used occasionally in children and is discussed in Chapter 19.

Cryotherapy involves the application of liquid nitrogen to lesional skin, which causes direct injury. It is most commonly used for warts (see Chapter 15) but can be selectively applied to keloids and molluscum contagiosum. Although spray delivery is possible, application with a cotton swab that is adapted with extra cotton to fit the size of the lesion allows better retention of the liquid nitrogen, provides better avoidance of nonlesional skin, and is less frightening for young children. More pedunculated lesions (or filiform warts) can be treated by grasping the lesion with a forceps and freezing the forceps near the tip rather than the lesion directly. Generally freezing is performed until there is a white ring around the lesion, often with two to three freeze-thaw cycles. Cryotherapy is painful and as a result is generally reserved for children 8 years of age and older. Alternative cryotherapy agents that contain dimethyl ether or chlorodifluoromethane achieve temperatures considerably lower than liquid nitrogen and are not as effective. Potential complications include hypopigmentation and atrophic scarring.

Cantharidin is an extract from the blister beetle, *Cantharis vesicatoria*, that leads to epidermal vesication after application to molluscum contagiosum lesions (see Chapter 15). It is applied precisely to the lesion using a wooden applicator, should not subsequently be occluded, and is rinsed off after 2 to 6 hours. Because the extent of blistering cannot be controlled (with some children developing extensive blisters and others virtually none, even with the same bottle of cantharidin and applicator), lesions near the eyes, on mucosae, and in occluded areas should not be treated with cantharidin. Blistering occurs in 24 to 48 hours, and crusting clears within about a week.

Curettage is a scraping technique used most commonly after topical anesthetic application for physical removal of molluscum contagiosum, especially for larger lesions for which cantharidin is less effective. Curettage can also be used after electrodesiccation (with a hyfrecator) to remove the desiccated tissue, most commonly for removal of a pyogenic granuloma (see Chapter 12). Most pediatric dermatologists avoid use of curettage in younger patients given the associated discomfort.

Biopsies and excisions are performed in pediatric patients as intervention, not just for diagnosis. The decision to remove a lesion therapeutically should be based on the indication and urgency for removal, the age and maturity of the pediatric patient, the location, and the expected cosmetic result. Careful explanation of the procedure to the parent(s) and child is important to allay concerns and manage expectations. If possible, the area to be biopsied or excised can be treated initially with a topical anesthetic cream (such as 4% lidocaine or 2.5% lidocaine/2.5% prilocaine) under a clear occlusive film to minimize any discomfort associated with subsequent injection of deeper anesthesia. Buffering the lidocaine with sodium bicarbonate and use of a 30-gauge needle also help to decrease the pain of injection; once buffered, lidocaine with epinephrine must either be kept refrigerated or

discarded after a week because of accelerated epinephrine degradation. Regional nerve blocks can be used selectively for larger excisions or cryotherapy. Distraction techniques such as conversation, listening to music, or watching a video can also allay fear at almost any age. Punch biopsy is most useful for removing lesions under 6 mm in diameter. For larger lesions and in cosmetically sensitive areas, an elliptical excision is preferred. Elliptical excisions ideally have their long axis following skin lines to minimize tension on the wound and to optimize the ultimate cosmetic appearance of the scar. Shave biopsies are appropriate for the superficial removal of skin tags (acrochordons) and more protuberant small nevi that are cosmetically problematic but can be followed by lesional regrowth and should not be performed if there is any concern about lesional atypia or malignancy. Surgical wounds of 4 mm or larger in diameter should be closed with suture; wounds which are 3 mm or less can be left to heal via secondary intention after hemostasis, although suturing of any lesion often gives a better cosmetic result. Although octylcyanoacrylates such as Dermabond are appropriate for closure of lacerations, the cosmetic result of their use in elective procedures may be suboptimal and is generally not recommended. Deep sutures are often required to close the deeper space of larger/deeper wounds (e.g., >6 mm in diameter) using buried absorbable suture materials. Although a variety of methods are available for closing at the surface, interrupted or running subcuticular suturing with nonabsorbable suture material is most often used. Steri-Strips are often used to further protect the wound from dehiscence.

The most common complications of biopsies and surgical excisions are wound infection, dehiscence, postoperative bleeding or hematoma (especially on the scalp), and contact dermatitis, especially to adhesives and topical antibiotics. Parents should be given clear, written postoperative instructions about keeping dressings in place (and the wound completely dry) for the first 48 hours, appropriate wound care thereafter, limitation in physical activity (generally 4 weeks without sports or gym if an excision), managing potential complications, and when to have sutures removed (typically 7 days for the face and 10 to 14 days on the body and extremities).

Light amplifications by stimulated emission of radiation (lasers) produce intense light energy at a specific wavelength that can be emitted as a pulse or continuous wave to target tissue components for destruction. After absorption of the light, heat is generated and the target tissue is selectively destroyed. This process of selective destruction has been called *selective photothermolysis* and carries the benefit of destruction of the target chromophores (substances that absorb specific wavelengths of light) with minimal damage to surrounding tissues.<sup>5</sup>

By far the most common laser utilized in children is the pulsed-dye laser (PDL; wavelength 585 to 595 nm), which targets hemoglobin and is used for a variety of vascular lesions including capillary malformations (port wine stains, salmon patches), macular (flat) infantile hemangiomas, ulcerated hemangiomas (in which case it helps speed reepithelialization), spider telangiectasias, and even small pyogenic

granulomas.<sup>6</sup> PDL has also been utilized (with more variable response) for inflammatory linear verrucous epidermal nevus, erythematous striae, warts, and even some inflammatory dermatoses such as psoriasis and eczema.

The response of a port wine stain to PDL therapy is variable and may depend on the depth of the dermal capillaries, location of the stain (i.e., central facial stains classically respond less to PDL therapy than lesions on the forehead or peripheral face), size of the stain, and age at the time treatment is initiated. Sequential treatment sessions are often necessary (generally at 4- to 8-week intervals), and multiple treatments may be necessary to achieve significant improvement.<sup>7</sup> Port wine stains located on the extremities tend to require more treatments than those located elsewhere.<sup>8</sup>

Other lasers utilized in pediatric patients include neodymium:yttrium aluminum garnet (Nd:YAG; 1064 nm), alexandrite (755 nm), diode (810 nm), Q-switched ruby (694 nm), and intense pulsed light (555 to 950 nm) lasers, which have shown variable benefit in port wine stains, venous malformations, deeper hemangiomas, and pigmented lesions (mongolian spots, nevus of Ota, Becker melanosis).<sup>5,9</sup> The xenon-chloride excimer laser (308 nm) provides a wavelength similar to narrow-band UVB therapy, with the advantage of being able to selectively treat a more targeted area of the skin. It has been demonstrated useful in psoriasis, vitiligo, and pityriasis alba.<sup>10-12</sup>

## Neonatal Skin

The skin of the infant differs from that of an adult in that it is thinner (40% to 60%), is less hairy, and has a weaker attachment between the epidermis and dermis.<sup>1</sup> In addition, the body surface area-to-weight ratio of an infant is up to five times that of an adult. The infant is therefore at a significantly increased risk for skin injury, percutaneous absorption, and skin-associated infection. Premature infants born before 32 to 34 weeks' estimated gestational age may have problems associated with an immature stratum corneum (the most superficial cell layer in the epidermis), including an increase in transepidermal water loss (TEWL). This increased TEWL may result in morbidity because of dehydration, electrolyte imbalance, and thermal instability. Interestingly, in the majority of premature infants an acceleration of skin maturation occurs after birth such that most develop intact barrier function by 2 to 3 weeks of life.<sup>2</sup> However, in extremely low-birthweight infants, this process may take up to 4 to 8 weeks.<sup>3</sup> In light of the elevated TEWL levels seen in premature infants, a variety of studies have evaluated the use of occlusive dressings or topical emollients in an effort to improve compromised barrier function.<sup>4-7</sup>

The risk of percutaneous toxicity from topically applied substances is increased in infants, especially those born prematurely.<sup>8,9</sup> Percutaneous absorption is known to occur through two major pathways: (1) through the cells of the stratum corneum and the epidermal malpighian layer (the transepidermal route) and (2) through the hair follicle-sebaceous gland component (the transappendageal route). Increased neonatal percutaneous absorption may be the result of the increased skin surface area-to-weight ratio as well as the stratum corneum immaturity seen in premature neonates. Although transdermal delivery methods may be distinctly advantageous in certain settings, extreme caution must be exercised in the application of topical substances to the skin of infants, given the risk of systemic absorption and potential toxicity. Table 2-1 lists some compounds reported in association with percutaneous toxicity in infants and children.

## SKIN CARE OF THE NEWBORN

The skin of the newborn is covered with a grayish-white, greasy material termed *vernix caseosa*. The vernix represents a physiologic protective covering derived partially from secretions of the sebaceous glands and in part as a decomposition product of the infant's epidermis. Vernix contains protein, lipids, and water and provides water-binding free amino acids that facilitate the adaptation from amniotic fluid immersion *in utero* to the dry ambient postnatal state.<sup>10</sup> Although its function is not completely understood, it may act as a natural protective cream to "waterproof" the fetus *in utero*, where it is submerged in the amniotic fluid.<sup>11</sup> Some studies suggest that vernix be left on as a protective coating for the newborn skin and that it be allowed to come off by itself with successive changes of clothing (generally within the first few weeks of life). It has been suggested that vernix-based topical creams may be effective in augmenting stratum corneum repair and maturation in infants and could play a role in the treatment of epidermal wounds.<sup>12</sup>

The skin acts as a protective organ. Any break in its integrity therefore affords an opportunity for initiation of infection. The importance of skin care in the newborn is compounded by several factors:

1. The infant does not have protective skin flora at birth.
2. The infant has at least one and possibly two open surgical wounds (the umbilicus and circumcision site).

3. The infant is exposed to fomites and personnel that potentially harbor a variety of infectious agents.

Skin care should involve gentle cleansing with a nontoxic, nonabrasive neutral material. During the 1950s, the use of hexachlorophene-containing compounds became routine for the skin care of newborns as prophylaxis against *Staphylococcus aureus* infection. In 1971 and 1972, however, the use of hexachlorophene preparations as skin cleansers for newborns was restricted because of studies demonstrating vacuolization in the central nervous system (CNS) of infants and laboratory animals after prolonged application of these preparations.<sup>13</sup> At the minimum, neonatal skin care should include gentle removal of blood from the face and head, and meconium from the perianal area, by gentle rinsing with water. Ideally, vernix caseosa should be removed from the face only, allowing the remaining vernix to come off by itself. However, the common standard of care is for gentle drying and wiping of the newborn's entire skin surface, which is most desirable from a thermoregulatory standpoint. For the remainder of the infant's stay in the hospital nursery, the buttocks and perianal regions should be cleansed with water and cotton or a gentle cloth. A mild soap with water rinsing may also be used at diaper changes if desired.

There is no single method of umbilical-cord care that has been proven to limit colonization and disease. Several methods include local application of isopropyl alcohol, triple dye (an aqueous solution of brilliant green, proflavine, and gentian violet), and antimicrobial agents such as bacitracin or silver-sulfadiazine cream. The routine use of povidone-iodine should be discouraged, given the risk of iodine absorption and transient hypothyroxinemia or hypothyroidism. A safer alternative is a chlorhexidine-containing product.<sup>14</sup>

## Physiologic Phenomena of the Newborn

Neonatal dermatology, by definition, encompasses the spectrum of cutaneous disorders that arise during the first 4 weeks of life. Many such conditions are transient, appearing in the first few days to weeks of life only to disappear shortly thereafter. The appreciation of normal phenomena and their differentiation from the more significant cutaneous disorders of the newborn is critical for the general physician, obstetrician, and pediatrician, as well as for the pediatric dermatologist.

At birth, the skin of the full-term infant is normally soft, smooth, and velvety. Desquamation of neonatal skin generally takes place 24 to 36 hours after delivery and may not be complete until the third week of life. Desquamation at birth is an abnormal phenomenon and is indicative of postmaturity, intrauterine anoxia, or congenital ichthyosis.

The skin at birth has a purplish-red color that is most pronounced over the extremities. Except for the hands, feet, and lips, where the transition is gradual, this quickly changes to a pink hue. In many infants, a purplish discoloration of the hands, feet, and lips occurs during periods of crying, breath holding, or chilling. This normal phenomenon, termed *acrocyanosis*, appears to be associated with an increased tone of peripheral arterioles, which in turn creates vasoconstriction, secondary dilation, and pooling of blood in the venous plexuses, resulting in a cyanotic appearance to the involved areas of the skin. The intensity of cyanosis depends on the degree of oxygen loss and the depth, size, and fullness of the involved venous plexus. Acrocyanosis, a normal physiologic phenomenon, should not be confused with true cyanosis.

**Table 2-1** Reported Hazards of Percutaneous Absorption in Infants and Children

Compound	Product	Toxicity
Alcohols	Skin antiseptic	Cutaneous hemorrhagic necrosis, elevated blood alcohol levels
Aniline	Dye used as laundry marker	Methemoglobinemia, death
Adhesive remover solvents	Skin preparations to aid in adhesive removal	Epidermal injury, hemorrhage, and necrosis
Benzocaine	Mucosal anesthetic (teething products)	Methemoglobinemia
Boric acid	Baby powder, diaper paste	Vomiting, diarrhea, erythroderma, seizures, death
Calcipotriol	Topical vitamin D <sub>3</sub> analog	Hypercalcemia, hypercalcemic crisis
Chlorhexidine	Topical antiseptic	Systemic absorption but no toxic effects
Corticosteroids	Topical anti-inflammatory	Skin atrophy, striae, adrenal suppression
Diphenhydramine	Topical antipruritic	Central anticholinergic syndrome
Lidocaine	Topical anesthetic	Petechiae, seizures
Lindane	Scabicide	Neurotoxicity
Mercuric chloride	Diaper rinses; teething powders	Acrodynia, hypotonia
Methylene blue	Amniotic fluid leak	Methemoglobinemia
N, N-dimethyl- <i>m</i> -toluamide (DEET)	Insect repellent	Neurotoxicity
Neomycin	Topical antibiotic	Neural deafness
Phenolic compounds (pentachlorophenol, hexachlorophene, resorcinol)	Laundry disinfectant, topical antiseptic	Neurotoxicity, tachycardia, metabolic acidosis, methemoglobinemia, death
Phenylephrine	Ophthalmic drops	Vasoconstriction, periorbital pallor
Povidone-iodine	Topical antiseptic	Hypothyroidism
Prilocaine	Topical anesthetic	Methemoglobinemia
Salicylic acid	Keratolytic emollient	Metabolic acidosis, salicylism
Silver sulfadiazine	Topical antibiotic	Kernicterus (sulfa component), agranulocytosis, argyria (silver component)
Tacrolimus	Topical immunomodulator	Elevated blood levels of immunosuppressive medication
Triple dye (brilliant green, gentian violet, proflavine hemisulfate)	Topical antiseptic for umbilical cord	Ulceration of mucous membranes, skin necrosis, vomiting, diarrhea
Urea	Keratolytic emollient	Uremia

## CUTIS MARMORATA

Cutis marmorata is a normal reticulated bluish mottling of the skin seen on the trunk and extremities of infants and young children (Fig. 2-1). This phenomenon, a physiologic response to chilling with resultant dilation of capillaries and small venules, usually disappears as the infant is rewarmed. Although a tendency for cutis marmorata may persist for several weeks or months, this disorder bears no medical significance and treatment generally is unnecessary. In some children cutis marmorata may tend to recur until early childhood, and in patients with Down syndrome, trisomy 18, and the Cornelia de Lange syndrome, this reticulated marbling pattern may be persistent. When the changes are persistent (even with rewarming) and are deep violaceous in color, cutis marmorata telangiectatica congenita (Fig. 2-2; see also Chapter 12) should be considered. In some infants a white negative pattern of cutis marmorata (cutis marmorata alba) may be created by a transient hypertonia of the deep vasculature. Cutis marmorata alba is also a transitory disorder and appears to have no clinical significance.

## HARLEQUIN COLOR CHANGE

Harlequin color change, not to be confused with harlequin ichthyosis (see Chapter 5), is occasionally observed in full-term infants but usually occurs in premature infants. It occurs when the infant is lying on his or her side and consists of reddening of one-half of the body with simultaneous blanching of the other half. Attacks develop suddenly and may persist for 30 seconds to 20 minutes. The side that lies uppermost is paler, and a clear line of demarcation runs along the midline of the body. At times, this line of demarcation may be

**Figure 2-1** Cutis marmorata. Reticulate bluish mottling that resolves with rewarming.

incomplete; when attacks are mild, areas of the face and genitalia may not be involved.

This phenomenon appears to be related to immaturity of hypothalamic centers that control the tone of peripheral blood vessels and has been observed in infants with severe intracranial injury as well as in infants who appear to be otherwise perfectly normal. Although the peak frequency of attacks of harlequin color change generally occurs between the second and fifth days of life, attacks may occur anywhere

**Figure 2-2** Cutis marmorata telangiectatica congenita. Violaceous, reticulate patches with subtle atrophy. These changes did not resolve with rewarming and were associated with mild ipsilateral limb hypoplasia.

from the first few hours to as late as the second or the third week of life.<sup>15</sup>

### BRONZE BABY SYNDROME

*Bronze baby syndrome* is a term used to describe infants who develop a grayish-brown discoloration of the skin, serum, and urine while undergoing phototherapy for hyperbilirubinemia. Although the exact source of the pigment causing the discoloration is not clear, the syndrome usually begins 1 to 7 days after the initiation of phototherapy, resolves gradually over a period of several weeks after phototherapy is discontinued, and appears to be related to a combination of photoisomers of bilirubin or biliverdin or a photoproduct of copper-porphyrin metabolism.<sup>16–18</sup> Infants who develop bronze baby syndrome usually have modified liver function, particularly cholestasis, of various origins.<sup>19</sup> Although not all babies with cholestasis develop bronze baby syndrome during phototherapy, those that do should be investigated for underlying liver disease.<sup>20</sup> The disorder should be differentiated from neonatal jaundice, cyanosis associated with neonatal pulmonary disorders or congenital heart disease, an unusual progressive hyperpigmentation (universal-acquired melanosis, the “carbon baby” syndrome),<sup>21</sup> and chloramphenicol intoxication (the “gray baby” syndrome), which is a disorder in infants with immature liver function who are unable to conjugate chloramphenicol and is characterized by elevated serum chloramphenicol levels, progressive cyanosis, abdominal distention, hypothermia, vomiting, irregular respiration, and vasomotor collapse.<sup>22</sup> A distinctive purpuric eruption on exposed skin has also been described in newborns receiving phototherapy and is possibly related to a transient increase in circulating porphyrins.<sup>23</sup> This condition, however, is unlikely to be confused with bronze baby syndrome.

### Cephalohematoma

A cephalohematoma is a subperiosteal hematoma overlying the calvarium. These lesions are more common after prolonged labor,

**Figure 2-3** Cephalohematoma. Note the sharp demarcation at the midline.

instrument-assisted deliveries, and abnormal presentations. They usually develop over the first hours of life and present as subcutaneous swellings in the scalp. They do not cross the midline (Fig. 2-3), because they are limited to one cranial bone, which helps to distinguish them from caput succedaneum (see the next paragraph). Occasionally, a cephalohematoma may occur over a linear skull fracture. Other potentially associated complications include calcification (that may persist radiographically for years), hyperbilirubinemia, and infection. Although infected lesions (which are rare) may require aspiration,<sup>24</sup> most lesions require no therapy with spontaneous resorption and resolution occurring over several months.

### Caput Succedaneum

Caput succedaneum is a localized edema of the newborn scalp related to the mechanical forces involved in parturition. It is probably related to venous congestion and edema secondary to cervical and uterine pressure, and as such is more common with prolonged parturition and seen most often in primigravidae. Caput succedaneum presents as a boggy scalp mass and may result in varying degrees of bruising and necrosis in addition to the edema, at times with tissue loss. In distinction to cephalohematoma, caput succedaneum lesions often cross the midline. These lesions tend to resolve spontaneously over 48 hours, and treatment is generally unnecessary. One possible complication in cases of severe caput succedaneum is permanent alopecia. *Halo scalp ring* refers to an annular alopecia that presents in a circumferential ring around the scalp in infants with a history of caput.<sup>25</sup> It represents a pressure necrosis phenomenon, and the hair loss may be transient or, occasionally, permanent.

### Complications from Fetal and Neonatal Diagnostic Procedures

Fetal complications associated with invasive prenatal diagnostic procedures include cutaneous puncture marks, scars or lacerations, exsanguination, ocular trauma, blindness, subdural hemorrhage, pneumothorax, cardiac tamponade, splenic laceration, porencephalic cysts, arteriovenous or ileocutaneous fistulas, digital loss (in 1.7% of newborns whose mothers had undergone early chorionic villus

sampling), musculoskeletal trauma, disruption of tendons or ligaments, and occasionally gangrene. Cutaneous puncture marks, which occur in 1% to 3% of newborns whose mothers have undergone amniocentesis, may be seen as single or multiple 1- to 6-mm pits or dimples on any cutaneous surface of the newborn (Fig. 2-4).<sup>26,27</sup>

Fetal scalp monitoring can result in infection, bleeding, or fontanel puncture, and prenatal vacuum extraction can produce a localized area of edema, ecchymosis, or localized alopecia. The incidence of scalp electrode infection varies from 0.3% to 5.0%, and although local sterile abscesses account for the majority of adverse sequelae, *S. aureus* or Gram-negative infections, cellulitis, tissue necrosis, subgaleal abscess, osteomyelitis, necrotizing fasciitis, and neonatal herpes simplex infections may also occur as complications of this procedure (Fig. 2-5).<sup>28–30</sup> It is not unusual for new parents to be under the false impression that fetal scalp electrodes are the cause of aplasia cutis congenita (ACC; see later in this chapter).

Scalp injuries sustained during the birth process tend to be minor and include lacerations, erosions, and ecchymoses. Injuries of the scalp and face occur in approximately 16% of vacuum-assisted deliveries and in 17% of forceps-assisted deliveries.<sup>31</sup>

Transcutaneous oxygen monitoring (application of heated electrodes to the skin for continuous detection of tissue oxygenation) and pulse oximetry may also result in erythema, tissue necrosis, and first- or second-degree burns. Although lesions associated with transcutaneous oxygen monitoring generally resolve within 48 to 60 hours,

**Figure 2-4** Amniocentesis scars. Multiple depressed scars on the thigh of an infant born to a mother who had amniocentesis during pregnancy. (Courtesy of Lester Schwartz, MD.)

**Figure 2-5** Staphylococcal scalp abscess. Fluctuant, erythematous nodule on the scalp of this 9-day-old infant as a complication of intrauterine fetal monitoring.

persistent atrophic hyperpigmented craters may at times be seen as a complication. Frequent (every 2 to 4 hours) changing of electrode sites and reduction of the temperature of the electrodes to 43° C, however, can lessen the likelihood of this complication.<sup>32,33</sup>

*Anetoderma of prematurity* refers to macular depressions or outpouchings of skin associated with loss of dermal elastic tissue seen in premature infants. Reports suggest that these cutaneous lesions may correlate with placement of electrocardiographic or other monitoring electrodes or leads.<sup>34,35</sup>

Calcinosis cutis may occur on the scalp or chest of infants or children at sites of electroencephalograph or electrocardiograph electrode placement, as a result of diagnostic heel sticks performed during the neonatal period, or after intramuscular or intravenous administration of calcium chloride or calcium gluconate for the treatment of neonatal hypocalcemia. Seen primarily in high-risk infants who receive repeated heel sticks for blood chemistry determinations, calcified nodules usually begin as small depressions on the heels. With time, generally after 4 to 12 months, tiny yellow or white papules appear (Fig. 2-6), gradually enlarge to form nodular deposits, migrate to the cutaneous surface, extrude their contents, and generally disappear spontaneously by the time the child reaches 18 to 30 months of age. Although calcified heel nodules are usually asymptomatic, children may at times show signs of discomfort with standing or wearing shoes. In such instances, gentle cryosurgery and curettage can be both diagnostic and therapeutic. Calcinosis cutis after electroencephalography or electrocardiography is more likely to be seen in infants and young children or individuals where the skin has been abraded and usually disappears spontaneously within 2 to 6 months. It can be avoided by the use of an electrode paste that does not contain calcium chloride, and like calcified heel sticks, they may be treated by gentle cryosurgery and curettage.<sup>36,37</sup>

## Abnormalities of Subcutaneous Tissue

Skin turgor is generally normal during the first few hours of life. As normal physiologic dehydration occurs during the first 3 or 4 days of life (up to 10% of birth weight), the skin generally becomes loose and wrinkled. Subcutaneous fat is normally quite adequate at birth and increases until about 9 months of age, thus accounting for the traditional chubby appearance of the healthy newborn. A decrease or absence of this normal panniculus is abnormal and suggests the possibility of prematurity, postmaturity, or placental insufficiency.

Sclerema neonatorum and subcutaneous fat necrosis (SCFN) are two disorders that affect the subcutaneous fat of the newborn. Although there is considerable diagnostic confusion between these two entities, there are several distinguishing features that enable a clinical differentiation (Table 2-2). Sclerema neonatorum seems to occur significantly less often than SCFN.

**Figure 2-6** Heel stick calcinosis. Firm, pink to yellow papule on the medial plantar heel in an infant who had multiple heel sticks as a newborn.

**Table 2-2** Features of Sclerema Neonatorum and Subcutaneous Fat Necrosis

Sclerema Neonatorum	Subcutaneous Fat Necrosis
Premature infants	Full-term or postmature infants
Serious underlying disease (sepsis, cardiopulmonary disease, diarrhea, or dehydration)	Healthy newborns; may have history of perinatal asphyxia or difficult delivery
Wax-like hardening of skin and subcutaneous tissue	Circumscribed, indurated, erythematous nodules and plaques
Whole body except palms and soles	Buttocks, thighs, arms, face, shoulders
Poor prognosis; high mortality	Excellent prognosis; treat associated hypercalcemia, if present

**Figure 2-7** Subcutaneous fat necrosis. Indurated, erythematous plaques on the shoulders and back of this 1-week-old boy.

## SCLEREMA NEONATORUM

Sclerema neonatorum is a diffuse, rapidly spreading, wax-like hardening of the skin and subcutaneous tissue that occurs in premature or debilitated infants during the first few weeks of life. The disorder, usually associated with a serious underlying condition such as sepsis or other infection, congenital heart disease, respiratory distress, diarrhea, or dehydration, is characterized by a diffuse nonpitting woody induration of the involved tissues. The process is symmetrical, usually starting on the legs and buttocks, and may progress to involve all areas except the palms, soles, and genitalia.<sup>38</sup> As the disorder spreads, the skin becomes cold, yellowish-white, mottled, stony hard, and cadaver-like. The limbs become immobile, and the face acquires a fixed mask-like expression. Infants with this disorder become sluggish, feed poorly, show clinical signs of shock, and in a high percentage of cases die.

Although the etiology of this disorder is unknown, it appears to represent a nonspecific sign of severe illness rather than a primary disease. Infants with this disorder are characteristically small or premature, debilitated, weak, cyanotic, and lethargic. In 25% of cases the mothers are ill at the time of delivery. Exposure to cold, hypothermia, peripheral chilling with vascular collapse, and an increase in the ratio of saturated to unsaturated fatty acids in the triglyceride fraction of the subcutaneous tissue (because of a defect in fatty acid mobilization) have been hypothesized as possible causes for this disorder but lack confirmation.<sup>39</sup>

The histopathologic findings of sclerema neonatorum consist of edema and thickening of the connective tissue bands around the fat lobules. Although necrosis and crystallization of the subcutaneous tissue have been described, these findings are more characteristically seen in lesions of SCFN.

The prognosis of sclerema neonatorum is poor, and mortality occurs in 50% to 75% of affected infants. In a series of 51 infants with sclerema neonatorum in a special-care nursery within a Bangladeshi hospital, the fatality rate was 98%.<sup>40</sup> In infants who survive, the cutaneous findings resolve without residual sequelae. There is no specific therapy, although steroids and exchange transfusion have been used.<sup>38</sup>

## SUBCUTANEOUS FAT NECROSIS

Subcutaneous fat necrosis (SCFN) is a benign, self-limited disease that affects apparently healthy, full-term newborns and young infants. It is characterized by sharply circumscribed, indurated, and nodular areas of fat necrosis (Fig. 2-7). The etiology of this disorder remains unknown but appears to be related to perinatal trauma, asphyxia, hypothermia, and in some instances, hypercalcemia.<sup>41,42</sup> Although the mechanism of hypercalcemia in SCFN is not known, it has been attributed to aberrations in vitamin D or parathyroid homeostasis. Birth asphyxia and meconium aspiration seem to be commonly associated. In one large series, 10 out of 11 infants with SCFN had been delivered via emergency cesarean section for fetal distress, and nine of the 11 had meconium staining of the amniotic fluid.<sup>43</sup> The relation-

ship between SCFN, maternal diabetes, and cesarean section, if any, is unclear. SCFN after ice-bag application for treatment of supraventricular tachycardia has been reported,<sup>44</sup> and it has also been observed after selective head or generalized cooling for hypoxic-ischemic encephalopathy.<sup>45,46</sup>

The onset of SCFN is generally during the first few days to weeks of life. Lesions appear as single or multiple localized, sharply circumscribed, usually painless areas of induration. Occasionally the affected areas may be tender, and infants may be uncomfortable and cry vigorously when they are handled. Lesions vary from small erythematous, indurated nodules to large plaques, and sites of predilection include the cheeks, back, buttocks, arms, and thighs. Many lesions have an uneven lobulated surface with an elevated margin separating it from the surrounding normal tissue. Histologic examination of SCFN reveals larger-than-usual fat lobules and an extensive inflammatory infiltrate, needle-shaped clefts within fat cells, necrosis, and calcification. Magnetic resonance imaging (MRI) reveals decreased T1 and increased T2 signal intensity in affected areas.<sup>47</sup>

The prognosis for SCFN is excellent. Although lesions may develop extensive deposits of calcium, which may liquefy, drain, and heal with scarring, most areas undergo spontaneous resolution within several weeks to months. Hypercalcemia is a rare association, and infants with this finding may require low calcium intake, restriction of vitamin D, and/or systemic corticosteroid therapy. Etidronate therapy has been reported for treatment of recalcitrant SCFN-associated hypercalcemia.<sup>48</sup> Infants should be monitored for several months after delivery, because the onset of hypercalcemia can be delayed for several months.<sup>43,49</sup> Other rare systemic complications may include thrombocytopenia, hypoglycemia, and hypertriglyceridemia, all of which tend to be mild and/or self-limited.

## Miscellaneous Cutaneous Disorders

### MILIARIA

Differentiation of the epidermis and its appendages, particularly in the premature infant, is often incomplete at birth. As a result of this immaturity, a high incidence of sweat-retention phenomena may be seen in the newborn. Miliaria, a common neonatal dermatosis caused by sweat retention, is characterized by a vesicular eruption with subsequent maceration and obstruction of the eccrine ducts. The pathophysiological events that lead to this disorder are keratinous plugging of eccrine ducts and the escape of eccrine sweat into the skin below the level of obstruction (see Chapter 8).

Virtually all infants develop miliaria under appropriate conditions. There are two principal forms of this disorder:

1. Miliaria crystallina (sudamina), which consists of clear superficial pinpoint vesicles without an inflammatory areola;

**Figure 2-8** Miliaria rubra. Multiple, erythematous, pinpoint macules and papules in an infant with atopic dermatitis who was being treated with overapplication of greasy emollients.

**Figure 2-9** Milia. Clustered, small, white papules on the lateral cheek.

2. Miliaria rubra (prickly heat), representing a deeper level of sweat gland obstruction and characterized by small discrete erythematous papules, vesicles, or papulovesicles (Fig. 2-8).

The incidence of miliaria is greatest in the first few weeks of life owing to the relative immaturity of the eccrine ducts, which favors poral closure and sweat retention. A pustular form of miliaria rubra has been observed in association with pseudohypoaldosteronism during salt-losing crises.<sup>50</sup>

Therapy for miliaria is directed toward avoidance of excessive heat and humidity. Light-weight cotton clothing, cool baths, and air conditioning are helpful in the management and prevention of this disorder. Avoidance of emollient overapplication (i.e., in infants with atopic dermatitis) should also be recommended, especially in warm, humid climates or in the winter when infants are bundled under heavy clothing.

## MILIA

Milia, small retention cysts, commonly occur on the face of newborns. Seen in 40% to 50% of infants, they result from retention of keratin within the dermis. They appear as tiny 1- to 2-mm pearly white or yellow papules. Particularly prominent on the cheeks, nose, chin, and forehead, they may be few or numerous and are often grouped (Fig. 2-9). Lesions may occasionally occur on the upper trunk, limbs, penis, or mucous membranes. Although milia of the newborn may persist into the second or third month, they usually disappear spontaneously during the first 3 or 4 weeks of life and accordingly require no therapy. Persistent milia in an unusual or widespread distribution, particularly when seen in association with other defects, may be a manifestation

**Figure 2-10** Sebaceous gland hyperplasia. Yellow-white, pinpoint papules on the nasal tip of this 2-day-old boy.

of hereditary trichodysplasia (Marie-Unna hypotrichosis), dystrophic forms of epidermolysis bullosa, Bazex or Rombo syndromes, or the oral-facial-digital syndrome, type I.

## BOHN NODULES AND EPSTEIN PEARLS

Discrete, 2- to 3-mm round, pearly white or yellow, freely movable elevations at the gum margins or midline of the hard palate (termed *Bohn nodules* and *Epstein pearls*, respectively) are seen in up to 85% of newborns. Clinically and histologically the counterpart of facial milia, they disappear spontaneously, usually within a few weeks of life, and require no therapy.

## SEBACEOUS GLAND HYPERPLASIA

Sebaceous gland hyperplasia represents a physiologic phenomenon of the newborn manifested as multiple, yellow to flesh-colored tiny papules that occur on the nose, cheeks, and upper lips of full-term infants (Fig. 2-10). A manifestation of maternal androgen stimulation, these papules represent a temporary disorder that resolves spontaneously, generally within the first few weeks of life.

## ACNE NEONATORUM

Occasionally infants develop a facial eruption that resembles acne vulgaris as seen in adolescents (Fig. 2-11). Although the etiology of this disorder is not clearly defined, it appears to develop as a result of hormonal stimulation of sebaceous glands that have not yet involuted to their childhood state of immaturity. In mild cases of acne neonatorum, therapy is often unnecessary; daily cleansing with soap and water may be all that is required. Occasionally, mild keratolytic agents or topical antibiotics may be helpful (see Chapter 8). Unusually severe or recalcitrant cases of acne neonatorum warrant investigation for underlying androgen excess.

A facial acneiform eruption in infants has been associated with the saprophytic *Malassezia* species and has been termed *neonatal cephalic pustulosis* (see Chapter 8). Lesions consist of pinpoint papules, papulopustules, or larger pustules, and they are located on the cheeks, chin, and forehead (Fig. 2-12). A correlation may exist between the clinical severity of lesions and the colonization with this fungal saprophyte.<sup>51,52</sup> In these infants, topical antifungal agents may lead to more rapid resolution of lesions.

## ERYTHEMA TOXICUM NEONATORUM

Erythema toxicum neonatorum (ETN), also known as *toxic erythema of the newborn*, is an idiopathic, asymptomatic, benign, self-limiting, cutaneous eruption in full-term newborns. Lesions consist of erythematous macules, papules, and pustules (Fig. 2-13), or a combination of these, and may occur anywhere on the body, especially the forehead, face, trunk, and extremities. The fact that these lesions

**Figure 2-11** Acne neonatorum. Erythematous papules and papulopustules on the cheek.

**Figure 2-12** Neonatal cephalic pustulosis. This 2-day-old male had numerous small and large pustules on the forehead, cheeks, and chin. They cleared rapidly over 1 week with ketoconazole cream.

(which histologically reveal follicular-centered eosinophils) often tend to spare the palms and soles may be explained by the absence of pilosebaceous follicles in these areas.

ETN often initially appears as a blotchy, macular erythema that then develops firm, 1- to 3-mm, pale yellow or white papules and pustules. The erythematous macules are irregular or splotchy in appearance, varying from a few millimeters to several centimeters in diameter. They may be seen in sharp contrast to the surrounding unaffected skin, may blend into a surrounding erythema, or may progress to a confluent eruption.

Although ETN appears most commonly during the first 3 to 4 days of life, it has been seen at birth and may be noted as late as 10 days of age.<sup>53</sup> Exacerbations and remissions may occur during the first 2 weeks of life, and the duration of individual lesions varies from a few hours to several days. The etiology of ETN remains obscure. One study suggested that it represents an immune response to microbial colonization of the skin at the hair follicle.<sup>54</sup> ETN incidence data are variable. Some authors report an incidence as low as 4.5%; others report incidences varying from 31% to 70% of newborns.<sup>55</sup> Two large prospective series of skin findings in newborns (one in the United States and

**Figure 2-13** Erythema toxicum neonatorum. Blotchy, erythematous macules and edematous papules.

one in Turkey) found incidences of 7% and 13.1%, respectively.<sup>56,57</sup> The incidence of ETN clearly appears to increase with increasing gestational age of the infant.<sup>58</sup> No sexual or racial predisposition has been noted.

ETN is usually diagnosed clinically. Skin biopsy, which is rarely necessary, reveals a characteristic accumulation of eosinophils within the pilosebaceous apparatus. The diagnosis can be rapidly differentiated from other newborn pustular conditions by cytologic examination of a pustule smear that with Wright or Giemsa staining reveals a predominance of eosinophils. Affected infants may have a peripheral eosinophilia. Although the eosinophilic response has led some observers to attribute the etiology of this disorder to a hypersensitivity reaction, specific allergens have never been implicated or confirmed.

Since erythema toxicum is a benign, self-limiting, asymptomatic disorder, no therapy is indicated. Occasionally, however, it may be confused with other pustular eruptions of the neonatal period, including transient neonatal pustular melanosis (TNPM), milia, miliaria, and congenital infections including candidiasis, herpes simplex, or bacterial processes. Of these, the congenital infections are the most important diagnostic considerations because of the implications for possible systemic involvement. Table 2-3 lists the differential diagnosis of the newborn with vesicles or pustules.

## EOSINOPHILIC PUSTULAR FOLLICULITIS

Eosinophilic pustular folliculitis (EPF) is an idiopathic dermatosis that occurs in both adults and infants. When it occurs in neonates or young infants, it may be clinically confused with other vesiculopustular disorders. Lesions consist of follicular pustules, most commonly occurring on the scalp and the extremities (Fig. 2-15). They tend to recur in crops, in a similar fashion to acropustulosis of infancy (see below), and some suggest that these conditions may be related.<sup>59,60</sup> As opposed to the adult form of EPF, the infancy-associated type does not reveal lesions grouped in an annular arrangement. EPF tends to present before 14 months of age in the majority of patients.<sup>61</sup> Histologic evaluation reveals an eosinophilic, follicular, inflammatory infiltrate, and peripheral eosinophilia may be present. EPF of infancy appears to be distinct from classic (adult) and human immunodeficiency virus (HIV)-associated EPF, although an infant with HIV and EPF has been reported.<sup>62</sup> Importantly, infantile EPF may occasionally be the presenting sign of hyperimmunoglobulinemia E syndrome (HIES) (see Chapter 3). Treatment for EPF is symptomatic, including topical corticosteroids and antihistamines, with eventual spontaneous resolution by 3 years of age in the majority of patients.<sup>61</sup> Topical tacrolimus may be useful in patients who are unresponsive to topical corticosteroids.<sup>63</sup>

## IMPETIGO NEONATORUM

Impetigo in newborns may occur as early as the second or third day or as late as the second week of life. It usually presents as a superficial

**Table 2-3** Differential Diagnosis of Vesicles or Pustules in a Newborn

Clinical Disorder	Comments
Acrodermatitis enteropathica	Periorificial erosive dermatitis common
Acropustulosis of infancy	Recurrent crops of acral pustules
Behçet syndrome	Oral and genital ulcers; may have cutaneous papules, vesicles, and pustules ( <b>Fig. 2-14</b> )
Eosinophilic folliculitis	Scalp and extremities most common sites
Epidermolysis bullosa	Trauma-induced blistering; bullae and erosions
Erythema toxicum neonatorum	Blotchy erythema, evanescent
Incontinentia pigmenti	XLD; linear and whorled patterns; may be vesicles, as well as warty lesions (hypopigmentation and hyperpigmentation occur later)
Infectious	
Bacterial	
Group A or B streptococci	
<i>Staphylococcus aureus</i>	Superficial blisters rupture easily
<i>Listeria monocytogenes</i>	
<i>Pseudomonas aeruginosa</i>	
Other Gram-negatives	
Fungal	
Candidiasis	Palms and soles involved; nail changes often present
Viral	
Herpes simplex	3 types: SEM, CNS, disseminated
Varicella zoster	
Cytomegalovirus	Blueberry muffin lesions more common
Spirochetal	
Syphilis	Red macules, papules; palm and sole scaling
Langerhans cell histiocytosis	Crusting, erosions, palms and soles, LAD
Miliaria	Especially intertriginous, occluded sites; crystallina type presents with clear vesicles without erythema; rubra type presents with red papules and papulopustules
Neonatal Behçet syndrome	
Neonatal cephalic pustulosis	Acneiform disorder, presenting with numerous pustules on the cheeks, forehead, chin; may respond to topical antifungal agents
Pustular psoriasis	
Scabies	Crusting, burrows; palms and soles usually involved
Transient neonatal pustular melanosis	Mainly affects black skin; peripheral collarettes; pigment persists for months
Urticaria pigmentosa	Stroking leads to urtication (Darier sign)
Vesiculopustular eruption of transient myeloproliferative disorder	Vesicles and pustules (face > elsewhere); usually in setting of trisomy 21

CNS, Central nervous system; LAD, lymphadenopathy; SEM, skin-eyes-mouth; XLD, X-linked dominant.

**Figure 2-14** Behçet syndrome. Shallow ulcerations on the scrotum, foreskin, and glans penis of an infant male with oral erosions and the human leukocyte antigen (HLA)-B51 group genotype. Note the associated papulopustular lesions on the medial thighs and buttocks, another characteristic feature of Behçet syndrome.

**Figure 2-15** Eosinophilic pustular folliculitis. Erythematous papules and pustules on the scalp of an infant female, who was subsequently diagnosed with hyperimmunoglobulinemia E syndrome.

**Figure 2-16** Neonatal *Staphylococcus aureus* pustulosis with multiple pustules in the diaper region. Note some superficial erosions with peripheral collarettes of scale. The culture was positive for *S. aureus*.

vesicular, pustular, or bullous lesion on an erythematous base. Vesicles and bullae are easily denuded, leaving a red, raw, and moist surface, usually without crust formation. Blisters are often wrinkled, contain some fluid, and are easily denuded. Lesions tend to occur on moist or opposing surfaces of the skin, as in the diaper area, groin, axillae, and neck folds. *S. aureus* pustulosis (or neonatal pustulosis) is a characteristic manifestation of cutaneous *S. aureus* infection in the neonate or infant. Patients have small pustules on an erythematous base (Fig. 2-16), often distributed in the diaper region. The lesions denude easily upon swabbing, and culture is positive for *S. aureus*. Streptococci may occasionally be causative. In term or late preterm neonates with localized involvement and without fever or systemic symptoms, evaluation for serious bacterial illness is generally not required, and treatment in the outpatient setting is often sufficient.<sup>64</sup> However, a complete blood cell count and blood culture is advisable given the rare association with bacteremia.

The term *pemphigus neonatorum* is an archaic misnomer occasionally applied to superficial bullous lesions of severe impetigo widely distributed over the surface of the body. However, a transient neonatal form of pemphigus vulgaris does exist and is caused by transplacental passage of antibodies from a mother with the same disease (see Chapter 13).

### SUCKING BLISTERS

Sucking blisters, presumed to be induced by vigorous sucking on the affected part *in utero*, are seen in up to 0.5% of normal newborns as 0.5- to 2-cm oval bullae or erosions on the dorsal aspect of the fingers, thumbs, wrists, lips, or radial aspect of the forearms. These lesions, which must be differentiated from bullous impetigo, epidermolysis bullosa, and herpes neonatorum, resolve rapidly and without sequelae.

### TRANSIENT NEONATAL PUSTULAR MELANOSIS

Transient neonatal pustular melanosis (TNPM) is a benign self-limiting disorder of unknown etiology characterized by superficial vesiculopustular lesions that rupture easily and evolve into hyperpigmented macules (Fig. 2-17). This disorder is seen in fewer than 1% of newborns<sup>65</sup> and occurs most commonly in infants with black skin. Lesions begin as superficial sterile pustules (Fig. 2-18) that rupture easily to leave a collarette of fine, white scale around a small hyperpigmented macule. Although the distribution may be diffuse, common areas of involvement include the inferior chin, forehead, neck, lower back, and shins. Rarely, vesicles that do not progress to pigmented macules may be detected on the scalp, palms, and soles.

Wright-stained smears of the pustules of TNPM, in contrast to lesions of ETN, demonstrate variable numbers of neutrophils, few or

**Figure 2-17** Transient neonatal pustular melanosis. Papules and papulopustules that rupture to leave a collarette of fine scales and eventual hyperpigmentation. (Courtesy of Nancy B. Esterly, MD.)

**Figure 2-18** Transient neonatal pustular melanosis. Tense pustules and collarettes of scale at sites of older lesions.

no eosinophils, and cellular debris. Histopathologic evaluation is usually unnecessary.

TNPM is a benign disorder without associated systemic manifestations, and therapy is unnecessary. The pustular lesions usually disappear within 24–48 h, leaving behind hyperpigmented macules that fade gradually, usually over several weeks to months. Occasionally, newborns may have solely the hyperpigmented macules, in which case it is presumed that the pustular phase occurred (and resolved) *in utero*.

### ACROPUSTULOSIS OF INFANCY

Acropustulosis of infancy, also known as *infantile acropustulosis* (IA), is an idiopathic pustular disorder with onset usually between birth and 2 years of age. It is characterized by recurrent, pruritic, vesiculopustular lesions that recur every few weeks to months. The lesions begin as pinpoint erythematous papules and enlarge into well-circumscribed discrete pustules.<sup>66</sup> They are concentrated on the palms (Fig. 2-19) and soles (Fig. 2-20) and appear in lesser numbers on the dorsal aspect of the hands, feet, wrists, and ankles. Occasional lesions may occur on the face and scalp.

The differential diagnosis of IA includes scabies, dyshidrotic eczema, pustular psoriasis, ETN, TNPM, impetigo, and subcorneal pustular dermatosis. However, the characteristic presentation and course of IA is usually distinctive enough to render a clinical diagnosis. A smear of pustule contents (or histologic evaluation) reveals large numbers of neutrophils and occasionally eosinophils.<sup>66–69</sup> Although the etiology of IA remains unclear, several authors have noted a possible

**Figure 2-19** Acropustulosis of infancy. Multiple tense erythematous papules and pustules on the palm of this 4-month-old girl.

**Figure 2-20** Acropustulosis of infancy. Tense pustules, some of which have ruptured, on the plantar and lateral surfaces of the foot of a 14-month-old female.

association with preceding scabies infestation.<sup>70-72</sup> IA appears to be common in internationally adopted children.<sup>73</sup>

Patients with IA experience fewer and less intense flares of their lesions with time, and the entire process usually subsides within 2 to 3 years. Pruritus, however, may be severe early in the course, making therapy desirable. Possible associations include irritability, sleeplessness, excoriation, and secondary bacterial infection. Systemic antihistamines, usually in high doses, may relieve pruritus. High-potency topical corticosteroids are quite effective for this condition,<sup>70</sup> and given the limited distribution of lesions, the epidermal thickness at affected (acral) sites, and the periodicity of flares, concerns regarding systemic absorption of these medications should be minimal. Dapsone has long been a recommended therapy for severe cases, but the risk-to-benefit ratio of this agent is not generally justified in patients with IA.

#### CONGENITAL EROSION AND VESICULAR DERMATOSIS

Congenital erosive and vesicular dermatosis healing with reticulated supple scarring is an uncommon disorder characterized by erosive and

**Figure 2-21** Congenital erosive and vesicular dermatosis healing with reticulated supple scarring. There is generalized, supple, reticulated scarring. Note also the associated scalp alopecia.

bullous lesions that, as the name implies, are present at birth and heal with characteristic scarring. Although its cause is unknown, it appears to represent a nonhereditary intrauterine event such as infection or amniotic adhesions, or perhaps an unusual healing defect of immature skin. The disorder generally involves skin of the trunk, extremities, scalp, face, and occasionally the tongue, with sparing of the palms and soles.

Congenital erosive and vesicular dermatosis occurs most often in premature infants and presents with extensive cutaneous ulcerations and intact vesicles that develop crusting and then heal during the first month of life. Occasionally, blistering may continue to occur beyond infancy.<sup>74,75</sup> Generalized, supple, reticulated scars occur with alternating elevated and depressed areas (Fig. 2-21). Up to 75% of the cutaneous surface may be involved, and the skin lesions have been described as having depressed hypopigmented regions alternating with normal to hyperpigmented zones.<sup>76,77</sup> Scars on the trunk and head, which often have a cobblestone-like appearance, may be oriented along the cutaneous lines of cleavage; on the limbs they tend to follow the long axes of the extremities.<sup>77-79</sup> Facial involvement was present in roughly 50% of published cases in one review.<sup>80</sup> Although the eyebrows are usually normal, alopecia may be noted on the scalp. Nails may be absent or hypoplastic, and affected areas on the tongue may manifest scarring and absence of papillae. Dentition is usually normal. Hyperthermia, especially in warm weather or after exertion, is common and although sweating is absent in scarred areas, compensatory hyperhidrosis in normal-appearing skin may be noted. Chronic conjunctivitis is a major continuing problem for these patients, and corneal scarring may occur.<sup>74,76</sup> Some patients have also been found to have neurologic defects, including mental and motor retardation, hemiparesis, microcephaly, pachygyria, cerebral palsy, and seizures.<sup>76,80</sup>

#### SEBORRHEIC DERMATITIS

Seborrheic dermatitis is a common, self-limiting condition of the scalp, face, ears, trunk, and intertriginous areas characterized by greasy scaling, redness, fissuring, and occasional weeping. It appears to be related to the sebaceous glands and has a predilection for so-called "seborrheic" areas where the density of these glands is high. It usually presents in infants with a scaly dermatitis of the scalp termed *cradle cap* (Fig. 2-22) and may spread over the face, including the forehead, ears, eyebrows, and nose. Other areas of involvement include the intertriginous zones, umbilicus, and anogenital region

**Figure 2-22** Seborrheic dermatitis of the scalp (cradle cap). Erythema and greasy yellow scales involving the scalp of an infant male who also had similar changes in the eyebrows.

**Figure 2-23** Seborrheic dermatitis. Erythema of the medial thighs, suprapubic region and buttocks. This presentation can be difficult to distinguish from infantile psoriasis, but the scaling tends to be more mild and the response to topical anti-inflammatory therapy more brisk. The whitish debris in this child represents the barrier cream that his parents had applied rather than scaling.

(Fig. 2-23). (For a more detailed discussion of seborrheic dermatitis and its therapy, see Chapter 3.)

### LEINER DISEASE

The term *Leiner disease* refers to a shared phenotype for a number of nutritional and immunologic disorders characterized by severe seborrheic dermatitis with exfoliation, failure to thrive, and diarrhea. The disorder may occur during the first week of life but generally starts around 2 to 4 months of age. Patients are particularly prone to recurrent yeast and Gram-negative infections. Among disorders that may show this phenotype are: deficiency or dysfunction of complement, Bruton agammaglobulinemia, severe combined immunodeficiency, and HIES.<sup>81-85</sup>

### DIAPER DERMATITIS

Diaper dermatitis is perhaps the most common cutaneous disorder of infancy and early childhood. The term is used to describe an acute

### Box 2-1 Differential Diagnosis of Diaper Dermatitis

- Chafing dermatitis
- Irritant contact dermatitis
- Diaper candidiasis
- Seborrheic dermatitis
- Psoriasis
- Intertrigo
- Jacquet dermatitis
- Perianal pseudoverrucous papules and nodules
- Miliaria
- Folliculitis
- Impetigo
- Scabies
- Nutritional deficiency (i.e., acrodermatitis enteropathica, cystic fibrosis, biotin deficiency)
- Allergic contact dermatitis
- Atopic dermatitis
- Granuloma glutaeale infantum

- Burns
- Child abuse
- Epidermolysis bullosa
- Congenital syphilis
- Varicella/herpes
- Tinea cruris
- Chronic bullous dermatosis of childhood
- Bullous mastocytosis

inflammatory skin reaction in the areas covered by the diaper. The incidence of diaper dermatitis is estimated to be between 7% and 35%, with a peak incidence at 9 to 12 months of age.<sup>86-88</sup>

The term *diaper rash* is commonly used as a diagnosis, as though the diverse dermatoses that may affect this region constitute a single clinical entity. In actuality, diaper dermatitis is not a specific diagnosis and is best viewed as a variable-symptom complex initiated by a combination of factors, the most significant being prolonged contact with urine and feces, skin maceration, and, in many cases, secondary infection with bacteria or *Candida albicans*. Although diaper dermatitis may often be no more than a minor nuisance, eruptions in this area may not only progress to secondary infection and ulceration but may become complicated by other superimposed cutaneous disorders or represent a manifestation of a more serious disease.

The three most common types of diaper dermatitis are chafing dermatitis, irritant contact dermatitis, and diaper candidiasis. However, the differential diagnosis of diaper dermatitis is broad (Box 2-1). In patients in whom a response to therapy is slow or absent, alternative diagnoses should be considered and appropriate diagnostic evaluations performed. The following sections contain a brief discussion of several potential causes of diaper dermatitis. Many of these entities are discussed in more detail in other chapters.

### Chafing Dermatitis

The most prevalent form of diaper dermatitis is the chafing or frictional dermatitis that affects most infants at some time. Generally present on areas where friction is the most pronounced (the inner surfaces of the thighs, the genitalia, buttocks, and the abdomen), the eruption presents as mild redness and scaling and tends to wax and wane quickly. This form responds quickly to frequent diaper changes and good diaper hygiene.

### Irritant Contact Dermatitis

Irritant contact diaper dermatitis usually involves the convex surfaces of the buttocks, the vulva, the perineal area, the lower abdomen, and the proximal thighs, with sparing of the intertriginous creases (Fig. 2-24). The disorder may be attributable to contact with proteolytic enzymes in stool and irritant chemicals such as soaps, detergents, and topical preparations. Other significant factors appear to be excessive heat, moisture, and sweat retention associated with the warm local environment produced by the diaper.

**Figure 2-24** Irritant contact diaper dermatitis. Erythema of the vulva, buttocks, and medial thighs. The inguinal creases were relatively spared.

The etiology of irritant contact diaper dermatitis is multifactorial, and past hypotheses have included potential roles for ammonia, bacteria and bacterial products, and urine pH. In 1921 when Cooke demonstrated that an aerobic Gram-positive bacillus (*Bacillus ammoniagenes*) was capable of liberating ammonia from urea, this organism was pinpointed as the etiologic agent of most diaper dermatoses.<sup>89</sup> More recent studies, however, have refuted the role of urea-splitting bacteria in the etiology of this disorder and incriminate a combination of wetness, frictional damage, impervious diaper coverings, and increase in skin pH. It is suggested that urinary wetness increases the permeability of the skin to irritants as well as the pH of the diaper environment, thus intensifying the activities of the fecal proteases and lipases, the major irritants responsible for this disorder.<sup>90,91</sup>

Several technological innovations in the design of disposable diapers and other diapering products have aimed to reduce moisture and irritancy in this environment, thus decreasing the risk of irritant dermatitis. The introduction of absorbent gelling materials into diaper technology was one such breakthrough and has been shown to result in less diaper dermatitis than conventional cellulose-core disposable diapers.<sup>92</sup> Other recent innovations include nonirritating disposable diaper wipes and diapers designed to deliver petrolatum-based formulations to the skin.<sup>93</sup>

A blistering, erosive contact dermatitis has been observed after oral ingestion (either intentional or accidental) of senna-containing laxatives.<sup>94,95</sup> Patients typically have well-demarcated, diamond-shaped eroded plaques with desquamation that in some cases initially could be mistaken for scalding burns. Prolonged contact with stool (i.e., via overnight wearing of the diaper) is often reported.

#### Allergic Contact Dermatitis

Although not traditionally considered a common cause for diaper dermatitis, allergic contact dermatitis has received increasing attention in the literature in recent years (see Chapter 3). Potential associations to consider include chemical constituents of the diaper (rubber additives, rubber accelerator compounds, adhesive resins), topically applied diaper products such as emollients and "butt balms" (emulsifiers), and baby wipes (fragrances and preservatives).<sup>96,97</sup> Disperse dyes, which are used to impart color to synthetic fabrics, can also be contact sensitizers and are found in some disposable diapers.

#### Diaper Candidiasis

Candidal (monilial) diaper dermatitis is a commonly overlooked disorder and should be suspected whenever a diaper rash fails to respond to usual therapeutic measures. Cutaneous candidiasis is a possible sequela of systemic antibiotic therapy and should be considered in any diaper dermatitis that develops during or shortly after antibiotic administration.<sup>98</sup>

Candidal diaper dermatitis presents as a widespread, beefy-red erythema on the buttocks, lower abdomen, and inner aspects of the

**Figure 2-25** Diaper candidiasis. Beefy-red, erythematous plaques with multiple red satellite papules and papulopustules.

**Figure 2-26** Oral candidiasis (thrush). Gray-white, cheesy patches and plaques of the buccal mucosa, tongue, and gingiva.

thighs. Characteristic features include a raised edge, sharp marginalization with white scales at the border, and pinpoint pustulovesicular satellite lesions (the diagnostic hallmark) (Fig. 2-25). Although cutaneous candidiasis commonly occurs in association with oral thrush (Fig. 2-26), the oral mucosa may be uninvolved. Infants harbor *C. albicans* in the lower intestine, and it is from this focus that infected feces present the primary source for candidal diaper eruptions.

If necessary, the diagnosis of candidal diaper dermatitis may be confirmed by microscopic examination of a potassium hydroxide preparation of skin scrapings, which reveals egg-shaped budding yeasts and hyphae or pseudohyphae. Growth of yeast on Sabouraud medium implanted with skin scrapings can also confirm the diagnosis, usually within 48 to 72 hours.

#### Seborrheic Dermatitis

Seborrheic dermatitis of the diaper area may be recognized by the characteristic salmon-colored, greasy plaques with a yellowish scale and a predilection for intertriginous areas (see above). Coincident involvement of the scalp, face, neck, and postauricular and flexural areas helps to establish the diagnosis. Seborrheic dermatitis of the diaper region may be difficult to distinguish from psoriasis.

**Figure 2-27** Psoriasis (diaper). Sharply demarcated, erythematous, scaly plaques involving the genitals and suprapubic region in this infant male.

**Figure 2-29** Acrodermatitis enteropathica. Eroded, erythematous patches and plaques in this 4-month-old boy with zinc deficiency. Note the associated balanoposthitis.

**Figure 2-28** Jacquet dermatitis. Severe diaper area erythema with ulcerated papules and islands of reepithelialization.

## Psoriasis

Psoriasis of the diaper area must also be considered in persistent diaper eruptions that fail to respond to otherwise seemingly adequate therapy (Fig. 2-27). The sharp demarcation of lesions suggests diaper area psoriasis, but the typical scaling of psoriasis may be obscured because of the moisture of the diaper region. The presence of nail changes and red, well-margined plaques with silvery mica-like scales on the trunk, face, axillae, umbilicus, or scalp may help confirm this diagnosis (see Chapter 4), although affected infants may have involvement limited to the diaper area.

## Intertrigo

Intertrigo (see Chapter 17) is a common skin eruption in the diaper area, particularly in hot weather or when infants are overdressed. It usually involves the inguinal creases, the intergluteal area, and the thigh creases (especially in chubby babies), and presents as bright red erythema often with a mild white-yellow exudate. Nondiapered areas of involvement include the anterior neck fold and the axillae.

## Jacquet Dermatitis

The term *Jacquet dermatitis* is used to describe a severe erosive diaper eruption with ulcerated papules or nodules (Fig. 2-28). In male infants, erosion and crusting of the glans penis and urinary meatus may result in painful or difficult urination.

## Perianal Pseudoverrucous Papules and Nodules

This is an eruption composed of verrucous (wart-like) papules has been observed to occur in children with incontinence of stool or urine. These patients have verrucous papules and nodules of the perianal and suprapubic regions, possibly representing a distinct reaction to severe irritant diaper dermatitis. Reported patients had a history of delayed ileoanal anastomosis for Hirschsprung disease, encopresis, or urinary incontinence.<sup>99–101</sup> The importance of this diagnosis lies in differentiating it from condylomata acuminata or other more serious dermatoses.

## Acrodermatitis Enteropathica

Acrodermatitis enteropathica, a disorder of zinc deficiency, may mimic a severe irritant contact dermatitis in the diaper area (see Chapter 24). Patients have a periorificial erosive dermatitis that is often most accentuated in the diaper region (Fig. 2-29) but also may involve the peri-oral face. Erythema and pustules may involve intertriginous or acral sites, and diarrhea, failure to thrive, and alopecia are commonly present.

## Langerhans Cell Histiocytosis

Lesions of Langerhans cell histiocytosis (LCH; see Chapter 10) may also have a predilection for the diaper area. This eruption, which often presents in a seborrheic dermatitis-like fashion, classically involves the groin, axillae, and retroauricular scalp. Palms and soles may also be involved. Characteristic lesions consist of yellowish to red-brown papules, often with concomitant erosive or purpuric qualities (Fig. 2-30). LCH should be considered in any infant with a recalcitrant or hemorrhagic seborrheic dermatitis-like eruption and/or flexural papules with discrete erosions. Lymphadenopathy is common, and multiorgan involvement (especially bones, liver, lung, mucosa, and middle ear) is possible. Skin biopsy with special stains for Langerhans cells is diagnostic.

## Treatment of Diaper Dermatitis

Before any consideration for therapy of diaper dermatitis, the appropriate etiology must be identified. Educating parents that diaper dermatitis is often recurrent is vital in an effort to prevent perceived management failure. The primary goals in preventing and treating diaper dermatitis include keeping the skin dry, protected, and infection-free.<sup>102</sup>

The primary goal in irritant or chafing dermatitis is to keep the area as clean and dry as possible. Frequent diaper changes, gentle cleansing with a moistened soft cloth or fragrance-free diaper wipe, exposure to air whenever possible, and the judicious use of topical therapy may be sufficient in most cases. Zinc oxide and petrolatum-based formulations tend to be most effective in forming a barrier to further skin contact with urine and feces. These products should be applied at every diaper

**Figure 2-30** Langerhans cell histiocytosis. Red-brown, purpuric eroded papules in a 3-month-old male. Note intertrigo-like erythema of the inguinal creases with superficial erosions.

change when acute dermatitis is present. Parents should be taught that cleansing the diaper area is necessary only when stool is present, as overwashing in itself can lead to irritation. A low-potency, nonfluorinated topical corticosteroid (i.e., 1% hydrocortisone) applied two to three times daily is appropriate until improvement is noted. Stronger steroids and combination antifungal-corticosteroid preparations should be avoided, given risks of local cutaneous side effects and, more importantly, systemic absorption because of increased skin penetration from occlusion effect.

Secondarily infected (bacterial) dermatitis should be treated with the appropriate systemic antibiotic. Candidal infection requires the use of a topical antifungal agent (i.e., nystatin, clotrimazole, econazole, miconazole). If there is evidence of *Candida* in the mouth (i.e., thrush) as well as the diaper area, topical therapy may be supplemented by oral nystatin. Oral fluconazole is useful for severe cutaneous candidiasis. Although gentian violet has been used for decades for the treatment of oral and diaper candidiasis, reports of bacterial infection and hemorrhagic cystitis in addition to the staining associated with its use suggest that gentian violet be avoided.<sup>103,104</sup> A combination product (0.25% miconazole nitrate, 15% zinc oxide, and 81.35% white petrolatum) is also available, has demonstrated efficacy, and offers the advantage of convenience.

### GRANULOMA GLUTEALE INFANTUM

Granuloma gluteale infantum is a benign disorder of infancy characterized by purple-red nodules in the skin of the groin, lower abdomen, and inner thighs (Fig. 2-31). Patients have usually received preceding therapy with topical corticosteroids. Although the appearance of these lesions may suggest a malignant process, granuloma gluteale infantum seems to represent a unique response to local inflammation, maceration, and possibly secondary infection (usually *C. albicans*). A similar eruption has been observed in elderly adults.<sup>105</sup> Histologic evaluation of biopsy tissue from granuloma gluteale infantum reveals a nonspecific inflammatory infiltrate, sometimes with giant cells.<sup>106,107</sup>

Lesions of granuloma gluteale infantum resolve completely and spontaneously within a period of several months after treatment of the initiating inflammatory process. Although intralesional corticosteroids or steroid-impregnated tape have been used, such therapy is not recommended.

## Developmental Abnormalities of the Newborn

### SKIN SIGNS OF OCCULT SPINAL DYSRAPHISM

Spinal dysraphism is a spectrum of disorders defined by absent or incomplete fusion of the midline bony elements and may include congenital spinal-cord anomalies.<sup>108</sup> Because occult spinal dys-

**Figure 2-31** Granuloma gluteale infantum. Erythematous to violaceous papulonodules on the labia majora of this infant with a history of potent topical corticosteroid use in the diaper region.

**Figure 2-32** Lumbosacral port wine stain associated with occult spinal dysraphism. Note the associated central depression in this boy who also had an underlying tethered spinal cord.

phism (OSD) can lead to irreversible neurologic complications, early recognition is desirable. Cutaneous or subcutaneous stigmata may be the presenting sign of OSD, and as such, a working knowledge of potentially associated lesions is vital. Lumbosacral skin lesions that may be associated with OSD and spinal cord defects include hypertrichosis (the classic "faun tail" or finer, lanugo hair), lipomas, vascular lesions (infantile hemangioma, port wine stain; Fig. 2-32), prominent sacral dimples, sinuses, appendages (skin tag, tail), ACC, and melanocytic nevi.<sup>109</sup> Gluteal cleft asymmetry or deviation is another useful finding. The presence of multiple findings increases the risk of OSD.<sup>110</sup> In one study, 11 of 18 patients with two or more congenital midline skin lesions had OSD, and the most common midline cutaneous lesions to be associated with OSD were lipomas (either isolated or in combination with other lesions).<sup>111</sup> In a prospective study of infants with lumbosacral infantile hemangiomas, the overall relative risk for spinal anomalies was 640; importantly, 35% of the infants with an isolated lumbosacral hemangioma (and no additional cutaneous findings) had spinal anomalies.<sup>112</sup>

The majority of simple midline dimples are not associated with OSD. Atypical dimples (>5 mm in size, further than 2.5 cm from the anus, associated with other lumbosacral lesions), on the other hand, have a significant risk of associated OSD.<sup>110</sup> The association of nevus simplex (small, dull-pink, vascular malformation, most commonly seen on the occipital scalp, glabella, or eyelids) of the sacrum and OSD is unclear, although most agree that these lesions, when occurring alone, do not predict an increased risk of underlying malformations. Cervical

OSD is significantly less common, and in those cases associated with cutaneous stigmata, more than one lesion is usually present.<sup>113</sup> It is important to remember that an isolated nevus simplex ("stork bite") of the posterior nuchal or occipital region is *not* an indicator of underlying OSD.

When OSD is being considered, radiographic imaging must be performed. MRI is the diagnostic modality of choice, especially with higher-risk cutaneous findings. Ultrasound screening may be considered in infants younger than 4 months (before ossification of the vertebral bodies is complete), with the advantages being that it is noninvasive and does not require sedation. However, ultrasonography is limited in that small cord lesions (i.e., lipomas or dermal sinus tracts) may be missed,<sup>110</sup> and the overall sensitivity is quite dependent on the experience of the ultrasonographer. In a study of 41 infants with lumbosacral infantile hemangioma, the sensitivity of ultrasound scanning in detecting spinal anomalies was only 50%, with a specificity of 77.8%.<sup>112</sup> In infants with low-risk lesions such as simple dimples or gluteal cleft deviation and without other high-risk findings (i.e., hypertrichosis, skin tags, lipoma, or other mass), the need for imaging is unclear. If it is performed, however, ultrasound may provide a reliable screening when interpreted by an experienced pediatric radiologist.<sup>114</sup> Early neurosurgical referral is indicated if underlying defects are diagnosed.

### DRUG-INDUCED FETAL SKIN MALFORMATIONS

There are numerous drugs, including alcohol, hydantoin, valproic acid, warfarin, aminopterin, and isotretinoic acid, that when taken by pregnant women produce an adverse effect on the fetus and newborn. Exposure to these drugs *in utero* may result in a variety of organ malformations, although specific skin malformations are rare. Teratogenic risks as they relate to skin have most commonly focused on antithyroid drugs, especially methimazole (MMI), and their possible role in causing ACC, (see below).

### CONGENITAL HEMIHYPERTROPHY

Idiopathic congenital hemihypertrophy is a developmental defect in which one side of the body is larger than the other. Although differences in symmetry are often detectable during the newborn period, they usually become more striking with growth of the child. The cutaneous findings most often associated with hemihypertrophy are hyperpigmentation, telangiectasia, abnormal nail growth, and hypertrichosis (Fig. 2-33). Body temperature and sweating differences have also been reported in patients with this disorder.<sup>115</sup>

Of particular significance is the fact that about 50% of persons with hemihypertrophy may have associated anomalies, including Wilms tumor, aniridia, cataracts, ear deformities, internal hemangiomas, genitourinary tract anomalies, adrenocortical neoplasms, and brain tumors. Therefore patients who exhibit congenital hemihypertrophy should be evaluated for potentially associated conditions. Associated tumors most commonly involve the kidney, adrenal gland, and liver.<sup>116</sup> In patients with hemihypertrophy combined with cutaneous vascular malformations (i.e., port wine stain), the possibility of Klippel-Trénaunay syndrome, Proteus syndrome, congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and scoliosis/skeletal and spinal anomalies (CLOVES) syndrome, or another syndrome comprising a vascular anomaly with hypertrophy should be considered (see Chapter 12).

### APLASIA CUTIS CONGENITA

Aplasia cutis congenita (ACC) is a congenital defect of the skin characterized by localized absence of the epidermis, dermis, and at times, subcutaneous tissues. Although ACC generally occurs on the scalp, it may also involve the skin of the face, trunk, and extremities. The diagnosis of ACC is usually a clinical one, and the histologic picture varies. Although most cases appear to be sporadic, a variety of potential associations including teratogens, limb abnormalities, epidermal nevi, underlying embryologic malformations, epidermolysis bullosa, malformation syndromes, and infections have been proposed.<sup>117</sup>

ACC classically presents as solitary or multiple, sharply demarcated, weeping or granulating, oval to circular, stellate defects ranging from

**Figure 2-33** Congenital hemihypertrophy with hypertrichosis. (From Hurwitz S, Klaus SN. Congenital hemihypertrophy with hypertrichosis. Arch Dermatol 1971;103:98–100. ©1971 American Medical Association. All rights reserved.)

**Figure 2-34** Aplasia cutis congenita. Sharply demarcated ulceration on the scalp of an infant with this disorder.

1 to 3 cm in diameter. Some 70% of scalp lesions are isolated, 20% are double, and in 8% of patients three or more defects may be present.<sup>118</sup> The most common location for ACC is the scalp, and in those cases 80% occur in close proximity to the hair whorl.<sup>119</sup> Although aplasia cutis may also affect the occiput, the postauricular areas, and the face, involvement of these areas appears to be relatively uncommon. Whereas most scalp defects are small, larger lesions may occur and can extend to the dura or the meninges. Although treatment is generally unnecessary, large scalp lesions (i.e., >4 cm<sup>2</sup>) may require surgery with grafting to prevent the potential complications of hemorrhage, venous (sagittal sinus) thrombosis, and meningitis.

At birth, the skin defect may vary from an ulceration with a granulating base (Fig. 2-34) to a superficial erosion or even a well-formed scar. As healing of open lesions occurs, the defect is replaced by

**Figure 2-35** Aplasia cutis congenita. Healed scar with alopecia near the hair whorl in this 8-month-old girl.

smooth, hairless scar tissue (Fig. 2-35), although sometimes the tissue is raised and keloidal. Some lesions may present as a translucent, glistening membrane (membranous aplasia cutis) and when surrounded by a ring of long, dark hair (the “hair collar sign”) may represent a forme fruste of a neural tube defect.<sup>120</sup> This membranous form of ACC may have a recognizable appearance on prenatal sonography as a round hypoechoic defect.<sup>121</sup>

Although most infants with ACC are otherwise well, defects that may occasionally be present include cleft lip and palate, ophthalmologic defects, limb reduction defects, cardiac anomalies, gastrointestinal tract malformations, spinal dysraphism, hydrocephalus, defects of the underlying skull, congenital midline porencephaly, spastic paralysis, seizures, mental retardation, and vascular anomalies.<sup>117</sup> Adams–Oliver syndrome (AOS), an autosomal dominant or recessive malformation syndrome caused by mutations in the *ARHGAP31*, *DOCK6*, or *RBPJ* genes, is the association of ACC with transverse limb defects and cardiac and CNS abnormalities.<sup>122,123</sup> The cardiac malformations in AOS may include ventricular septal defects, tetralogy of Fallot, left-sided obstructive lesions, and truncus arteriosus.<sup>124</sup> Up to 50% of patients with trisomy 13 may have scalp ACC, and it may also occur at an increased rate in patients with 4p syndrome. Therefore any patient with signs of scalp ACC and congenital anomalies warrants chromosomal evaluation. Oculocerebrocutaneous (Delleman) syndrome is the association of orbital cysts, cerebral malformations, and focal skin defects including ACC-like lesions and skin tags.<sup>125,126</sup> Other findings in this syndrome include CNS malformations, clefting, and microphthalmia/anophthalmia. ACC in association with fetus papyraceus (vanishing twin syndrome) typically presents with bilateral symmetric buttock and lower extremity involvement as well as truncal lesions.<sup>127</sup>

The etiology of ACC remains unknown. Although most cases are sporadic, familial case reports have suggested autosomal dominant inheritance with reduced penetrance. Incomplete closure of the neural tube or an embryologic arrest of skin development has been suggested as an explanation for midline lesions. This hypothesis, however, fails to account for lesions of the trunk and limbs. In such instances, vascular abnormality of the placenta, with a degenerative rather than an aplastic or traumatic origin, has been postulated as the cause of the cutaneous defects.<sup>128</sup> Antithyroid drugs, most notably MMI, have long been hypothesized as causative teratogens in some cases of ACC. Although causality remains unproven, there are multiple reports of affected infants born to mothers treated with MMI during pregnancy, both as an isolated manifestation and as part of the presentation of “MMI embryopathy,” which includes dysmorphism, gastrointestinal tract malformations, and developmental delay.<sup>129</sup> Propylthiouracil has been recommended as the first-line agent in the management of hyperthyroidism during pregnancy, given its equal effectiveness and lack of reports of teratogenic ACC.<sup>130</sup> Recently a heterozygous missense mutation in *BMS1* (which affects ribosomal function) was identified in autosomal dominant ACC.<sup>131</sup>

**Figure 2-36** Setleis syndrome. A child with bilateral depressed oval areas on the temples, upwardly slanting eyebrows, narrowed palpebral fissures, and large lips. (Courtesy of Seth Orlow, MD.)

Recognition of ACC and differentiation of it from forceps or other birth injury will help prevent possible medicolegal complications occasionally encountered with this disorder. In patients with localized sporadic lesions, aside from cutaneous scarring, the prognosis of ACC is excellent. With conservative therapy to prevent further tissue damage and secondary infection, most small defects of the scalp heal well during the first few weeks to months of life. With aging of the child, most scars become relatively inconspicuous and require no correction. Those that are large and obvious can be treated with plastic surgical reconstruction.

### Setleis Syndrome

Setleis syndrome was initially described in 1963 by Setleis and colleagues, who described five children of three families, all of Puerto Rican ancestry, who had unique characteristic clinical defects confined to the face.<sup>132</sup> Patients have atrophic skin at the temples (historically likened to forceps marks), coarse facial appearance, absent or duplicated eyelashes of the upper eyelids (distichiasis), eyebrows that slant sharply upward and laterally, and periorbital puffiness (Fig. 2-36). Lips may be large with an inverted V contour. Although traditionally believed to have normal intelligence, patients with Setleis syndrome may have associated developmental delay.<sup>133</sup>

Reports of Setleis syndrome have suggested both autosomal recessive and autosomal dominant modes of inheritance,<sup>133,134</sup> and variable expressivity and reduced penetrance may be observed.<sup>135</sup> Setleis syndrome is considered by some to be a form of focal facial dermal dysplasia (see Chapter 6).<sup>136</sup> Recently, homozygous nonsense mutations in *TWIST2* have been confirmed in cohorts with the Setleis phenotype.<sup>137,138</sup>

### OTHER DEVELOPMENTAL DEFECTS

A congenital dermal sinus or dermoid cyst is a developmental epithelium-lined tract (or cyst) that extends inward from the surface of the skin. Since midline fusion of ectodermal and neuroectodermal tissue occurs at the cephalic and caudal ends of the neural tube, the majority of such defects are seen in the occipital and lumbosacral regions. Dermoids, however, can occur anywhere.

Dermal sinus openings may be difficult to visualize, particularly in the occipital scalp region where they may be hidden by hair. A

**Figure 2-37** Dermoid cyst. This mobile, nontender, subcutaneous nodule was present at birth in this 5-month-old girl. The lateral mid-forehead distribution is slightly higher than most dermoids, which present most often in the lateral eyebrow region.

**Figure 2-38** Dermoid sinus. Small sinus ostium at the superior nasal bridge. This patient had no intracranial extension.

localized thickening of the scalp, hypertrichosis, or dimpling in the midline of the neck or back should alert the physician to the possibility of such an anomaly. These sinuses are of clinical importance as portals for infection that may give rise to abscesses, osteomyelitis, or meningitis.

Dermoid cysts most commonly occur on the orbital ridge, presenting as a nontender, mobile subcutaneous nodule in the eyebrow/orbital ridge region (Fig. 2-37). In this location, there is no association with deep extension. About 3% of dermoids are located in the nasal midline<sup>109</sup> (including glabella, nasal dorsum, and columella), and recognition of these lesions is vital because of the potential for deep extension and CNS communication. Congenital midline nasal masses may represent not only dermoids but also cephaloceles, gliomas, hemangiomas, and a variety of less common neoplasms or malformations. It is vital to consider the diagnostic possibilities carefully when a child's parents seek treatment for a nasal midline mass, given the potential for intracranial connection seen with some of these disorders. Invasive diagnostic procedures should never be performed until radiologic evaluation has been completed.

In midline nasal dermoid cysts or dermal sinuses, an overlying sinus ostium may be present, sometimes with a white discharge or protruding hairs (Fig. 2-38). Presence of such a pit may indicate a higher likelihood of intracranial extension.<sup>139</sup> MRI or computed tomography (CT) of suspicious areas should be performed to evaluate for an underlying tract and CNS connection. Management of dermal sinuses and dermoid cysts consists of surgical excision, in an effort to prevent local infection and, in the case of intracranial extension, meningitis and/or abscess formation. Lesions of the lateral forehead or orbital ridge do not require radiographic imaging before surgical excision.

A cephalocele is a herniation of cranial contents through a defect in the skull. Cephaloceles develop as a result of faulty separation of neuroectoderm from surface ectoderm in early gestation and occur most commonly at the occiput, followed by the dorsal nose, orbits, and forehead. These lesions present as a compressible mass that transilluminates with light.<sup>109</sup> Occasionally, an overlying blue hue may be present, which at times can suggest the incorrect diagnosis of deep hemangioma. A useful diagnostic feature is the enlargement of the lesion that may be seen with any maneuver that results in increased intracranial pressure (such as crying or straining). This temporary change is caused by the patent connection between a cephalocele and the CNS. Hypertelorism, facial clefting, and brain malformations may be seen in conjunction with a cephalocele.<sup>140</sup> Surgical resection is the

treatment of choice, and multidisciplinary care (plastic surgery, neurosurgery) may be indicated.

A nasal glioma is an ectopic neuroectoderm from early development and may occur in extranasal (60%) or intranasal (30%) locations and less commonly in both extranasal and intranasal sites. This lesion presents as a firm, noncompressible, flesh-colored nodule, sometimes with a blue-red hue, and most often situated at the root of the nose. Hypertelorism may result, and no fluctuation in size is seen, because these lesions have no intracranial connection. An intranasal lesion presents as a protruding mass from the nose, simulating a nasal polyp. *Heterotopic brain tissue* is a term that has been used to similarly describe a rare developmental anomaly that occurs most often on the head and neck, especially in the nasal area, and usually without intracranial communication.<sup>141,142</sup> Surgical excision is the treatment of choice for these lesions.

Congenital fistulas of the lower lip (congenital lip pits) may be unilateral or bilateral and may be seen alone or in association with other anomalies of the face and extremities. They are characterized by single or paired, circular or slit-like depressions on either side of the midline of the lower lip at the edge of the vermillion border. These depressions represent blind sinuses that extend inward through the orbicularis oris muscle to a depth of 0.5 cm or greater. They may occasionally communicate with underlying salivary glands. Excision of lip pits is unnecessary unless mucous gland secretions are problematic.

Congenital lip pits may be inherited as an autosomal dominant disorder with penetrance estimated at 80%. They may be seen alone or, in 70% of patients, in association with cleft lip or cleft palate. Other associated anomalies include clubfoot, talipes equinovarus, syndactyly, and the popliteal pterygium syndrome (an autosomal dominant disorder with clefting, filiform eyelid adhesions, pterygium, genitourinary anomalies, and congenital heart disease).<sup>143</sup>

Skin dimpling defects (depressions, deep pits, or creases) in the sacral area and over bony prominences may be seen in normal children and infants with diastematomyelia (a fissure or cleft of the spinal cord), congenital rubella or congenital varicella-zoster syndromes, deletion of the long arm of chromosome 18, and Zellweger (cerebro-hepatorenal), Bloom, and Freeman-Sheldon (craniocarpotarsal dysplasia, "whistling face") syndromes.

Amniotic constriction bands may produce congenital constriction deformities, and congenital amputation of one or more digits or extremities of otherwise normal infants may occur. The deformities are believed to result from intrauterine rupture of amion with formation of fibrous bands that encircle fetal parts and produce permanent constriction of the underlying tissue.<sup>144</sup> Acquired raised bands of

**Figure 2-39** Acquired raised bands of infancy. Numerous linear raised bands on the back of an infant who had similar bands on the extremities. (Courtesy of Sarah L. Chamlin, MD.)

**Figure 2-40** Sock-line hyperpigmentation. Erythematous to hyperpigmented curvilinear streak on the lower leg of a 1-year-old female whose mother noted the changes shortly after dressing her in tight-fitting socks.

infancy (also known as *raised limb bands*) are linear skin-colored plaques that develop postnatally on the extremities of infants and involve no constrictive defects (Fig. 2-39). They may also occasionally occur on the trunk. Although some argue that these findings are distinct from amniotic constriction bands,<sup>145</sup> coexistence with congenital constriction bands<sup>146</sup> and prenatal ultrasound observation of amniotic bands<sup>147</sup> in reported patients suggests a potential overlap of these two conditions. Sock-line hyperpigmentation (also known as *sock-line bands*) has been described as circumferential, unilateral, or bilateral hyperpigmented streaks on the calf (Fig. 2-40) that are seen in otherwise-healthy children and acquired during infancy and may be related to the wearing of elastic socks or elastic pant legs.<sup>148</sup> It is believed to be distinct from acquired raised bands, must be differentiated from child abuse with a looped cord, and is usually self-limited.<sup>149</sup> These lesions have also been observed on the posterior heel of infants

**Figure 2-41** Preauricular sinus with ulceration. This lesion was prone to recurrent inflammation and infection and ultimately was surgically excised.

after wearing heel-length socks.<sup>150</sup> Damage to adipose tissue with inflammation and secondary postinflammatory changes have been hypothesized as the cause.

Preauricular pits and sinus tracts may develop as a result of imperfect fusion of the tubercles of the first two branchial arches. Unilateral or bilateral, these lesions present as small skin pits that may become infected or result in chronic preauricular ulcerations (Fig. 2-41), retention cysts, or both, necessitating surgical excision. Accessory tragi are fleshy papules, with or without a cartilaginous component, that contain epidermal adnexal structures. Usually seen in the preauricular area, they may also occur on the neck (anterior to the sternocleidomastoid muscle). Accessory tragi may be solitary or localized (Fig. 2-42, A) or multifocal, occurring along the embryologic migration line extending from the preauricular cheek to the mouth angle (Fig. 2-42, B). Although generally seen as an isolated congenital defect, they may be associated with other branchial arch syndromes (i.e., oculoauriculovertebral or Goldenhar syndrome). The prevalence of preauricular pits and tags is estimated at around 0.5% to 1.0%.<sup>151,152</sup>

An important consideration with preauricular pits and tags is that of potential associations, the most common concerns being those of hearing or genitourinary defects. Several studies have demonstrated an increased incidence of hearing impairment in the setting of isolated pits or tags, thus suggesting that hearing assessment should be performed in any newborn with these lesions.<sup>153,154</sup> The data regarding genitourinary malformations are more controversial, with studies both supporting and refuting an association with preauricular pits or tags.<sup>152,155</sup> It appears that when these preauricular lesions occur in the absence of other dysmorphic or syndromic features, such associations are less likely.

Branchial cleft cysts and sinuses, formed along the course of the first and second branchial clefts as a result of improper closure during embryonic development, are generally located along the lower third of the lateral aspect of the neck near the anterior border of the sternocleidomastoid muscle. Lesions may be unilateral or bilateral and may open onto the cutaneous surface or may drain into the pharynx. Although these lesions may present in childhood, they more commonly come to medical attention during adulthood because of recurrent inflammation. Treatment consists of complete surgical removal or marsupialization (exteriorization, resection of the anterior wall, and suturing of the cut edges of the remaining cyst to the adjacent edges of the skin).

Thyroglossal cysts and sinuses are located on or near the midline of the neck, and may open onto the skin surface, extend to the base of the tongue, or drain into the pharynx. Clinically, they present as a midline neck cyst that moves with swallowing (Fig. 2-43). These lesions represent persistence of the embryonic structure associated with normal thyroid descent, and occasionally may contain ectopic thyroid tissue. Although surgical excision is the treatment of choice, care must be exercised to preserve aberrant thyroid tissue in order to prevent postsurgical hypothyroidism.

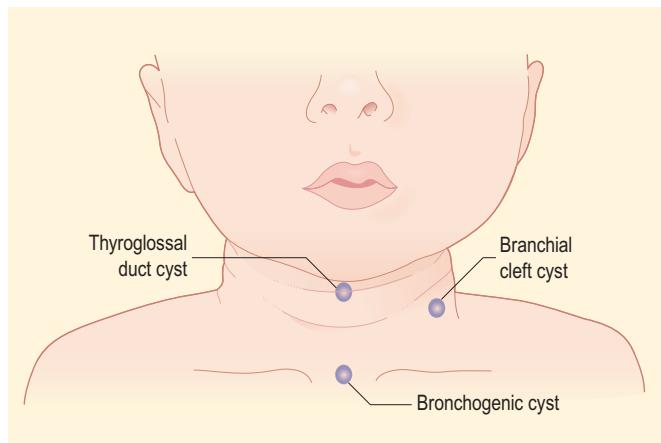

**Figure 2-42** Accessory tragi. These fleshy papules may present in a solitary/localized fashion (**A**) or in a multifocal form, occurring along the embryologic migration line extending from the preauricular cheek to the mouth angle (**B**).

**Figure 2-43** Thyroglossal duct cyst. This congenital nodule of the anterior midline neck was noted to move upward with swallowing.

Bronchogenic cysts present early, usually at birth, as a nodule or draining pit, usually over the suprasternal notch. These lesions may develop from ectopic elements of the tracheobronchial tree or may represent ectopic branchial cleft cysts. Surgical excision is the treatment of choice. **Figure 2-44** shows the locations of several types of congenital neck cysts.

**Figure 2-44** Congenital sinuses of the neck.

Congenital cartilaginous rests of the neck (also known as *wattles*) occur as small fleshy appendages on the anterior neck or over or near the lower half of the sternocleidomastoid muscle. Treatment consists of surgical excision with recognition of the fact that these cutaneous appendages may contain cartilage. Pterygium colli, congenital folds of skin extending from the mastoid region to the acromion on the lateral aspect of the neck, may be seen in individuals with Turner, Noonan, Down, lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, deafness (LEOPARD), or multiple pterygium syndromes; trisomy 18; short-limbed dwarfism; and combined immunodeficiency disease.

Supernumerary nipples (polythelia), present at times in males as well as females, are manifested as small brown or pink, concave, umbilicated, or elevated papules along or slightly medial to the embryologic milk line. They are most common on the chest or upper abdomen and occasionally are seen in other sites including the face, neck, shoulder, back, genitals, or thighs. Although much has been written about a relatively high incidence of renal malformation in patients with supernumerary nipples, current studies suggest that this anomaly in an otherwise apparently normal individual does not appear to be a marker of urinary tract malformation.<sup>156–158</sup>

There is a variety of developmental anomalies that may occur in the umbilical region. Urachal cyst or sinus is a lesion that represents persistence of the embryonic urachus, a fibrous cord that develops from the urogenital sinus. A midline nodule near the umbilicus may result, and at times urine drainage may be seen from a fistula connecting the umbilicus to the bladder. Vitelline (omphalomesenteric duct) remnant may present as an umbilical polyp or an umbilicoileal fistula that drains feces onto the skin surface. Complete excision is the treatment of choice for these anomalies.

## Congenital Infections of the Newborn

Viral, bacterial, and parasitic infections during pregnancy can be associated with widespread systemic involvement, serious permanent sequelae, and a variety of cutaneous manifestations in the newborn. This section discusses the most significant of these: congenital rubella, congenital varicella-zoster syndrome, neonatal varicella, neonatal herpes, congenital parvovirus B19 infection, congenital syphilis (CS), cytomegalic inclusion disease, congenital Epstein-Barr virus (EBV) syndrome, and congenital toxoplasmosis.

### CONGENITAL RUBELLA

Congenital rubella syndrome (CRS) was initially identified in 1941 by Norman Gregg, an Australian ophthalmologist who observed an unusual form of congenital cataracts in babies of mothers who had had rubella during pregnancy.<sup>159</sup> It occurs after a maternal rubella

**Figure 2-45** Congenital rubella with blueberry muffin lesions. Multiple violaceous, infiltrative papules and nodules in this newborn with congenital rubella.

infection during the first 16 weeks of pregnancy and only rarely when infection is acquired later in gestation. Earlier gestation directly correlates with the likelihood of CRS. Overall, the incidence of CRS in the United States has declined notably in parallel with the decline in rubella cases since licensure of the rubella vaccine in 1969. During 2004 through 2012, however, 79 cases of rubella and six cases of CRS were reported in the United States and were either import-associated or from unknown sources.<sup>160</sup> Occasional rubella outbreaks, such as those that occurred during the 1990s, have been related to a variety of factors, including occurrence in settings in which unvaccinated adults congregate, in unvaccinated foreign-born adults, and among children and adults in religious communities with low levels of vaccination coverage.<sup>161,162</sup> Studies suggest that young Hispanic women represent a population at elevated risk for delivering an infant affected by CRS, and thus this population needs to be targeted specifically for immunization.<sup>162,163</sup> Importantly, rubella virus continues to circulate in other parts of the world (i.e., Africa) where rubella vaccination programs are not established and increases the risk of imported rubella in the United States and subsequent CRS.<sup>160</sup>

Clinical manifestations of CRS are characterized by the classic triad of congenital cataracts, deafness, and cardiac defects (especially patent ductus arteriosus). *In utero* growth restriction may occur during the last trimester of pregnancy. CNS involvement may result in microcephaly, meningoencephalitis, and mental retardation. Other features include pigmentary retinopathy, hepatosplenomegaly, jaundice, radiolucent bone lesions in metaphyses, and thrombocytopenia.<sup>164</sup> Some infants with CRS may show few manifestations at birth or may be asymptomatic, but findings usually manifest over subsequent months. Occasionally, CRS findings may not become manifest until the second year of life.<sup>165</sup>

The most distinct cutaneous feature of CRS is a diffuse eruption composed of blue-red infiltrative papules and nodules and occasionally smaller purpuric macules, measuring 2 to 8 mm in diameter, representing so-called "blueberry muffin" lesions (Fig. 2-45). Blueberry muffin lesions are usually present at birth or within the first 24 hours, and new lesions rarely appear after 2 days of age. They may be observed in association with a variety of disorders, usually either infectious or neoplastic (Box 2-2). Histologic evaluation reveals extramedullary hematopoiesis, characteristic of viral infection of the fetus and not unique to infants with CRS but also seen in patients with congenital toxoplasmosis, cytomegalovirus (CMV) infection, erythroblastosis fetalis, congenital leukemia, and twin-twin transfusion syndrome. Other cutaneous manifestations in CRS may include a generalized nonspecific maculopapular eruption, reticular erythema of the face and extremities, hyperpigmentation, and recurrent urticaria. Vasomotor instability, manifested by poor peripheral circulation with generalized mottling and acral cyanosis, may also occur.

## Box 2-2 Differential Diagnosis of the Newborn with "Blueberry Muffin" Lesions

- Dermal (extramedullary) hematopoiesis
- Congenital infection
  - Toxoplasmosis
  - Rubella
  - Cytomegalovirus
  - Enterovirus
  - Parvovirus B19
- Erythroblastosis fetalis
- Inherited hemolytic diseases
- Twin-twin transfusion
- Neoplastic
  - Neuroblastoma
  - Leukemia
  - Histiocytosis
  - Alveolar rhabdomyosarcoma

The diagnosis of CRS should be suspected in infants with one or more characteristic findings including congenital cataracts, pigmentary retinopathy, cardiac defects, deafness, thrombocytopenia, hepatosplenomegaly microcephaly, or blueberry muffin lesions. The diagnosis may be confirmed by isolation of rubella virus from respiratory secretions, urine, cerebrospinal fluid (CSF), or tissue. Neonatal immunoglobulin (Ig) M rubella-specific antibodies or IgG antibodies that persist beyond the time expected for passively transferred immunity are also diagnostic. Real-time reverse transcription polymerase chain reaction (rRT-PCR) can also be performed on throat/nasopharyngeal swabs, serum and urine.

There is no specific therapy for CRS apart from supportive therapy and recognition of potential disabilities. Because of the high incidence of ophthalmic complications, regular ophthalmologic examinations are indicated. Infants who are congenitally infected may shed virus in urine and the nasopharynx for several months to 1 year and should be considered contagious until that time. The majority of infants who acquire CRS early in gestation will have permanent neurologic and audiologic sequelae, and long-term multidisciplinary care is indicated. A long-term follow-up study of 50 Australian patients with CRS revealed aortic valve disease in 68% and increased incidences of diabetes, thyroid disorders, early menopause, and osteoporosis compared with the general population.<sup>166</sup>

Congenital rubella can be effectively prevented by immunization with live rubella virus vaccine, and universal vaccination is recommended. Current efforts focus on immunizing high-risk populations with two doses of rubella vaccine, with a special effort to vaccinate populations at increased risk including college students, military recruits, and healthcare and daycare workers.<sup>165</sup> Because of the high risk of fetal damage, women known to have contracted maternal rubella during the early months of pregnancy may consider abortion. Although limited data suggest that administration of immunoglobulin to the mother may reduce the amount of viremia and damage when given as early as possible after exposure, it does not appear to prevent congenital infection.

## CONGENITAL VARICELLA SYNDROME

Congenital varicella syndrome, also known as *fetal varicella syndrome*, refers to a spectrum of congenital anomalies that may be seen in neonates born to women who contract varicella-zoster virus (VZV) infection during the first 20 weeks of gestation. Overall it is quite rare, probably because primary varicella infection during pregnancy is uncommon, since the majority of women have acquired immunity by child-bearing age.<sup>167</sup> The incidence of congenital varicella syndrome after maternal infection is estimated at around 0.4% to 1%, and the highest risk seems to be when infection is acquired between 13 and 20 weeks of gestation.<sup>168,169</sup> Primary VZV infection in a pregnant woman most often results in the birth of a normal newborn, related to either to lack of transmission to the fetus or self-limited fetal infection. Although there are rare reports of fetal sequelae in infants born

to mothers who develop herpes zoster infection (shingles) during pregnancy, this association is extremely rare.<sup>168,170</sup> Infants born to mothers with a history of maternal varicella during gestation appear to be at increased risk for infantile herpes zoster (shingles). Implementation of universal varicella vaccination programs has been demonstrated to result in reduction of both congenital varicella and neonatal varicella infections.<sup>171</sup>

Congenital varicella syndrome may present with various findings, including low birthweight, ophthalmologic defects (including microphthalmia, Horner syndrome, cataracts, and chorioretinitis), neurologic defects (including mental retardation, seizures, cortical atrophy, encephalomyelitis, and developmental delay), limb hypoplasia with flexion contractures and malformed digits, and gastrointestinal and genitourinary defects.<sup>167</sup> Cutaneous findings include vesicles and/or scarring (often depressed and pigmented) in a dermatomal distribution, although several affected newborns have been reported with cutis aplasia-like absence of skin.

Because the risk of fetal malformation in an infant born to a mother exposed to VZV during pregnancy is so slight, therapeutic abortion is not necessarily indicated. As noted, the majority of women who contract varicella during pregnancy have children with no evidence of the syndrome. Studies to date are inconclusive with regard to the utility of serologic or polymerase chain reaction (PCR)-based testing of fetal blood or amniotic fluid.<sup>172</sup> Prenatal ultrasound may reveal disseminated organ calcifications.<sup>173</sup> Studies suggest that the use of varicella-zoster immunoglobulin (VZIG) may clearly modify or prevent disease in the mother who has been exposed and is susceptible. Treatment of mothers with severe varicella with acyclovir or valacyclovir may be considered. Most important is screening of women of childbearing age without a history of varicella for antibody and offering vaccination when indicated. Susceptible females who are already pregnant should be counseled about avoiding contact with individuals who have chickenpox and about the availability of VZIG should it become necessary.

Neonatal varicella is a varicella infection of the newborn that occurs when a pregnant woman develops chickenpox during the last few weeks of pregnancy or the first few days postpartum. In such instances, the timing of the onset of disease in the mother and her newborn is critical. If the disease onset in the mother is 5 or more days before delivery or in the newborn during the first 4 days of life, the infection tends to be mild. In contrast, if the onset in the mother is within 5 days before delivery to 2 days after delivery or in the newborn between 5 and 10 days of birth, the infant's infection is often severe and disseminated (Fig. 2-46), with pneumonia, hepatitis, or meningoencephalitis and severe coagulopathy and a mortality rate of around 30%. In an effort to prevent neonatal varicella infection, VZIG (or intravenous immunoglobulin [IVIG] if the former is unavailable) should be given as soon as possible after delivery to all infants in whom the mother has the onset of varicella within 5 days before or within 48 hours after delivery, and these infants are also candidates for intravenous acyclovir therapy.<sup>174</sup>

**Figure 2-46** Neonatal varicella. Disseminated, erythematous papules, vesicles, and erosions.

## NEONATAL HERPES

Neonatal herpes simplex virus (HSV) infection may range from a mild, self-limited illness to one with devastating neurologic consequences or even death. The overall incidence in the United States is estimated at 9.6 per 100,000 births.<sup>175</sup> Up to 70% of neonatal HSV infections are caused by type 2 ("genital") HSV, and the disease is acquired either by ascending *in utero* infection or by spread during delivery through an infected birth canal (perinatal transmission). Infection of the newborn may also be acquired by intrauterine infection because of maternal viremia with transplacental spread or by postnatal hospital or household contact with other infants or persons with oral HSV infection.<sup>176-178</sup> Of infants with neonatal HSV, 85% acquire their infection during birth, 10% postnatally, and 5% from *in utero* exposure.<sup>179</sup> Congenital (intrauterine) HSV infection, which is not the focus of this section, is a rare disorder (approximately 5% of all neonatal HSV disease) resulting from intrauterine infection and is characterized by skin vesicles or scarring, chorioretinitis, microphthalmia, microcephaly, and abnormal brain CT findings.<sup>180</sup> Importantly, the majority of infants with cutaneous involvement have lesions at birth or within 12 hours of life (significantly earlier than infants with neonatal herpes).<sup>181</sup>

The risk of neonatal HSV infection in an infant born vaginally to a mother with primary genital infection is high (40% to 50%), whereas the risk to an infant born to a mother with recurrent infection is much lower, around 2% to 5%. The lower rate of transmission with recurrent maternal disease may reflect decreased viral load and partial protection of the fetus by transplacentally acquired antibodies.<sup>182</sup> Most babies with neonatal HSV become infected from mothers who are asymptomatic.

The clinical presentation of neonatal HSV has traditionally been divided into three separate patterns: skin, eyes, and/or mouth (SEM) disease; CNS disease; and disseminated disease. These presentations are summarized in Table 2-4. The exact frequency of the various forms is unclear, given partial overlap of patterns in some patients and potential delays in the appearance of CNS disease. Most infants affected with neonatal HSV become sick during the first 4 weeks of life, and in two-thirds, during the first week of life. SEM disease appears to be the least severe and associated with the most favorable prognosis. However, although most infants have SEM disease, 60% to 70% will progress to more diffuse involvement.<sup>183</sup>

Presenting features of neonatal HSV include skin lesions, fever, respiratory distress, and CNS dysfunction. The latter includes seizures, lethargy, poor feeding, irritability, and hypotonia. The skin eruption may vary from erythematous macules to individual or grouped vesicles (Fig. 2-47) or a widespread generalized vesicobullous eruption affecting the skin and buccal mucosa. The vesicles of neonatal HSV may become pustular after 24 to 48 hours and eventually becomes

**Table 2-4** Clinical Presentations of Neonatal Herpes

Type	Incidence* (%)	Skin Vesicles (%)	Comment
SEM disease	45	80-85	May progress to more severe infection, especially without early therapy
CNS disease	30	60-70	Clinical overlap with neonatal bacterial sepsis
Disseminated	25	75-80	Respiratory collapse, liver failure and DIC common

CNS, Central nervous system; DIC, disseminated intravascular coagulopathy; SEM, skin, eyes, and/or mouth.

\*Approximate incidence out of all neonatal herpes patients.

**Figure 2-47** Neonatal herpes simplex infection. Clustered vesicles on an erythematous base in this newborn with congenital herpes simplex infection, skin, eyes, and/or mouth (SEM type).

crusted or ulcerated. Other skin findings may include purpuric, petechial, or zosteriform lesions, as well as large bullae with skin denudation similar to those seen in epidermolysis bullosa.<sup>184</sup> Skin lesions occur most often on the scalp and face, and in breech deliveries they have a predilection for the presenting part. Occasionally, the scalp of the infant may reveal diffuse edematous swelling resembling that seen in caput succedaneum. Rather than resolving spontaneously during the first week, this swelling may become necrotic with resultant drainage and eschar formation and irregularly grouped herpetic vesicles. Fetal scalp monitoring is a risk factor for HSV, because the virus more readily gains entry into the lacerated scalp. Eye involvement, seen only in around 5% of affected infants, may present with conjunctivitis or pathognomonic keratitis.

The disseminated form of neonatal HSV may affect several organs, especially the liver, adrenal glands, lungs, and the CNS. This form is associated with the highest mortality—up to 60%. In the absence of skin lesions or other pathognomonic features, disseminated disease may be difficult to diagnose and should always be considered in the neonate who has risk factors for HSV, possible sepsis (especially if a lack of response to antimicrobial therapy is noted), unexplained pneumonitis (especially in the first week of life), or unexplained nonspecific findings such as thrombocytopenia, coagulopathy, hepatitis, or fever.<sup>183</sup> In addition, infants with an unexplained CSF pleocytosis (usually lymphocytic) merit consideration for the diagnosis of HSV.

The diagnosis of HSV infection in the newborn can be confirmed in a variety of ways. In the presence of skin lesions, a Tzanck smear can be performed on scrapings from the base of an unroofed vesicle and microscopically reveals multinucleated cells and nuclear inclusions. The Tzanck smear, however, is highly operator-dependent and thus may have a relatively low sensitivity; it is also not specific. Direct fluorescent antibody study of skin lesion scrapings has a high sensitivity (80% to 90%), excellent specificity,<sup>185</sup> and readily available results. The gold standard for diagnosis of HSV infections remains viral culture, which can be taken from skin (especially vesicular fluid), eyes, mouth, CSF, rectum, urine, or blood.<sup>183</sup> Serologic studies generally are not useful in diagnosing neonatal HSV infection, because of the slow serologic response of the newborn and the potential confounding factor of transplacental antibody. PCR studies have been a major advance in the diagnosis of neonatal HSV infection and are especially useful for diagnosing CNS infection. Skin biopsy is rarely indicated, but if it is performed reveals characteristic intraepidermal vesicle formation with ballooning degeneration and multinucleation.

Other laboratory findings that may be suggestive of neonatal HSV infection include abnormal coagulation studies, thrombocytopenia, and elevated liver transaminases. Evaluation of CSF in those with CNS or disseminated disease often reveals a lymphocytic pleocytosis and elevated protein, although these findings may be absent in early disease and are not specific for HSV.<sup>186</sup> Electroencephalography and neuroimaging with MRI should also be performed.<sup>186</sup>

The outcome of neonatal HSV infection is quite variable. Prospective data on outcomes were gathered by the Collaborative Antiviral Study Group and revealed that the following were risk factors for mortality: CNS and disseminated disease, decreased level of consciousness at start of therapy, and prematurity. In those with disseminated disease, pneumonitis and disseminated intravascular coagulopathy were important risk factors.<sup>176</sup> Morbidity was greatest in infants with encephalitis, disseminated infection, seizures, or infection with HSV-2 (vs. HSV-1).

Education is vitally important in the prevention of HSV (and therefore neonatal HSV) during pregnancy. Studies have shown that women at greatest risk of acquiring the infection during pregnancy are those who are seronegative and whose partners are HSV-positive. It appears that acquisition of infection with seroconversion completed before labor does not affect the outcome of the pregnancy, whereas infection acquired near the time of labor is associated with neonatal HSV and perinatal morbidity.<sup>187</sup> Overall, 70% of infants with neonatal HSV are born to mothers who do not manifest any sign or symptom of genital infection at the time of delivery. Cesarean delivery should be offered to women with active HSV lesions at the time of labor, although not all cases of neonatal HSV can be prevented.<sup>180</sup> The use of acyclovir during pregnancy is controversial, although it may shorten the period of active lesions in the mother. In instances where there is a known history of maternal HSV, use of fetal scalp electrodes should be avoided whenever possible. Viral cultures in mothers with suspected genital HSV during the last few weeks before delivery and routine prophylactic cesarean section for asymptomatic women have not been demonstrated useful and are not routinely recommended.

Newborns with vesicular lesions or suspected HSV should be isolated (contact precautions), evaluated thoroughly for systemic infection, and treated with empiric antiviral therapy. Ophthalmologic evaluation should be performed, and prophylactic topical ophthalmic preparations such as idoxuridine, vidarabine, or trifluorothymidine solution should be initiated. In addition to antiviral therapy, supportive measures are often indicated, including management of seizures, respiratory distress, hemorrhage, and metabolic aberrations. Women with active HSV infection may handle and feed their infants provided they use careful hand-washing techniques and wear a disposable surgical mask or dressing to cover the lesions until they have crusted and dried. There is no unequivocal evidence that HSV is transmitted by breast milk or that breastfeeding by a mother with recurrent HSV infection poses a risk to the infant. It therefore appears that if all precautions are utilized, breastfeeding by a mother with recurrent HSV may be acceptable. After hospital discharge, affected infants should be monitored closely, because 5% to 10% will develop a recurrent infection requiring therapy within the first month of life.<sup>188</sup>

Both vidarabine and acyclovir have been demonstrated effective in the treatment of neonatal HSV. However, because of its safety profile, acyclovir is the treatment of choice.<sup>172</sup> Early studies suggested a dose range of 15 to 30 mg/kg per day for affected infants, but it was subsequently demonstrated that higher dosages are more effective. The survival rate for patients with disseminated HSV treated with high-dose acyclovir (60 mg/kg per day) was significantly higher, with a borderline significant decrease in morbidity.<sup>189</sup> Toxicity was limited to transient neutropenia during therapy, suggesting the importance of monitoring absolute neutrophil counts. Treatment recommendations are for 14 days for SEM disease and 21 days for CNS and disseminated disease.<sup>186,190</sup> Oral acyclovir suppression for 6 months after acute therapy is recommended for surviving infants with CNS disease, given the demonstrated improved neurodevelopmental outcomes.<sup>191</sup> Algorithmic guidelines on the management of asymptomatic neonates born to women with active genital herpes lesions have been published.<sup>192,193</sup>

## CONGENITAL PARVOVIRUS B19 INFECTION

Human parvovirus B19, the same virus that causes erythema infectiosum (fifth disease), may be transmitted by a gravid female to the fetus and may result in anemia, hydrops fetalis, and even intrauterine fetal demise. The cellular receptor for B19, a virus that lytically infects erythroid precursor cells, is globoside or P-antigen, which is found on erythroblasts and megakaryocytes.<sup>194</sup> Overall, up to 65% of pregnant

females are immune to B19 and therefore not at risk,<sup>195</sup> and the majority of infants born to mothers with B19 infection are delivered at term and asymptomatic. The greatest risk appears to be when infection is acquired before 20 weeks' gestation, and the overall incidence of fetal loss is between 1% and 9%.<sup>196–198</sup> Fetal B19 infection may result in severe anemia, high-output cardiac failure, generalized edema, pleural and pericardial effusions, and polyhydramnios. Although skin findings are not a major feature of congenital B19 infection, blueberry muffin lesions have been described.<sup>199</sup>

In infants who survive congenital B19 infection, there appears to be no increased risk of congenital anomalies or developmental aberrations. Pregnant women exposed to B19 should be reassured regarding the relatively low potential risk and offered serologic testing. Detection of B19 antigens in amniotic fluid or B19 deoxyribonucleic acid (DNA) via PCR are other methods available for diagnostic confirmation.<sup>200</sup> If acute B19 infection is confirmed, serial fetal ultrasonography should be performed to assess for signs of *in utero* infection. Management of severely afflicted fetuses includes fetal digitalization and *in utero* blood transfusions.

## CONGENITAL SYPHILIS

As a result of advances in the detection and treatment of syphilis during the years after the Second World War, the incidence of neonatal syphilis dropped to relatively insignificant levels by the mid-1950s. Since 1959, however, the incidence of primary and secondary syphilis has increased, with a resultant resurgence in the incidence of CS. Surveillance data reported to the Centers for Disease Control and Prevention (CDC) by 50 states and the District of Columbia from 1992 to 1998 revealed 942 deaths among 14,627 cases of CS, resulting primarily from untreated, inadequately treated, or undocumented treatment of syphilis during pregnancy.<sup>201</sup> In the United Kingdom, the number of babies reported with CS increased from two in 1996 to 14 in 2005.<sup>202</sup> A review of national surveillance data from 2003 through 2008 revealed an increase in the CS rate from 8.2 cases per 100,000 live births in 2005 to 10.1 cases per 100,000 live births in 2008. This increase paralleled the increase in primary and secondary syphilis among females from 2004 through 2007, and it was noted that the CS rates increased primarily in the South and among infants born to black mothers.<sup>203</sup> Such data reveal that CS still represents a public health problem and highlight the fact that early prenatal care via early detection and treatment of maternal syphilis is an essential component in CS prevention in neonates.

CS is a disorder in which the fetus becomes infected with the spirochete *Treponema pallidum*, usually after the 16th week of pregnancy. The risk of fetal transmission is estimated to be 70% to 100% for untreated early syphilis.<sup>204</sup> The widely varied manifestations of CS are determined in part by the stage of maternal syphilis, stage of the pregnancy at the time of infection, rapidity of maternal diagnosis, and treatment and immunologic reaction of the fetus.<sup>205</sup> Up to 40% of fetuses with CS are stillborn, and among affected live newborns, two-thirds are symptom-free at birth. Perinatal associations with CS include premature delivery, low birthweight, and small size for gestational age.<sup>206</sup>

The clinical manifestations of CS are divided into lesions of early CS (appearing before 2 years of age) and late CS (occurring after 2 years of age). Skin lesions of early CS are generally infectious, and because there is no primary stage, they may resemble those of acquired secondary syphilis. They differ from those of the second stage of syphilis in that the fetal lesions are generally more widely distributed, more severe, and of longer duration. Lesions of late CS represent either a hypersensitivity reaction on the part of the host or scars and deformities that are direct consequences of infection.

### Early Congenital Syphilis

Fetal infection with *T. pallidum* results in multisystem involvement with considerable variation in clinical expression. Although infants with CS commonly exhibit no external signs of disease at the time of birth, many experience clinical manifestations within the first month. Those with florid manifestations at birth appear to be more severely infected, are often premature, and usually have a poor prognosis. Recently, a retrospective review demonstrated that premature infants

**Figure 2-48** Congenital syphilis. Erythema, scaling, and fissuring of the plantar surfaces in early congenital syphilis.

are more likely to display characteristic features of early CS, including skin findings, hepatosplenomegaly, thrombocytopenia, and radiographic findings in long bones as neonates, as compared with full-term infants.<sup>207</sup>

The most common clinical manifestations of early CS are summarized in Table 2-5. Rhinitis (snuffles) is commonly the first sign of CS. Cutaneous lesions of CS are seen in one-third to one-half of affected infants and may be quite varied. Most common is a diffuse papulo-squamous eruption that includes the palms and soles, comparable with the rash seen in secondary syphilis in older patients. Vesiculobullous lesions are relatively rare, but when they involve the palms and soles are highly diagnostic of CS. The palms and soles are often fissured, erythematous, and indurated with a dull red, shiny appearance (Fig. 2-48). Concomitant with these changes, desquamation in large, dry flakes may occur over the entire body surface area. Flat, moist, wart-like lesions (condylomata lata) commonly appear in moist areas of skin in infants with CS and are extremely infectious. Intractable diaper dermatitis is occasionally present. Mucous patches, which present as fissures at mucocutaneous junctions, are among the most characteristic and most infectious of the early lesions seen in CS.

Necrotizing funisitis, spiral zones of red and blue umbilical cord discoloration interspersed with streaks of chalky white (hence the term *barber-pole umbilical cord*), has been described as a commonly overlooked, early diagnostic feature of CS. The external smooth surface of the umbilical cord without evidence of exudation apparently differentiates necrotizing funisitis from acute bacterial funisitis, an inflammation of the umbilical cord seen in newborns with acute bacterial infection.<sup>208</sup>

Hepatomegaly, when present, is often associated with icterus and occasionally ascites, splenomegaly, and generalized lymphadenopathy. The jaundice, together with anemia, edema, and cutaneous changes, produces a peculiar dirty, whitish brown (*café-au-lait*) appearance to the skin. Hemolytic anemia and occasional thrombocytopenia are common features of early CS. When occurring with hepatosplenomegaly, jaundice, and large numbers of nucleated erythrocytes in the peripheral circulation, an erroneous diagnosis of erythroblastosis fetalis may be made. Nephrotic syndrome and pneumonitis are occasionally present.

Although only 15% of infants with CS show clinical signs of osteochondritis at birth, 90% show radiologic evidence of osteochondritis and/or periostitis after the first month of life. Syphilitic osteochondritis may occur in any bone but is found most often in the long bones

**Table 2-5** Manifestations of Early Congenital Syphilis

System	Specific Features	Comment
Constitutional	Fever, wasting	
Nasal	Snuffles (nasal discharge)	Commonly the first sign 2–6 weeks of life Ulceration of nasal mucosa If deep, may involve cartilage and result in "saddle-nose deformity"
Hematologic	Hemolytic anemia Thrombocytopenia	
Lymphoid	Lymphadenopathy	Epitrochlear nodes highly suggestive
Visceral	Hepatosplenomegaly	50% to 75% of patients Icterus, jaundice, ascites associated
Mucocutaneous	Papulosquamous lesions  Condylomata lata Mucous patches	Diffuse eruption Palms and soles red, fissured ( <b>Fig. 2-42</b> ) Bright pink-red, fades to coppery brown Rare vesiculobullous lesions Eventual widespread desquamation Flat, wart-like lesions in moist areas (especially anogenital, nares, mouth angles) Present in 30% to 35% Weeping, fissuring at mucocutaneous junctions Extend out from lips in radiating fashion When deep, may leave scars (rhagades) of perioral region
Osseous	Osteochondritis  Periostitis  Dactylitis	15% of patients, especially long bones of extremities; often focal Usually asymptomatic, but severe involvement may lead to subepiphyseal fracture and painful pseudoparalysis of Parrot Most pronounced at 2–6 months of life Usually diffuse Calcification and thickening of cortex may lead to permanent deformity (i.e., frontal bossing, anterior bowing of tibia or saber shins) Affects small bones of hands/feet
CNS	CSF abnormalities	Increased protein, mononuclear pleocytosis, (+) CSF-VDRL

CNS, Central nervous system; CSF-VDRL, cerebrospinal fluid-Venereal Disease Research Laboratories test.

of the extremities. Radiographic findings consist of increased widening of the epiphyseal line with increased density of the shafts, spotty areas of translucency, and a resultant moth-eaten appearance. In most cases, the bony lesions are asymptomatic, but in some infants severe involvement may lead to subepiphyseal fracture with epiphyseal dislocation and extremely painful pseudoparalysis of one or more extremities (so-called "pseudoparalysis of Parrot"). Dactylitis, a rare form of osteochondritis of the small bones of the hands and feet that usually appears between 6 months and 2 years of age, may also occur.

Periosteal lesions are seldom present at birth. Periostitis of the frontal bones of the skull, when severe, may contribute to the flat overhanging forehead that persists as a stigma of children severely infected in infancy. The radiologic changes of periostitis are usually most pronounced between the second and sixth months of life and rarely persist beyond the age of 2 years. Lesions are usually diffuse (in contrast to the localized involvement characteristic of lesions of osteochondritis) and often extend the entire length of the involved bone. First seen as a thin, even line of calcification outside the cortex of the involved bone, the lesions progress and additional layers of opaque tissue are laid down, with the resulting "onion-peel" appearance of advanced periostitis. This eventually produces calcification and thickening of the cortex and, when severe, a permanent deformity. In the tibia, this results in an anterior bowing referred to as *saber shins*. In the skull it is seen (in 30% to 60% of patients) as frontal or parietal bossing.

Even though clinical evidence of CNS involvement is a relatively uncommon finding, CSF abnormalities may be detected in 40% to 50% of infants with CS. Recently IgM immunoblotting and PCR assay on serum or CSF were shown to be most predictive of CNS infection.<sup>209</sup> Clinical evidence of meningitis with a bulging fontanel, opisthotonos, and convulsions generally portends a poor prognosis. Low-grade syphilitic meningitis may result in a mild degree of hydrocephalus, and children with CNS involvement continuing beyond the period of

### Box 2-3 Signs of Late Congenital Syphilis

- Clutton joints (knee effusions)
- Eighth cranial nerve deafness\*
- Frontal bossing
- Gummas (skin, subcutaneous, and bone inflammation and ulceration)
- Higouménakis sign (thickening of inner third of clavicle)
- Hutchinson teeth\* (peg-shaped upper central incisors)
- Hydrocephalus
- Interstitial keratitis\*
- Mental retardation
- Mulberry molars
- Ocular changes (retinitis, optic nerve atrophy)
- Paroxysmal cold hemoglobinuria
- Rhagades (perioral fissuring)
- Saber shins
- Saddle nose
- Short maxillae

\*Hutchinson triad.

infancy may go on to demonstrate marked residua with varying degrees of physical and mental retardation.

### Late Congenital Syphilis

Late CS refers to the findings that persist beyond 2 years of age. It also includes varying signs and stigmata of CS in individuals in whom the diagnosis was overlooked or in those patients who were inadequately treated early in the course of the disease. Signs of late CS are summarized in **Box 2-3**, and a few are discussed in more detail here.

Perhaps the most pathognomonic signs of late CS are the dental changes. The deciduous teeth are prone to caries but show no specific abnormalities characteristic of this disorder. The term *Hutchinson*

incisors is applied to deformities of the permanent upper central incisors, and the condition is characterized by central notching with tapering of the lateral sides toward the biting edge (so-called "screwdriver teeth"). The simultaneous appearance of interstitial keratitis, Hutchinson incisors, and eighth nerve deafness is called the *Hutchinson triad*. Although described as a time-honored sign of CS, owing to the relative infrequency of eighth nerve deafness, this triad is actually extremely uncommon and rarely observed. The "mulberry molar" is a malformation of the lower first molars. The mulberry appearance is created by poorly developed cusps crowded together on the crown. Since these teeth are subject to rapid decay, mulberry molars are rarely seen past puberty. When present, however, they are pathognomonic of CS.

*Higouménakis sign* refers to unilateral thickening of the inner third of the clavicle and is commonly described as a manifestation of late CS. Because fracture of the middle third of the clavicle is the most common fracture occurring at birth, consequent healing and thickening of the involved bone often produces a clinical picture similar to that seen with Higouménakis abnormality. This finding should therefore not be considered a reliable stigma of late CS.

Paroxysmal cold hemoglobinuria is characterized by shaking chills and dark urine within 8 hours of cold exposure, and it may also occur as a manifestation of late CS. It is usually seen in patients with late CS who did not receive treatment, and although it is not pathognomonic, it is highly suggestive of late congenital or untreated acquired syphilis.

### Diagnosis and Treatment of Congenital Syphilis

Determination of the maternal serologic status for syphilis is standard of care in hospitals, and no newborn infant should be discharged without this information being known.<sup>210</sup> All infants born to mothers who are seropositive require a thorough clinical and laboratory examination, namely a quantitative nontreponemal syphilis test (i.e., Venereal Disease Research Laboratories [VDRL], rapid plasma reagent [RPR]), and preferably the same as that performed on the mother so that the titers can be compared. Further evaluation of the infant should occur if the mother received no therapy, inadequate therapy, therapy less than 1 month before delivery, therapy without the expected drop in antibody titer, or therapy before pregnancy with insufficient serologic follow-up examination.<sup>210</sup> Confirmation of a reactive nontreponemal test is accomplished with a specific treponemal test, such as the fluorescent treponemal antibody absorption (FTA-ABS) test and the microhemagglutination test for *T. pallidum* (MHA-TP). Placental changes may be a useful adjunct in the diagnosis of CS, and include necrotizing funisitis (see above in *Early Congenital Syphilis* section), villous enlargement, and acute villitis.<sup>211</sup> Diagnosis may be confirmed by positive darkfield examination from the umbilical vein or from moist lesions of the skin or mucous membranes.

Serologic tests in the newborn must be interpreted with caution, because their results may be caused by passive transfer of nontreponemal and treponemal antibodies from the mother and their antibody response may be delayed. A serologic titer in the newborn higher than that of the mother, however, is diagnostic. Additionally, since maternal IgM antibodies do not cross the placenta, detection of IgM in the infant indicates active infection.<sup>202</sup> If no other indications of active infection are evident, with serologic titers equal to or lower than the maternal titer, infants should be monitored closely, with repeated titers taken at appropriate intervals. In cases of passive transfer of antibody, the neonatal titer should not exceed that of the mother and should revert to negative within 4 to 6 months. In cases in which the mother is infected late in pregnancy, both mother and child may be nonreactive at delivery. In such instances, clinical signs and rising titers during the ensuing weeks will confirm the diagnosis.

Evaluation of the infant suspected of having CS should include a thorough physical examination, ophthalmologic evaluation, serologic studies, CSF-VDRL and cellular/protein analysis, long bone and chest radiographs, complete blood cell and platelet count, and liver function studies.<sup>210</sup>

Parenteral penicillin G is the treatment of choice for all forms of syphilis. Once the diagnosis of CS is confirmed, treatment should commence immediately with aqueous crystalline penicillin G in a dosage of 100,000 to 150,000 units/kg per day intravenously, divided every

12 hours during the first 7 days of life and every 8 hours thereafter, for a total of 10 days. Procaine penicillin G in a dosage of 50,000 units/kg per dose administered intramuscularly once daily for 10 days is an alternative. Treated infants should be monitored closely, with evaluations at 1, 2, 3, 6, and 12 months of age and nontreponemal tests at 2 to 4, 6, and 12 months after conclusion of treatment, until results become nonreactive, or the titer has decreased fourfold.<sup>210</sup>

Infants with evidence of CNS involvement should receive crystalline penicillin G at a dosage of 200,000 to 300,000 units/kg per day given every 4 to 6 hours for 10 to 14 days. Because studies with benzathine penicillin suggest inadequate penetration of the CNS of newborns when serum penicillin levels are low, its use for CS with CNS involvement is not recommended. However, some experts recommend a single intramuscular dose of benzathine penicillin G at 50,000 units/kg after the course of intravenous aqueous crystalline penicillin in children older than 2 years of age who have late and previously untreated CS.<sup>210</sup>

### CYTOMEGALIC INCLUSION DISEASE

Cytomegalic inclusion disease in the newborn is a generalized infection caused by the CMV, a DNA virus of the herpes virus group. It is the most common intrauterine infection in the United States.<sup>212</sup> CMV can be transmitted from person to person via urine, saliva, tears, and genital secretions, as well as via the transplacental route from mother to fetus. Congenital CMV infection occurs in 0.3% to 2.4% of all live births in developed countries,<sup>213</sup> and primary CMV infections are reported in 1% to 4% of seronegative pregnant women. The risk of viral transmission to the fetus is estimated at 30% to 40%.<sup>214</sup> CMV transmission has been reported far less often in association with nonprimary maternal infection.<sup>213</sup> In infants with congenital infection, around 5% to 18% are symptomatic at birth.<sup>215</sup> Although the majority of infected infants are asymptomatic, sequelae of congenital CMV infection in symptomatic patients may range from mild defects to severe or fatal disease. Infants of Native American and African-American descent have a disproportionately greater risk of mortality from congenital CMV infection compared to whites, Asians, and Hispanics.<sup>212</sup>

CMV is generally transmitted from a pregnant mother with inapparent infection across the placenta to the fetus late in gestation, although it can also be transmitted by passage through an infected maternal genital tract at the time of delivery or by postnatal CMV-positive blood transfusion. Postnatal transmission may also occur after consumption of infected breast milk, and low birthweight and early postnatal virus transmission are risk factors for symptomatic infection in this setting.<sup>216</sup> In the United States, the CMV seroprevalence is around 50%, leaving several women of reproductive age at risk for maternal infection.<sup>217</sup> Congenital infection is usually suspected based on fetal ultrasound findings including hydrops, intrauterine growth restriction, microcephaly, ventriculomegaly, and periventricular calcifications. Prematurity occurs in up to 34% of infants with symptomatic congenital CMV infection.<sup>218</sup> Although maternal immunity to CMV was once believed to protect the fetus from infection, it is now known that symptomatic congenital infection can occur after a recurrent maternal infection.<sup>219,220</sup> Because most congenital CMV infections are asymptomatic, diagnosis is most commonly made in infants who manifest several features of the syndrome.

Clinical findings of congenital CMV infection include jaundice, hepatosplenomegaly, anemia, thrombocytopenia, protracted interstitial pneumonia, chorioretinitis, deafness, microcephaly, hypotonia and eventual mental retardation. Cerebral calcifications (often paraventricular) may be noted on imaging studies. Cutaneous manifestations include jaundice, petechiae and purpura, a generalized maculopapular eruption, and a generalized blueberry muffin eruption similar to that seen in infants with congenital rubella and toxoplasmosis. Although extremely rare, vesicular lesions have also been reported in infants with this disorder. Most symptomatic cases of congenital CMV infection are fatal within the first 2 months of life. Those who survive often manifest severe neurologic defects including microcephaly, mental retardation, deafness, spastic diplegia, seizures, chorioretinitis, optic nerve atrophy, and blindness. In infants infected with CMV who do not manifest clinical symptoms at birth, 5% to 15%

develop late-onset sequelae such as hearing loss, chorioretinitis, mental retardation, and neurologic defects.<sup>221</sup>

The gold standard for diagnosis of congenital CMV infection remains the detection of virus in saliva, blood, or urine during the first few weeks of life.<sup>213</sup> Viral recovery or a strongly positive serum IgM anti-CMV antibody is considered diagnostic. PCR is becoming increasingly popular in the diagnosis of CMV disease and can be applied to urine, blood, saliva, and/or CSF. It offers more rapid results and increased sensitivity. Later in infancy, differentiation between intrauterine and perinatal infection is difficult unless signs of intrauterine infection such as chorioretinitis or ventriculitis are present. When the diagnosis remains in doubt, persistent or rising complement-fixation titers may provide confirmatory evidence. Electron microscopic examination for viral particles in urine samples is a rapid diagnostic technique that can also be used, if available. Quantitative PCR examinations on peripheral blood leukocytes can be used to monitor viral load in infected newborns who are infected with CMV.

Prenatal diagnosis should be reserved for pregnancies in which ultrasonographic findings suggest suspicion for CMV fetal infection.<sup>215</sup> Available methods include CMV isolation from amniotic fluid and identification of CMV DNA by PCR analysis. Demonstration of IgM anti-CMV antibody in percutaneous umbilical blood samples is also diagnostic, but this test is more difficult and has a lower sensitivity. Diagnosis of primary CMV infection in pregnant women is achieved with sensitive IgM and IgG avidity serologic assays, as well as conventional and molecular detection of virus in blood.<sup>222</sup>

There is no consistently effective therapy for congenital CMV infection, and prognosis for the patient with severe involvement is poor. Ganciclovir has been used, although large-scale studies are lacking, and its use is associated with significant toxicity. One phase II collaborative study of ganciclovir treatment in symptomatic congenital CMV revealed hearing improvement or stabilization in 16% of patients but only a temporary decrease in CMV excretion in the urine.<sup>223</sup> Intravenous ganciclovir therapy is recommended in the management of babies with symptomatic congenital CMV disease involving the CNS, and treatment should be initiated within the first month of life. Valganciclovir, the oral prodrug of ganciclovir, has been used as an alternative.<sup>224,225</sup>

## CONGENITAL EPSTEIN–BARR VIRUS SYNDROME

Because the majority of young adults are seropositive for EBV, primary infection during pregnancy is uncommon. Although features of congenital EBV infection such as micrognathia, cryptorchidism, cataracts, hypotonia, erythematous skin eruptions, hepatosplenomegaly, lymphadenopathy, and persistent atypical lymphocytosis have been reported, the low rate of EBV infection in pregnancy makes it difficult to assess the full extent of this risk. A recent prospective study comparing women with serologic evidence of primary, recurrent, or undefined infection to a control group found no differences in pregnancy outcome, birthweights, or incidence of congenital anomalies, suggesting that EBV infection during pregnancy does not represent a significant teratogenic risk.<sup>226</sup>

## CONGENITAL TOXOPLASMOSIS

Toxoplasmosis is a parasitic disorder caused by *Toxoplasma gondii*, an intracellular protozoan that may invade multiple tissues including muscle (including the heart), liver, spleen, lymph nodes, and the CNS. Although up to 23% of adolescents and adults may have laboratory evidence of *T. gondii* infection, most are asymptomatic or associated with self-limited symptoms.<sup>227</sup> However, infections in pregnant women may result in serious infantile sequelae if transmitted to the fetus, most notably mental retardation, seizures, and blindness. Toxoplasmosis is transmitted to the fetus transplacentally, and the greatest risk of transmission (60% to 90%) is when acute infection occurs during the third trimester. The severity of fetal infection tends to be greater when infection is acquired during the first trimester. Toxoplasmosis is postnatally transmitted to humans via consumption of raw or inadequately cooked meat (especially pork, lamb, mutton, and wild game)<sup>228</sup> or inadvertent ingestion of oocysts from cat feces in litter or soil.<sup>229</sup>

Most pregnant women with acute *T. gondii* infection are asymptomatic without any obvious signs.<sup>228</sup> The highest burdens of congenital toxoplasmosis are found in South America, parts of the Middle East, and some low-income countries in Africa.<sup>229</sup>

Fetal infection with *T. gondii* may result in stillbirth or prematurity. Signs and symptoms of congenital toxoplasmosis may be present immediately at birth or develop during the first few weeks of life and include fever, malaise, vomiting and diarrhea, lymphadenopathy, hepatosplenomegaly, microphthalmia, cataracts, microcephaly, pneumonitis, pericarditis, bleeding diathesis, and seizures. The classic triad of congenital toxoplasmosis consists of chorioretinitis, hydrocephalus, and intracranial calcifications. Up to 80% of patients develop visual or learning disabilities later in life. Hearing impairment, potentially resulting in deafness, may also occur.<sup>230</sup>

Cutaneous findings of congenital toxoplasmosis include a generalized rubella-like maculopapular eruption that generally spares the face, palms, and soles. Blueberry muffin-like lesions (representing extramedullary hematopoiesis) may be present, as may a scarlatiniform eruption or subcutaneous nodules. The skin eruption usually develops during the first weeks of illness, persists for up to 1 week, and may be followed by desquamation or hyperpigmentation.

Laboratory findings in patients with congenital toxoplasmosis are nonspecific and may reveal anemia, eosinophilia, thrombocytopenia, and at times severe leukopenia. The CSF may be xanthochromic and may contain leukocytes, erythrocytes, and an elevated level of protein. Skull radiographs of affected infants may reveal diffuse, punctate comma-shaped intracranial calcifications.

The diagnosis of congenital toxoplasmosis is made via the combination of clinical findings, serologic studies, DNA-based testing and, occasionally, parasite isolation. Identification of *T. gondii*-specific IgG and IgM antibodies are the most commonly used diagnostic modality, although the clinical significance of IgG antibodies is difficult to interpret during the first 6 months of life. Detection of *Toxoplasma*-specific IgA antibodies in the congenitally infected neonate may be more sensitive than IgM detection.<sup>231</sup> Peripheral blood, CSF, urine, and amniotic fluid specimens should be subjected to PCR testing for *T. gondii*.<sup>231</sup> Much attention has been focused on the prenatal diagnosis of toxoplasmosis, and in addition to maternal serologic studies other available methods include IgG avidity studies, the Sabin–Feldman dye test, and PCR analysis of amniotic fluid. Cordocentesis for evaluation of fetal blood serologies is rarely utilized in the current era.

Most newborns with toxoplasmosis are asymptomatic or have only mild symptomatology, although many may have learning disabilities later in life. Because of the serious sequelae that may develop, even in asymptomatic infants, congenital toxoplasmosis should be treated whether or not the infection is clinically apparent. If fetal infection is confirmed, recommended treatments for the mother have included various combinations of sulfadiazine, pyrimethamine, folic acid, and spiramycin.<sup>232,233</sup> Pyrimethamine combined with sulfadiazine, with folic acid supplementation, is recommended as initial therapy for congenital infection for up to one year. For mild disease, some experts recommend alternating this regimen monthly with spiramycin, during months 7 to 12 of treatment.<sup>231</sup>

The prognosis for infants with toxoplasmosis is variable, although infants who have predominantly CNS involvement have a uniformly poor prognosis. Affected infants may suffer from chorioretinitis with subsequent blindness, microcephaly, hydrocephaly, or mental retardation.

# 3

# Eczematous Eruptions in Childhood

Eczematous eruptions are characterized as inflamed papules and plaques, often in association with pruritus and serous discharge. The specific subtype of eczematous dermatitis is based upon the clinical morphology, distribution of lesions, and in many cases the history of exposure. Biopsy of the skin in these conditions is usually not helpful except to consider alternative diagnoses with distinct histopathologic features. In children, by far the most prevalent type of eczematous eruption is atopic dermatitis (AD).

## Atopic Dermatitis

AD, one of the most common skin disorders seen in infants and children, begins during the first 6 months of life in 45% of children, the first year of life in 60% of affected individuals, and before 5 years of age in at least 85% of affected individuals.<sup>1</sup> Although the term *eczema* is commonly used, AD is a more precise term to describe this subset of dermatitis or inflammation of skin. The concept of *atopy* (derived from the Greek *atopia*, meaning *different* or *out of place*) was originated by Coca and Cooke in 1923.<sup>2</sup> Although initially only asthma and allergic rhinitis were included in this category, Wise and Sulzberger in 1933 coined the term AD,<sup>3</sup> noting the association of this form of eczema with other atopic disorders.

### PREVALENCE AND ASSOCIATION WITH OTHER ATOPIC DISORDERS

The prevalence of AD in American children is 10% to 13%,<sup>4,5</sup> which is consistent with the prevalence in Scandinavia<sup>6,7</sup> and Japan<sup>8</sup> and represents a marked increase during the past several decades. Studies performed before 1960 estimated the prevalence to be up to 3%.<sup>9</sup> Of these, 67% have mild disease, 26% have moderate disease, and 7% have severe AD.<sup>5</sup> AD severity is increased in older children, the eldest child in the family, and in children with African-American or Hispanic race/ethnicity.<sup>5</sup> AD occurs more often in urban areas than in rural areas, in blacks, in smaller families, and in higher socioeconomic classes, suggesting that exposure to antigenic pollutants and lack of exposure to infectious agents or other antigenic triggers early in life may play a role in the development of the dermatitis. The subsequent steady increase has paralleled the increase seen in children with asthma, suggesting a shared mechanism or triggers. In fact, AD is often the first manifestation of the “atopic march,” with the later development of sensitization to foods and environmental allergens, asthma and allergic rhinitis. Children with AD overall have a threefold increased risk of developing asthma and a threefold increased risk of developing allergic rhinitis compared with children without AD. Greater severity, earlier onset, persistence of the AD, and parental history of allergic disease further increase the odds of developing other atopic disorders.<sup>7</sup> Overall, asthma occurs in up to 50% of children who develop AD during the first 2 years of life; allergic rhinitis develops in 43% to 80% of children with AD.<sup>10</sup> In addition to the higher prevalence of comorbid asthma, hay fever, and food allergies, severe AD in children is correlated with poorer overall health, impaired sleep, and increased healthcare utilization.<sup>11</sup> Some have classified AD into an immunoglobulin (Ig) E-associated form (“true” or “extrinsic” AD in 70% to 80% of patients) and a non-IgE-associated form (“non-atopic” or “intrinsic” AD). Although the significance of having high IgE levels is unclear, recent biomarker studies in adults have shown that individuals with intrinsic AD show similar activation of T helper (Th) 2 cytokines, but increased Th17 cytokines in comparison with adults with extrinsic AD.<sup>12</sup>

### GENETIC ALTERATIONS

A role for causative genetic alterations is suggested by the concordance of 77% in monozygotic twins<sup>13</sup> and the greater probability of having AD if one or, even more so, both parents have AD.<sup>14</sup> Loss-of-function mutations in profilaggrin (*FLG*) cause ichthyosis vulgaris, a common genetic disorder characterized by dry, scaling skin and hyperlinear palms (see Chapter 5) that has long been known to be associated with AD. Mutations in *FLG* occur in 10% to 30% of AD patients.<sup>15-19</sup> In addition to the tight linkage of AD with genes of the epidermal differentiation complex (particularly encoding filaggrin),<sup>20</sup> genome-wide association (GWA) studies have shown numerous other associated loci, primarily suggesting a role for epidermal barrier function and innate-adaptive immunity in the pathogenesis of AD.<sup>21</sup>

### UNDERSTANDING ATOPIC DERMATITIS PATHOMECHANISM AS A GUIDE TO THERAPY

The “inside-out” concept of AD pathogenesis focuses on immune abnormalities as being primary, whereas the “outside-in” theory considers the epidermal barrier dysfunction (a form of “innate immunity”) as primary. Nevertheless, AD results from the complex interaction between immune dysregulation, epidermal barrier dysfunction, and environmental interactions with skin.<sup>22,23</sup> Understanding these alterations have led to new therapies for AD (see the Management section).

In the acute phase of AD, environmental triggers including irritants, allergens, microbes, and mechanical injury (scratching or rubbing) activate the skin’s innate immune system, which includes epidermal Langerhans cells, keratinocytes, and local immune cells.<sup>24-25</sup> Expression of cytokines, particularly thymic stromal lymphopoietin (TSLP), interleukin (IL)-25 and IL-33, activate group 2 innate lymphoid cells (ILC2s), leading to Th2 cell activation.<sup>26</sup> Th2 cells express IL-4, -5, and -13, which promote eosinophilia and IgE production but suppress the expression of epidermal barrier proteins as well as antimicrobial peptides such as  $\beta$ -defensins and cathelicidin. This reduction in antimicrobial peptide production likely contributes to the propensity toward development of skin infection in AD patients.<sup>27</sup> TSLP and another Th2 cytokine, IL-31, are thought to mediate AD pruritus.<sup>28,29</sup> Systemic circulation of keratinocyte-derived TSLP has been suggested to promote the development of allergic sensitization in both the gastrointestinal (GI) tract and the lungs.<sup>30,31</sup>

Recent studies show that AD T cells also differentiate into Th22 cells, which produce IL-22 and thereby stimulate expression of keratinocyte S100As.<sup>32,33</sup> IL-22 has been implicated in the thickening of skin with lichenification. The role of Th17 cells in AD is not well understood, but increased levels of IL-17 are found (although not to the extent of Th2 cytokines and IL-22), particularly in patients with intrinsic (vs. extrinsic) AD.<sup>12</sup> With chronic AD, the Th2 and Th22 cytokine profiles are accentuated, and in addition, Th1 cytokines are detected (predominantly interferon- $\gamma$ ).<sup>32</sup>

Elevation of cytokines and chemokines in lesional and nonlesional skin, as well as in blood, are biomarkers of disease activity. In adult AD skin, the levels of IL-13, IL-22, CCL17 (TARC), and S100A biomarkers have been found to correlate with disease responses to cyclosporine A<sup>34</sup> and narrow-band ultraviolet light.<sup>35</sup> In the blood, levels of IL-33,<sup>36</sup> Th2 and Th22 cytokines/chemokines,<sup>37</sup> and periostin,<sup>38</sup> a Th2 cytokine-induced extracellular matrix protein, are increased in AD and correlate with disease severity.

The intact epidermis itself also plays a role in the skin’s innate immune system, because it functions as a barrier against water loss (preventing dry skin) and penetration of high molecular weight

### Box 3-1 Clinical Criteria for Atopic Dermatitis

#### Essential Feature

Pruritus (or parental reporting of itching or rubbing) in past 12 months

#### Plus Must Have at least Three of the Following

- History of generally dry skin in past year
- Personal history of allergic rhinitis or asthma (or history in first-degree family member if child <4 years old)
- Onset before 2 years of age (unless currently <4 years of age)
- History of skin crease involvement (antecubital or popliteal fossae; front of ankles; neck; periorbital)
- Visible flexural dermatitis (if child <4 years, include cheeks or forehead, and extensor surface of limbs)

Modified from Brenninkmeijer EE, Schram ME, Leeflang MM, et al. Diagnostic criteria for atopic dermatitis: a systematic review. *Br J Dermatol* 2008;158:754–65. © 2008 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.

allergens such as dust mite antigens, foods, and microbes. This barrier can be altered by decreased expression of structural proteins (particularly filaggrin) and lipids (particularly ceramides) or by increased expression of proteases (especially kallikrein 5) that break down barrier proteins and increase TSLP.<sup>39–41</sup> Filaggrin is the major component of the stratum granulosum of epidermis and binds to keratin. Its precursor, profilaggrin, contains 10 to 12 monomers of filaggrin, and fewer monomers within the profilaggrin gene (i.e., 10 vs. 12) have been linked to an increased risk of developing AD,<sup>42</sup> which complements the known increased risk of developing AD with filaggrin insufficiency from null mutations in profilaggrin, as occurs in patients with ichthyosis vulgaris (see Chapter 5).<sup>43,44</sup> Filaggrin is also broken down into amino acids, such as urocanic acid, that promote skin hydration, providing another explanation for the dry skin of AD and ichthyosis vulgaris. AD in association with mutations in *FLG* has been shown to be more severe and more persistent.<sup>45</sup> Although little is known about epidermal lipids in AD, decreased content of long-chain ceramides<sup>46</sup> may also contribute to the defect, and many emollients now contain ceramides in an effort to correct the ceramide deficiency. One moisturizer contains both ceramides and filaggrin breakdown products (Cetaphil Restoraderm cream).<sup>47</sup>

## CLINICAL FEATURES

The cardinal features of AD are pruritus, chronicity, and the age-specific morphology and distribution of lesions (Box 3-1).<sup>48</sup> Extent of involvement may range from mild and limited, for example to flexural areas, to generalized and severe. AD has been divided into phases based on patient age and the distribution of lesions (infantile, childhood, and adult), but there is considerable overlap (e.g., infants may show the typical distribution of adult AD).

The infantile phase of AD reflects the manifestations of AD from birth to 6 months of age. It is characterized by intense itching, erythema, papules, vesicles, oozing, and crusting. In infants, it usually begins on the cheeks, forehead, or scalp (Figs. 3-1, 3-2, and 3-3) and then may extend to the trunk (Fig. 3-4) or particularly the extensor aspects of the extremities in scattered, ill-defined, often symmetrical patches. Generalized xerosis is common. Exacerbation of facial dermatitis on the medial cheeks and chin is often seen concomitant with teething and initiating foods. This localization likely reflects exposure to irritating saliva and foods, although contact dermatitis or urticaria may contribute. By 8 to 10 months of age the extensor surfaces of the arms and legs often show dermatitis (Fig. 3-5), perhaps because of the role of friction associated with crawling and the exposure of these sites to irritant and allergenic triggers such as those found in carpets. Although dermatitis of the antecubital and popliteal fossae, periorbital areas, and neck are more commonly involved in older children and adolescents, these sites may be affected in infants and young children as well (Fig. 3-6). Typically, lesions of AD spare the groin and diaper area during infancy (Fig. 3-7), which aids in the diagnosis. This sparing likely reflects the combination of increased hydration in the diaper area, protection from triggers by the diaper, and inaccessibility

**Figure 3-1** Acute atopic dermatitis (AD) on the cheek of an infant. Note the tremendous edema and exudation typical of infantile AD.

**Figure 3-2** Atopic dermatitis (AD) and seborrheic dermatitis. The seborrheic dermatitis of this 2-month-old boy with AD and severe combined immunodeficiency cleared within a few months, but the facial dermatitis persisted and required topical immunosuppressive therapy.

**Figure 3-3** Atopic dermatitis and the headlight sign. Note the relative sparing of the midface and immediate perioral area.

**Figure 3-4** Atopic dermatitis on the trunk and extremities of an infant.

**Figure 3-5** Involvement of the extensor surfaces of the legs and arms are commonly seen during the infantile phase of atopic dermatitis beginning at about 8 months of age, concomitant with crawling and exposure to irritant and allergenic triggers.

**Figure 3-7** Relative sparing of the diaper area is typical in infants with atopic dermatitis, likely owing to the occlusion of this site and protection from scratching and rubbing, as well as from allergenic triggers.

**Figure 3-8** Extensive lichenification on the legs of this affected toddler. Note the follicular accentuation and relative sparing of the popliteal areas.

**Figure 3-6** Although antecubital and popliteal fossa involvement is typical of the childhood and adult phases of atopic dermatitis, infants not uncommonly will show involvement at these fold areas. This infant is demonstrating his response to the pruritus.

to scratching and rubbing. The “headlight sign” has been used to describe the typical sparing of the nose and medial cheeks in AD, even when there is extensive facial involvement elsewhere (see Figs. 3-2 and 3-3).

Not uncommonly, infants initially show signs of seborrheic dermatitis, particularly during the first month or two of life. The associated pruritus and the dry (rather than greasier) scale suggest the combination of both disorders (see Fig. 3-3); the seborrheic component usually clears by 6 to 12 months, whereas the AD features persist. Alopecia may accompany the scalp involvement because of inflammation and chronic rubbing.

The childhood phase of AD usually occurs from 2 years of age to puberty. Affected persons in this age group are less likely to have exudative and crusted lesions and have a greater tendency toward chronicity and lichenification (Fig. 3-8). Eruptions are characteristically drier and more papular and often occur as circumscribed scaly patches. The classic areas of involvement in this group are the wrists, ankles, hands, feet, neck, and antecubital and popliteal regions (Figs. 3-9 and 3-10). Facial involvement switches from cheeks and chin to periorbital (Fig. 3-11) and perioral, the latter sometimes manifesting as “lip-licker’s dermatitis” (see Figs. 3-33 and 3-50). Dermatitis of

**Figure 3-9** Xerosis with erythema, fissuring, and crusting on the neck and periauricular area in this 10-year-old boy.

**Figure 3-12** Nipple eczema occasionally occurs in infants and children with AD and is exacerbated by the rubbing of clothes on the affected nipples.

**Figure 3-10** Atopic dermatitis with irritant dermatitis on the dorsal aspect of the hand. Note the fissuring, which can be quite uncomfortable.

**Figure 3-13** Papular atopic dermatitis (AD) is more commonly seen in African-American children with AD and can be difficult to distinguish from lichen nitidus (see Fig. 4-53) and juvenile frictional lichenoid dermatosis (see Fig. 3-44).

**Figure 3-11** Facial atopic dermatitis in children and adolescents typically affects the periorbital and perioral areas.

the nipples (Fig. 3-12) occurs in some infants and children and can be exacerbated by rubbing on clothing. Pruritus is often severe. Some children with AD show “nummular” or coin-shaped lesions with sharply defined oval scaly plaques on the face, trunk, and extremities (see **Nummular Dermatitis** section). In African-American children, the lesions of AD are often more papular and follicular-based (see Fig. 3-7; Fig. 3-13). Although localization at flexural areas is more common, some children show an inverse pattern with involvement primarily of extensor areas. Lymphadenopathy may be a prominent feature in affected children (Fig. 3-14), reflecting the role of lymph nodes in handling local infection and inflammation. Nail dystrophy may be seen when fingers are affected, indicating involvement of the nail matrix; children may show secondary staphylococcal or pseudomonadal paronychia.

The adult phase of AD begins later in childhood and often continues into adulthood. Predominant areas of involvement include the flexural folds (Fig. 3-15), the face and neck, the upper arms and back, and the dorsal aspect of the hands, feet, fingers, and toes. The eruption is characterized by dry, scaling erythematous papules and plaques and by the formation of large lichenified plaques from lesional chronicity. Weeping, crusting, and exudation may occur from the AD itself, but usually is the result of superimposed staphylococcal

**Figure 3-14** Lymphadenopathy is a common accompanying feature of severe atopic dermatitis (AD), especially when the AD is associated with infection.

**Figure 3-15** Involvement of popliteal and antecubital areas is characteristic in children and adolescents with atopic dermatitis. Note the patches of postinflammatory hypopigmentation on the legs.

infection or allergic contact dermatitis (ACD). Prurigo nodularis, well-circumscribed, usually hyperpigmented thickened papules, most common on the lower extremities, is most commonly seen during adolescence (Fig. 3-16).

Postinflammatory hypopigmentation may be seen at any age, especially in individuals with darker skin (see Fig. 3-15; Fig. 3-17). The pigmentary changes are transient and are reversible when the underlying inflammation is controlled; however, 6 months or more may be required for repigmentation, and sun exposure will accentuate the differences between uninvolved and hypopigmented skin areas. In contrast, hyperpigmentation is predominantly noted at sites of lichen-

**Figure 3-16** Prurigo nodularis. Well-circumscribed, usually hyperpigmented lichenified papules, most common on the lower extremities. Recurrent gouging of these intensely pruritic papules results in scarring.

**Figure 3-17** Postinflammatory hypopigmentation of atopic dermatitis (AD). Postinflammatory hypopigmentation occurs as a sequela of the inflammation of AD and is particularly prominent during summer months when the surrounding unaffected skin tans after exposure to ultraviolet light. The postinflammatory hypopigmentation is not scarring and tends to clear spontaneously after several months if further flares of dermatitis at the site are prevented.

ification, because the thickened epidermis accumulates epidermal melanin pigment, especially in darker skinned individuals. Children with lichenification show accentuation of skin markings (see Fig. 3-8; Figs. 3-18 and 3-19). Parents may mistake the postinflammatory pigment change seen in some children for scarring or a toxicity of topically applied medications and need reassurance. AD lesions are not usually scarring, but secondary infection and deep gouging of lesions can leave residual scarring and permanent depigmentation (see Fig. 3-19).

#### OTHER CLINICAL SIGNS

Several other clinical signs are seen with increased incidence in children with AD, although they may appear in children without AD as well. Dermographism, a manifestation of the triple response of Lewis that occurs in approximately 5% of the normal population, is characterized by a red line, flare, and wheal reaction. A red line

**Figure 3-18** Lichenification. Accentuation of skin markings are notable in thickened, lichenified skin of chronic atopic dermatitis. In darker-skinned individuals, hyperpigmentation tends to be associated with the lichenification.

**Figure 3-20** White dermographism is the paradoxical blanching of skin after stroking.

**Figure 3-19** Lichenification with mild crusting and depigmentation from gouging at the ankle.

**Figure 3-21** Lichen spinulosus is commonly seen in children with dry skin and sometimes with atopic dermatitis. The characteristic, usually round collections of tiny, discrete flat-topped papules are usually asymptomatic.

develops within 15 seconds at the exact site of stroking, followed within 15 to 45 seconds by an erythematous flare (because of an axon-reflex vasodilation of arterioles). The response finally eventuates in a wheal (because of transudation of fluid from the injured capillaries in the original stroke line) 1 to 3 minutes later. Individuals with AD often demonstrate a paradoxical blanching of the skin termed *white dermographism* (Fig. 3-20). The initial red line is replaced, generally within 10 seconds, by a white line without an associated wheal. Patients with AD may also show circumoral pallor, thought to relate to local edema and vasoconstriction.

Follicular hyperkeratosis or chicken-skin appearance, particularly on the lateral aspects of the face, buttocks, and outer aspects of the upper arms and thighs, is termed *keratosis pilaris* (see Figs. 7-24 and 7-25). Keratosis pilaris is not seen at birth but is common from early childhood onward and often persists into adulthood. Each lesion represents a large cornified plug in the upper part of the hair follicles, often with surrounding inflammation and vasodilation. Keratosis pilaris is more commonly associated with AD in children with ichthyosis vulgaris. Moisturizers alone tend to be insufficient as therapy for

keratosis pilaris, and keratolytic agents such as urea or  $\alpha$ -hydroxy acids are required. Their use is limited, however, by the increased potential for irritation in children with AD. Treatment should be discouraged unless of significant cosmetic importance, because keratosis pilaris is almost always asymptomatic.

Lichen spinulosus manifests as round collections of numerous tiny, skin-colored to hypopigmented dry spiny papules (Fig. 3-21).<sup>49</sup> More common in African-American children, lichen spinulosus usually occurs on the trunk or extremities. Lesions tend to be asymptomatic and may respond to application of emollients and mild topical corticosteroids. Children with AD also show an increased incidence of pityriasis alba, nummular dermatitis, dyshidrotic eczema, and juvenile plantar dermatosis (see related sections).

**Figure 3-22** Atopic pleats. Accentuated lines or grooves (Dennie-Morgan folds) are seen below the margin of the lower eyelids. This is a sign of the allergic diathesis and is not specific to atopic dermatitis. Note the mild periorbital dermatitis with hyperpigmentation and the lip-licker's dermatitis.

**Figure 3-23** Milia. Note that this child has numerous milia of the periorbital area, small inclusion cysts that are often a sign of chronic rubbing of the skin from periorbital dermatitis and/or allergic conjunctivitis. Milia clear spontaneously but after months to years.

Individuals with atopic disorders have a distinct tendency toward an extra line or groove of the lower eyelid, the so-called “atopic pleat” (Fig. 3-22). Seen just below the lower lid of both eyes, the atopic pleat may be present at birth or shortly thereafter and is often retained throughout life. This groove (commonly referred to as a *Dennie-Morgan fold*) may result from edema of the lower eyelids and skin thickening; it represents a feature of the atopic diathesis rather than a pathognomonic marker of AD. The atopic pleat has been found with increased incidence in African-American children.<sup>50</sup> Slate-gray to violaceous infraorbital discolorations (“allergic shiners”), with or without swelling, are also seen in patients with allergies and in patients with AD. Allergic shiners are thought to be a manifestation of vascular stasis induced by pressure on underlying venous plexuses by edema of the nasal and paranasal cavities; the swelling and discoloration become more prominent as a result of repeated rubbing of the eyes and postinflammatory pigment darkening. Another clinical feature, an exaggerated linear nasal crease, is caused by rubbing of the nasal tip (the so-called “allergic salute”) and occurs in 7% of schoolchildren.<sup>51</sup> Milia (tiny inclusion cysts; see Chapter 9) of the periorbital area are common in preadolescents (Fig. 3-23), may resemble acne, and are thought to result from the recurrent rubbing.

Many patients with atopic conditions exhibit an increased number of fine lines and accentuated markings of the palms (Fig. 3-24). These accentuated palmar markings often are a clue to the concurrent diagnosis of ichthyosis vulgaris (see the previous discussion of the pathomechanism and also Chapter 5), a relatively common

**Figure 3-24** Accentuated palmar creases. Hyperlinearity of the palms is a sign of concurrent ichthyosis vulgaris (see Chapter 5), a genetic disorder of skin associated with an increased risk of atopic dermatitis.

semi-dominant genetic disorder seen with increased incidence in children with AD. Although individuals with either AD or ichthyosis vulgaris may show accentuated markings on the palms and soles, the characteristic generalized scaling with larger and more severe scaling on the lower extremities, worsening during winter months, and often positive family history of patients with ichthyosis vulgaris further helps to distinguish these conditions.

Allergic keratoconjunctivitis (AKC) is a chronic noninfectious inflammatory condition and is one of the most severe ophthalmic complications associated with atopic dermatitis. AKC has been described in up to 30% of children with AD. It typically begins during late teenage years but has been described as early as 7 years of age.<sup>52</sup> Patients experience chronic itching and pain of the eyes, as well as tearing, redness, and blurred vision. It requires prompt and effective treatment to prevent permanent vision loss; moderate to severe eye irritation, increased redness, discharge, and any visual symptoms are features that require more urgent referral to an ophthalmologist. Complications of AKC include cataracts, keratoconus, infectious keratitis, blepharitis, tear dysfunction, and steroid-induced glaucoma. Treatment options include a combination of mast cell inhibitors, antihistamines, corticosteroids, and calcineurin inhibitors.

Posterior subcapsular cataracts have been described in up to 13% of adult patients with severe AD.<sup>53</sup> Rarely seen in children, these cataracts are usually asymptomatic. Keratoconus (elongation and thinning of the corneal surface) has been reported in about 1% of patients with AD and seems to develop independently of cataracts.<sup>53</sup> Keratoconus is exacerbated by continuous rubbing of the eyes and may require corneal transplantation.

## INFECTIOUS COMPLICATIONS

In contrast to a prevalence of a carrier state in 5% to 20% of individuals who have no atopic condition, *Staphylococcus aureus* is recovered in up to 90% of patients from lesions of AD—up to 76% from uninvolved (normal) skin and 50% to 60% from the anterior nares.<sup>54–56</sup> The increased adherence of *S. aureus* to the epidermal cells of individuals with AD<sup>57</sup> and a failure to produce endogenous antimicrobial peptides in the inflamed skin of patients with AD may account for the high rate of *S. aureus* colonization and infection. Although secondary infection in AD is usually from *S. aureus* (72%), 16% of cultures in infected patients with AD yield *S. pyogenes*, and 14% are mixed cultures.<sup>58</sup> Patients infected with group A streptococcus were more likely to be febrile, to have facial and periorbital involvement, have bacteremia and cellulitis, and to be hospitalized compared with those infected with *S. aureus* alone.<sup>58</sup>

The pyoderma associated with AD is usually manifested by erythema with exudation and crusting (Fig. 3-25), particularly at sites of scratching, and occasionally by small pustules at sites of dermatitis (Fig. 3-26). This complication must be considered whenever a flare of

**Figure 3-25** Staphylococcal infection in atopic dermatitis. Sites of excoriation on the dorsal aspects of the hand are oozing and crusted. Note the erythema and mild associated edema. Fissuring often occurs on the hands and feet, as seen on the right thumb. Both the dermatitis and the infection improved with oral administration of cephalaxin, and the use of daily baths with sodium hypochlorite helped to maintain control while minimizing crusting.

**Figure 3-27** Methicillin-resistant *S. aureus* (MRSA) infection in atopic dermatitis (AD). (A) Staphylococcal pustulosis on the knees in a girl with severe AD and recurrent MRSA infections. (B) Her father has an MRSA abscess on the arm. Decolonization of the entire family is important.

**Figure 3-26** Staphylococcal infection in atopic dermatitis (AD). Discrete nongrouped pustules and crusting overlying erythema and swelling of the periorbital area of a child with severe AD.

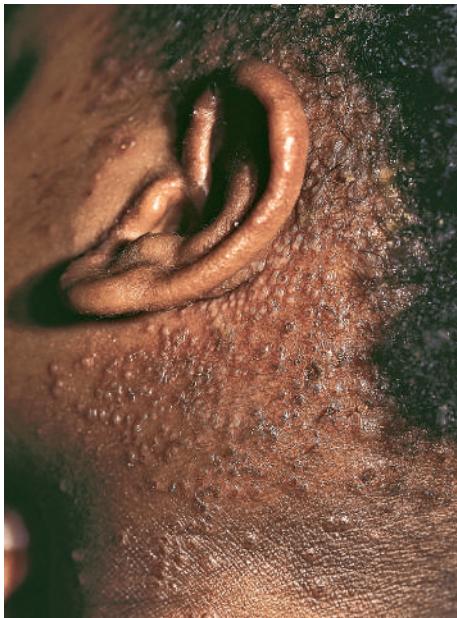

chronic AD develops or fails to respond to appropriate therapy. *S. aureus* exacerbates the AD through: (1) release of superantigen toxins, which enhance T-cell activation; (2) activation of superantigen-specific and allergen-specific T cells<sup>59</sup>; (3) expression of IgE antistaphylococcal antibodies<sup>60,61</sup>; and (4) increased expression of Th2 cytokines (including IL-31 and TSLP, which are known to cause pruritus directly) and increased expression of IL-22,<sup>62</sup> which is associated with epidermal thickening. Superantigen production also increases the expression of an alternative glucocorticoid receptor that does not bind to topical corticosteroids, leading to resistance.<sup>63</sup> Other factors produced by *S. aureus* are likely to exacerbate AD as well.<sup>64</sup> These observations emphasize the role of *S. aureus* as an important trigger of AD and endorse therapies that decrease the numbers of bacteria on the skin.

Although methicillin-resistant *S. aureus* (MRSA) colonization and superinfection of AD is increasing, the majority of children with AD harbor methicillin-sensitive *S. aureus* (MSSA).<sup>54,65</sup> MRSA infection may manifest as pustules (Fig. 3-27, A), abscesses (Fig. 3-27, B) or crusting that is indistinguishable clinically from MSSA infection but much more difficult to eradicate; suppression of MRSA often requires that the entire family (including pets, who can harbor MRSA) be treated initially or even on an intermittent basis to reduce colonization and familiar infections, such as with intranasal mupirocin ointment and once to twice weekly bleach baths or sodium hypochlorite-containing cleansers.

Greater cutaneous dissemination of certain viral infections has also been noted in children with AD and has been attributed to defects in the generation of antimicrobial peptide and the relative deficiency of Th1 cytokine generation and cytotoxic T-cell function. Molluscum

contagiosum is a cutaneous viral infection of childhood that most commonly affects the trunk, axillae, antecubital, popliteal fossae, and crural areas (see Chapter 15). Lesions are usually small, dome-shaped papules that often show central umbilication. The often-extensive molluscum lesions tend to be most numerous at sites of active dermatitis and can induce pruritus as well as dermatitis around the molluscum papules ("molluscum dermatitis").

Eczema herpeticum (EH, also termed Kaposi varicelliform eruption) describes the explosive development of a vesiculopustular eruption caused by herpes simplex virus in an individual with an atopic condition. Children with more severe AD and other atopic conditions are at greatest risk.<sup>66</sup> Herpes simplex virus has been associated with having fewer circulating and skin-resident T cells that express interferon- $\gamma$ .<sup>67</sup> The clustering and often umbilication of the vesicles is characteristic (Figs. 3-28 and 3-29), with sites of the dermatitis most commonly affected. The diagnosis can be verified by direct fluorescent assay and

**Figure 3-28** Eczema herpeticum (Kaposi varicelliform eruption). Grouped vesiculopustular lesions on the face, retroauricular, and neck areas. Several of the pustules are beginning to show umbilication.

**Figure 3-29** These small, round umbilicated vesicles and punched out erosions are typical lesions of herpes simplex infection.

viral culture. If these tests are not available, a Tzanck test can be performed by scraping the floor of vesicles and, after staining the smear with Giemsa or Wright stain, searching for multinuclear virus "giant cells" or balloon cells.

Hospitalization may be necessary, especially in infants under 1 year of age and in association with fever and/or systemic symptoms.<sup>68</sup> Early administration of acyclovir has been shown to lead to better outcomes for EH,<sup>69</sup> and use of topical corticosteroids or calcineurin inhibitors has not been associated with poorer outcomes in children hospitalized with EH.<sup>70</sup> Systemic antibiotics should be administered if secondary bacterial infection is strongly suspected but should not be used empirically.<sup>71</sup> Eczema vaccinatum was a problem when smallpox vaccinations were compulsory, most commonly contracted by accidental contact with a recently vaccinated individual. The global threat of bioterrorism and consideration of smallpox vaccinations has again brought to attention the risk of eczema vaccinatum for patients, particularly children, with AD.<sup>72</sup> Eczema vaccinatum is characterized by the widespread cutaneous dissemination of vaccinia viral lesions that manifest as firm, deep-seated vesicles or pustules that are all in the same stage of development (see Chapter 15). Lesions may become umbilicated or confluent. *Eczema coxsackium* is a recently coined term to describe the unusual cutaneous concentration in sites of previous or current AD of vesicles and erosions from Coxsackie A6 and, less commonly, Coxsackie A16 infection, which could be confused with EH.<sup>73,74</sup> Fever, oral erosions/ulcerations, and sore throat/mouth are among the most common associated symptoms. Lesions clear spontaneously in an average of 12 days but may persist for a month. Reactivity to *Malassezia* has been blamed for recalcitrant AD of the head and neck in adolescents. Although there are no documented differences in *Malassezia* species colonization, patients with head and neck AD are more likely to have positive skin-prick test results and *Malassezia*-specific IgE compared with healthy control subjects and patients with atopy without head and neck dermatitis. These patients may benefit from a 1- to 2-month course of daily itraconazole or fluconazole followed by long-term weekly treatment.<sup>75</sup>

## DIFFERENTIAL DIAGNOSIS

AD is a chronic fluctuating disease. The distribution and morphology of lesions vary with age, but itching is the cardinal symptom of this disorder. Although many skin conditions may occasionally resemble AD, certain characteristics assist in their differentiation.

Seborrheic dermatitis is characterized by a greasy yellow or salmon-colored scaly eruption that may involve the scalp, cheeks, trunk, extremities, and diaper area. The major differentiating features include a tendency toward earlier onset, characteristic greasy yellowish or salmon-colored lesions with a predisposition for intertriginous areas, a generally well-circumscribed eruption, and a relative absence of pruritus (see below). Infants may show both atopic and seborrheic dermatitis (see Fig. 3-2), with progression or persistence of the atopic lesions as the seborrheic dermatitis subsides.

Contact dermatitis can be divided into irritant contact dermatitis and ACD. Primary irritant dermatitis is commonly seen in infants and young children. It is most commonly seen on the cheeks and the chin (owing in part to the irritation of saliva), the extensor surfaces of the extremities (as a result of harsh soaps, detergents, or rough fabrics), and the diaper area (primarily from feces and vigorous cleansing). Primary irritant dermatitis is generally milder, less pruritic to asymptomatic, and not as eczematous and oozing as the eruptions seen in association with AD. Irritant dermatitis may also result from bubble baths, personal care products, and in handled materials such as modeling clays. Irritant contact dermatitis to saliva and to exposure to harsh soaps and fabrics occurs more often in children with concomitant AD. Although the diaper area in AD is typically normal, irritant diaper dermatitis can occur.

ACD, although relatively uncommon in the first few months of life, can mimic almost any type of eczematous eruption and is characterized by a well-circumscribed pruritic, erythematous, papular, and vesicular eruption. Although such eruptions involute spontaneously on identification and removal of the cause, this disorder often requires a carefully detailed history and prolonged observation before the true causative agent is identified. ACD to nickel occurs often in children

with AD<sup>76</sup> and may be misdiagnosed as recalcitrant periumbilical AD. Patients with recalcitrant AD may have concomitant allergic contact reactions, particularly to nickel and less often to topically applied medications and emollients, suggesting the role for patch testing.<sup>77</sup> Positive patch tests for potential allergens other than nickel have been described in up to 45% of children with AD,<sup>76,78,79</sup> and half of these are reactions to components in the emollients (avena extract; wheat protein; calendula; lanolin). Children with AD may react to fragrance, antiseptics (chlorhexidine), and even their topical steroid.<sup>78,80,81</sup>

Nummular dermatitis is a distinctive disorder characterized by coin-shaped lesions. Measuring 1 cm or more in diameter, lesions of nummular dermatitis develop on dry skin and are more often seen during dry winter months. The eruption is characterized by discrete erythematous round plaques formed by the confluence of papules and vesicles (Figs. 3-30 and 3-31). Nummular lesions tend to be more recalcitrant to topical therapy and, not uncommonly, become infected so that concomitant treatment of secondary staphylococcal infection and measures to limit staphylococcal overgrowth (such as dilute sodium hypochlorite baths) should be considered.

The lesions of psoriasis, another common skin disease of children, are bright red and topped with loosely adherent silvery micaceous

scale (see Chapter 4). Psoriatic lesions usually show a sharply delineated edge and have a predilection for the extensor surfaces (particularly the elbows and knees), the scalp, the buttock, and the genital regions. Approximately 5% of children with psoriasis also show dermatitis, either as typical psoriasis and atopic dermatitis lesions or a psoriasiform dermatitis; these children often have a family history of both atopy and psoriasis.

Scabies in infants and children is commonly complicated by eczematous changes because of scratching and rubbing of involved areas or the application of harsh topical therapeutic agents. The diagnosis of scabies is best made by the history of itching, a characteristic distribution of lesions, the recognition of primary lesions (particularly the pathognomonic burrow when present), positive identification of the mite on microscopic examination of skin scrapings, and the presence of infestation among the patient's family or associates (see Chapter 18).

Langerhans cell histiocytosis (LCH) most commonly occurs before 3 years of age (see Chapter 10). In affected neonates, reddish-brown, purpuric, crusted papules or vesiculopapules are typically present. In infants this skin eruption is often characterized as a scaly, erythematous seborrheic eruption on the scalp, behind the ears, and in the intertriginous regions. On close inspection the presence of reddish-brown, petechial or purpuric lichenoid papules or vesicular or crusted papules in infants is typical. Cutaneous biopsy and identification of CD1a+ Langerhans cells by immunostaining confirms the diagnosis of LCH.

Acrodermatitis enteropathica is an autosomal recessive disorder characterized by vesiculobullous eczematoid lesions of the acral and periorificial areas, failure to thrive, diarrhea, alopecia, nail dystrophy, and frequent secondary bacterial or candidal infection (see Chapters 2 and 24). The characteristic distribution of lesions accompanied by listlessness, diarrhea, failure to thrive, and low serum zinc levels differentiate lesions of acrodermatitis enteropathica from those of AD. Usually a disorder in formula-fed babies with the hereditary form, acrodermatitis enteropathica may also occur in breastfed babies owing to deficient zinc secretion into maternal breast milk.

Dermatitis during the neonatal or infantile periods is also seen in immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, which manifests with early onset intractable diarrhea and type 1 diabetes mellitus as well.<sup>82-84</sup> The disorder is often fatal during the first year of life. The cutaneous manifestations are seen in 70% of affected babies and tend to be the first sign.<sup>82</sup> Although an atopic-like dermatitis is most common, the eruption has also been described as psoriasiform or resembling ichthyosiform erythroderma. Lesions are often pruritic, secondarily infected by *S. aureus*, and resistant to treatment with topical corticosteroids. Other common cutaneous manifestations include severe cheilitis, onychodystrophy, and alopecia.

Infections of the upper and lower airways and GI tract are also common, and affected patients may succumb to sepsis. Food allergies and high levels of IgE and eosinophils are also associated. The autoimmune enteropathy is characterized by persistent, watery, and sometime mucoid or bloody diarrhea during the neonatal period, resulting in malabsorption and failure to thrive. The type 1 diabetes is difficult to control and results from lymphocytic infiltration of the pancreas. Other autoimmune symptoms, such as hypothyroidism, cytopenia, hepatitis, nephropathy, and arthritis can develop in patients who survive the initial acute phase.

IPEX syndrome results from mutations in *FOXP3*, leading to absent or dysfunctional regulatory T cells and self-reactive T-cell activation and proliferation. Detection of enterocyte autoantibodies helps to make the diagnosis.<sup>85</sup> Treatment generally includes supportive care and systemic immunosuppressive therapy (steroids, methotrexate, tacrolimus), although rapamycin has shown promise. Stem-cell transplantation is the curative treatment<sup>84</sup> if a suitable donor can be found.

Typical AD may be a feature of several forms of immunodeficiency, most notably in Wiskott–Aldrich syndrome (WAS) and the hyperimmunoglobulinemia E syndrome (HIES) (see related sections). These disorders are distinguished from AD by their recurrent noncutaneous infections and other characteristic features (e.g., thrombocytopenic purpura, bloody diarrhea, and purpuric lesions in WAS and facial and intertriginous staphylococcal abscesses in HIES).

**Figure 3-30** Nummular dermatitis. Characterized by well-defined, round (coin-shaped or nummular) plaques of vesiculopapules overlying erythema and edema. Oozing and secondary infection are common.

**Figure 3-31** Nummular dermatitis. Some patients show multiple nummular plaques.

## PROGNOSIS AND EFFECT ON QUALITY OF LIFE

Although studies in the past have shown that AD tends to clear in 43% of children by age 3 and in up to 70% by puberty,<sup>86,87</sup> recent studies have shown a 1-year prevalence of AD in adults of up to 10.2%<sup>88</sup> and that more than 80% of children with mild to moderate AD have recurrent symptoms or require medication use at least into the second decade of life.<sup>45</sup> Longitudinal studies are needed to verify data suggesting that most patients with AD have persistence of at least some form of their skin disease (often hand eczema) into adulthood.

The quality of life in infants, children, and adolescents with moderate to severe dermatitis is significantly reduced,<sup>89</sup> and having severe AD during childhood can have a great impact on psychosocial development.<sup>90</sup> Infants with AD have been shown to be excessively dependent and fearful. Sleep disturbance affects up to 60% of children with AD overall and 83% of children during flares. Neurocognitive function is impaired in children with sleep problems.<sup>91</sup> Even in clinical remission, children with AD show more sleep disturbance than healthy children,<sup>92</sup> including increased nocturnal wakefulness and a longer latency to rapid-eye-movement (REM) sleep.<sup>92</sup> Recent studies have also shown a strong association of AD with attention-deficit/hyperactivity disorder (ADHD)<sup>93–95</sup> that is associated with more severe disease and sleep deprivation,<sup>96</sup> reinforcing the impact of these factors on neurocognitive function. Disfigurement associated with moderate to severe AD, coupled with the reduction in sleep, restlessness, and fatigue at school, as well as limitations in participation in sports, isolates the affected child and strains relationships with peers and with teachers. AD is also associated with an increased odds ratio of depression, anxiety, conduct disorder, and learning delay.<sup>97</sup> Children with AD have a higher risk of injury requiring medical attention, related both to comorbid psychiatric and behavioral disorders and their atopy.<sup>97</sup>

As a chronic disorder that requires frequent attention, the family carries a high financial burden of parental missed days from work for doctor visits and home care, lost wages owing to interruption of employment, expensive medications, and the costs of special or additional bedding, clothes, and food. The socioeconomic impact of AD in the United States alone is estimated to be \$364 million to \$3.8 billion annually.<sup>98</sup> The demonstrated average reduction by 1 to 2 hours of parental sleep nightly also translates into increased parental stress<sup>99</sup> and the tendency of affected children to cosleep with parents affects family dynamics.<sup>100</sup> These stressful psychological factors often exacerbate the AD, as may concurrent infectious illness or the stress of assignments at school.

## MANAGEMENT

The management of AD requires patient and parent education,<sup>101</sup> avoidance of irritants and allergic triggers, good moisturization, and use of anti-inflammatory medications<sup>102</sup> (Table 3-1). Patient compliance is the main reason for poor outcome and is fueled by concerns about the use of topical corticosteroids and calcineurin inhibitors (see below). Aggressively but safely managing AD flares is important in preventing the exacerbation of disease by delayed or inadequate treatment. The National Eczema Association (NEA) offers a website for education and patient support ([www.nationaleczema.org](http://www.nationaleczema.org)). Age-specific structured educational programs have improved objective and

subjective severity scores,<sup>103</sup> and educational videos may improve severity beyond direct education.<sup>104</sup> Written action plans have been shown to improve adherence to therapy.<sup>105</sup> Several new reviews of AD management for children have been published.<sup>106–110</sup>

### Use of Emollients and Bathing

In general, dryness is worse during cold months when it is aggravated by heat in the house and low humidity. Key to maintaining hydration is the application of a good emollient, particularly within minutes after bathing. In general, the thicker and greasier the emollient, the higher the content of oil relative to water and the more effective the emollient (e.g., ointment is better than cream, which is better than lotion). Nevertheless, nonointment emollients, particularly ceramide-dominant creams, can be substituted when use of a greasy ointment is objectionable and may have inherent anti-inflammatory properties. Some patients, especially those with sensory issues and poor tolerance of ointments and creams, find oils to be helpful, although in general oils do not penetrate the skin as well as oil–water mixtures. Purified sunflower seed oil improves the AD skin barrier, whereas olive oil and mustard seed oil are detrimental to skin barrier recovery and can cause erythema,<sup>111,112</sup> emphasizing that oils are not interchangeable. Similarly, virgin coconut oil is superior to mineral oil in reducing AD severity<sup>113</sup> and to olive oil in decreasing *S. aureus*.<sup>114</sup> “Barrier repair” agents, such as N-palmitoyl ethanolamine (MimyX),<sup>115</sup> ceramide-dominant, physiological-lipid based cream (EPI Ceram),<sup>116</sup> and MASO63DP (Atopiclair),<sup>117</sup> also show mild anti-inflammatory properties and may be beneficial for children with mild to moderate AD but are much more costly than emollients.

### Preventing the Development of Atopic Dermatitis with Early Use of Emollients

Infants in at-risk families (i.e., with at least one parent or sibling who has AD) have a 30% to 50% chance of developing AD by 2 years of age.<sup>118</sup> Early evidence suggests that limiting the use of skin cleansers and applying an oil-in-water emollient at least once daily may lower the risk<sup>119–121</sup> or decrease the AD severity.<sup>122</sup>

Water hardness has been shown to be associated with an increased prevalence of AD,<sup>123,124</sup> and a preliminary analysis suggests that hard water also increases the development of AD in at-risk infants. Although ion-exchange water softeners do not lower the prevalence of AD,<sup>125</sup> other techniques to soften water without adding ions have yet to be tested. Several trials have shown no protective effect of maternal dietary avoidance during pregnancy and in most cases during lactation on the incidence of AD during the first 18 months of life.<sup>126</sup>

### Use of Bathing for Atopic Dermatitis

Although water exposure can increase xerosis through evaporative loss, daily baths hydrate the skin, especially if the water loss is prevented by emollient application within a few minutes after bathing. Baths are also fun for infants and children, contribute to parent–child bonding, and remove surface bacteria and desquamated scale. Whether to limit the duration of bathing is controversial, but many recommend limiting the bath to approximately 10 minutes. Older children and adolescents should be instructed to avoid excessively warm baths and showers. Only mild soaps with lower pH to suppress protease activation (such as Dove or Basis) or soapless cleansers (such

**Table 3-1** Management of Mild, Moderate, and Severe Forms of Atopic Dermatitis

\*Barrier repair may be accomplished by application of effective emollients or from barrier-repair agents.

as Cetaphil, CeraVe, or Aquanil) should be used if a cleanser is felt to be needed. Bubble baths are contraindicated in moderate to severe AD. Bath oils are only slightly beneficial and because they tend to make the tub slippery should be used sparingly and cautiously.

The addition of dilute sodium hypochlorite (bleach) to the bath (1 mL/L or  $\frac{1}{4}$  cup per half-tub of water) or use of a sodium hypochlorite wash is helpful in controlling the dermatitis of children who with a history of skin infection (see **Topical Anti-Inflammatory Medications** section).<sup>54</sup> Although the antibacterial effect has been implicated in AD improvement, the recently demonstrated anti-inflammatory effect of sodium hypochlorite<sup>127</sup> may also play a role (see **Treatment of Secondary Cutaneous Infections** section). Children may complain about sitting in a tub bath because of stinging, particularly during acute exacerbations with raw skin and crusting. In such instances, the addition of 1 cup of salt or baking soda may make the bath more tolerable until more aggressive therapy such as treatment of the secondary infection with oral antibiotics leads to improvement.

Wet wraps of plain water can be applied at night after bathing and emollient or after application of the topical anti-inflammatory agent to decrease pruritus and the sensation of burning at night.<sup>128-130</sup> Short-term use (up to 14 days) of wet wraps over topical corticosteroids is more efficacious than wraps over bland emollients alone but can be associated with transiently increased steroid absorption. Although wet gauze bandage wraps (such as Kerlix or Kling) are often used in a hospital setting, dressing the young child at home in moist pajamas and socks that cling to the skin and are topped by a dry layer to avoid excessive cooling can be very soothing and promote sleep. Unna boots can also be loosely applied to the legs or arms at night (under self-adherent wraps) to decrease pruritus and protect from scratching.

Open wet compresses may be useful in children with weeping, oozing, or crusted lesions. Aluminum acetate (as in Burow solution, 1:20 or 1:40) is germicidal and suppresses the weeping and oozing of acutely inflamed lesions. Burow solution 1:40 is prepared by dissolving one packet or effervescent tablet (Domeboro) in a pint of cool or tepid tap water. These compresses are applied with a soft cloth such as a man's handkerchief or strips of bed-sheeting two to three times daily for 10 to 15 minutes for up to 5 days. Washcloths and heavy toweling interfere with evaporation and therefore are not as effective. Compresses should be lukewarm, moderately wet (not dripping), and remoistened at intervals. After the compress, the topical anti-inflammatory agent may be applied.

### Avoidance of Irritant Triggers

Many patients have problems with eccrine sweating and sweat retention during the summer months, leading to increased pruritus, especially in the face of lichenification and significant dermal inflammation. The increased vasodilation of already inflamed skin from increased summer heat further contributes to pruritus and cutaneous warmth. Nevertheless, children with AD should be encouraged to participate as actively in sports as possible. Swimming is an excellent sport for children with AD if exposure to chlorinated pool water is tolerated. Children should be coated with an emollient (after sunscreen application) as a protectant against pool chemicals; rinsing immediately after swimming with application of emollient may decrease the risk of irritation. Children should also be kept cool after application of the thick emollient, or if sweating is anticipated, a less occlusive moisturizer should be applied. Air-conditioning is important during hot weather to decrease pruritus. The pruritus and erythematous papules of miliaria rubra, which can develop when sweating and are prevented by an occlusive moisturizer, can be confused by parents with exacerbation of the dermatitis, setting up a cycle of worsening involvement from repeated application of the occlusive emollient. Recognition and education in decreasing the frequency of emollient application are vital in this situation.

Overdressing children during winter months should also be avoided to prevent overheating. The low humidity of winter months and use of indoor heating also increases skin xerosis and may promote dermatitis; humidifiers maybe useful but may increase the exposure to mold allergens if they are not cleaned often. Saliva is a major irritant for infants with AD, and exposure to large amounts of saliva with teeth-ing and eating, including saliva mixed with food, exacerbates the

facial dermatitis. Protecting the face before meals or naptime with a thick, protective emollient may be helpful. Similarly, older children with AD are at risk for lip-licker's dermatitis because of the irritant effects of saliva.

Attention to clothing is also important. Soft cotton clothing is recommended over wool or other harsh materials, which tend to precipitate itching and scratching, and in one study fabric softener decreased skin dryness.<sup>131</sup> There is only low-quality evidence regarding AD improvement or decrease in bacterial colonization from use of special textiles, particularly silk and silver-coated cotton, but there is no evidence of harm.<sup>132</sup> Affected children should avoid use of harsh soaps and detergents, fabric softeners, products with fragrance, and bubble baths. Smoking of cigarettes in homes of children with AD should be avoided, because it can lead to an increase in irritation and pruritus and may also increase the tendency toward subsequent development of asthma.<sup>133</sup>

### Avoidance of Triggering Allergens

It may be possible to identify potential allergen triggers by taking a careful history and doing selective allergy tests.<sup>134</sup> However, triggers that can easily be avoided are difficult to find for most affected individuals, and without a documented or proven food allergy, avoiding potentially allergenic foods as a means of managing AD is not recommended. Testing for allergy to milk, egg, peanut, wheat, and soy is recommended in children younger than 5 years of age with moderate to severe AD who have persistent AD despite optimized management with topical therapy and/or have a reliable history of an immediate reaction after ingestion of a specific food.<sup>135,136</sup> Food antigen-specific IgE (sIgE) levels correlate better than a radioallergosorbent test (RAST) and prick tests,<sup>137</sup> but the level of sIgE is not clinically useful for predicting the development of clinically relevant food allergy. Negative skin-prick tests or serum allergen-specific IgE levels are highly predictive at eliminating potential allergens. However, at 6 months of age, 83% of patients with severe AD show IgE food sensitization to milk, eggs, and/or peanuts, and 65% of these children retain food sensitivity by 12 months of age. In comparison, 5% of 6-month-old infants and 11% of 12-month-old infants without atopy show IgE food sensitization.<sup>138</sup> Fewer than 40% of children with moderate to severe AD with food sensitization show reactivity during food challenges,<sup>139</sup> and many of these eruptions are urticarial. In a recent longitudinal study, 16% of more than 1000 infants with AD (all severities) developed food allergies, particularly to peanut (7%), milk (4%), and egg (4%) with the highest risk in infants with greater AD severity.<sup>140</sup> Foods may also induce extracutaneous manifestations in pediatric patients with AD, particularly involving the GI tract. Foods may also act as irritants, especially citrus foods, and that reactions to chemicals in foods, such as tartrazine or other colorings, may occur. For children in whom food allergies are suspected to be relevant, comangement with a pediatric allergist is recommended.

Despite the fact that maternal dietary antigens are known to cross the placenta, most studies have provided no evidence that avoidance of maternal dietary antigens during pregnancy or lactation has a protective effect during the first 18 months of life on the development of AD or on food sensitization by 7 years of age.<sup>126,141</sup> As a result, breastfeeding without restricting maternal diet as a strategy to prevent food allergy is recommended until 4 to 6 months unless contraindicated for medical reasons.<sup>136</sup> Despite earlier studies suggesting the opposite, more recent analyses have shown that peanut, milk, and wheat intake during pregnancy is associated with reduced allergy and asthma in children,<sup>142,143</sup> although reduction in developing AD only correlated with wheat consumption.<sup>143</sup> As a result, hydrolyzed infant formulas, rather than cow's-milk or soy-milk formulas can be given to at-risk infants who are not exclusively breastfed if available and affordable, but they may not affect the risk of AD. Solid foods, including potentially allergenic foods, should not be delayed beyond 4 to 6 months of age in at-risk infants.<sup>144,145</sup>

The most common food allergens often contaminate other foods and are difficult to avoid entirely. Restrictions in diet should not worsen the quality of the patient's and family's life more than the AD itself. Challenges of agents that may trigger IgE reactivity are best conducted under medical observation, because anaphylaxis has occasionally been reported. It should be remembered that excessively restrictive

diets in atopic children may lead to weight loss, calcium deficiency, hypovitaminosis, and kwashiorkor.<sup>146</sup> Proper nutritional counseling and supplementation should be included in management, including warning against the use of protein-poor rice and almond milk for cow's milk, hydrolyzed, and elemental formulas. After the first few years of life, the risk of significant reactivity to food diminishes (particularly with eggs, milk, soy, and wheat). Unless a careful dietary history suggests food sensitivity as a trigger, improvement through dietary manipulation in children older than 5 years is rarely noted.

In contrast to potential reactivity to foods, reactivity of children and adolescents with AD to aeroallergens increases with age. The most common aeroallergen triggers are house-dust mites (*Dermatophagoides pteronyssinus*), grass pollens, animal dander, and molds, particularly *Alternaria*. Plant pollens, particularly ragweed, also contain an oleoresin capable of producing sensitization and eczematous contact dermatitis. Air-borne dermatitis may involve the exposed surfaces of the face, neck, arms, legs, and "V" area of the chest but can be distinguished from photosensitivity, which results in sharper lines of demarcation between normal skin and eczematous skin. Exacerbation of facial dermatitis during pollen season or after children contact a pet should alert parents to the possibility of allergy to an aeroallergen or contact allergen (see [Allergic Contact Dermatitis](#) section). Cat exposure during infancy can increase the risk of developing AD,<sup>147</sup> especially in infants with an *FLG* mutation.<sup>148</sup> Cat exposure in children with AD has been shown to increase the risk of developing asthma, although dog exposure may be protective.<sup>149</sup> Epicutaneous application of aeroallergens by atopy patch test on unaffected atopic skin shows reactivity as an eczematoid patch in 30% to 50% of patients with AD but tends to be negative in patients with only respiratory allergy to these triggers or in healthy volunteers. However, patch tests have not been standardized, and their performance and interpretation vary widely. The value toward AD control of mite-allergen avoidance measures (encasing mattresses and pillows, washing bedding in hot water weekly, vacuuming living areas and bedrooms frequently, keeping only soft nonfurry toys, cleaning carpets regularly or removing them, and eliminating pets) is controversial, and a meta-analysis found no value in encasing mattresses to prevent allergic diseases or symptoms.<sup>150</sup> Immunotherapy for food allergies or aeroallergens has long been controversial as treatment for AD, unlike its efficacy for treating allergic rhinitis and extrinsic asthma; recent double-blind, placebo-controlled studies, however, suggest some value of specific oral and sublingual immunotherapy, including to peanuts.<sup>151,152</sup>

### Topical Anti-inflammatory Medications

Topical corticosteroids have been the mainstay of treatment for AD (see [Table 3-1](#)), and are available in a wide range of potencies from the weakest class VII corticosteroids (e.g., hydrocortisone acetate) to the ultrapotent class I steroids ([Table 3-2](#)). The use of more potent topical corticosteroids, particularly when applied to large surface areas, under occlusion, or for long periods may lead to adverse effects ([Box 3-2](#)), most commonly local atrophy. The face and intertriginous areas are the most susceptible sites and may show local effects, even when

weaker steroids are used for prolonged periods. Because of their increased body surface area-to-weight ratio, small children have the greatest risk of systemic absorption of topically applied steroids. Concern about the use of topical steroids has led to "steroid phobia" among families and even physicians.<sup>153</sup> As a result, compliance may be decreased and weak topical steroids insufficient for adequate control may be used. In a recent study, 81% of parents or adult patients with AD had fears about the use of topical steroids, and 36% admitted nonadherence as a result.<sup>154</sup> Recently, topical steroid addiction has been cited as an adverse effect of topical corticosteroids, but it is virtually never seen in children with AD who use topical steroids and should not discourage the use of topical steroids in pediatric patients. In older patients with AD, this disorder is characterized by a burning/stinging, sharply delineated erythematous eruption, primarily on the face and genital region, occurring days to weeks after discontinuation of prolonged, inappropriate, and frequent use of moderate-to-high-potency topical corticosteroids.<sup>155</sup> In general, group I corticosteroids are not recommended for patients younger than the age of 12 years, should not be used in intertriginous areas or under occlusion, and require a rest period after 14 days of use. Use of this group of ultrapotent steroids is usually reserved for lichenified plaques and recalcitrant dermatitis of the hands and feet and should be limited. Considering the widespread use of topical corticosteroids, few local adverse reactions occur when topical steroids are carefully chosen and used appropriately based on site of application and severity of the dermatitis ([Fig. 3-32](#)).<sup>156</sup> As such, even potent topical corticosteroids may safely be used in small areas for short periods.

The choice of treatment will depend on the severity and localization of the dermatitis, the age of the pediatric patient, and the history of use of topical anti-inflammatory agents. The least potent preparation that adequately controls the disease process should be used. For children with mild to moderate disease, intermittent use of a low-strength topical steroid with emollient application to maintain clearance usually suffices. However, children with moderate to severe disease often show a cycle of rapid recurrent flaring when topical anti-inflammatory suppression is discontinued. A commonly used regimen to maintain control in these children while minimizing the risk of chronic steroid application is to apply midpotency to potent topical steroids for acute flares (e.g., for a few days to up to 2 weeks twice daily) followed by intermittent therapy with topical steroid.<sup>157</sup> or to avoid continuing steroid altogether, with a topical calcineurin inhibitor. Studies have suggested that topical calcineurin inhibitors can be applied three times weekly to recurrently affected sites to retain control of the dermatitis once improved with the use of topical steroids.<sup>158,159</sup>

The potency of a topical corticosteroid is largely determined by vasoconstrictor assay and is related to its vehicle as well as to

**Figure 3-32** Steroid-induced atrophy. Although unusual, steroid-induced atrophy in this patient with atopic dermatitis resulted from the twice-daily application of a class III–IV topical steroid over 1 year. Note the excellent control of the dermatitis but the obvious striae and prominence of veins because of atrophy of overlying skin.

### Box 3-2 Potential Side Effects of Topical Corticosteroids

#### Local Cutaneous Side Effects

- Atrophy
- Striae
- Periorificial granulomatous dermatitis
- Acne
- Telangiectasia
- Erythema
- Hypopigmentation
- Ocular effects
- Cataracts
- Glaucoma

#### Systemic Side Effects

- Hypothalamic–pituitary–adrenal axis suppression

**Table 3-2** Relative Potencies of Topical Corticosteroids (From Most Potent to Weakest)

Class	Drug	Dosage Form(s)	Strength (%)
I. Very high potency	Augmented betamethasone dipropionate	Ointment	0.05
	Clobetasol propionate	Cream, ointment, foam	0.05
	Diflorasone diacetate	Ointment	0.05
	Halobetasol propionate	Cream, ointment	0.05
II. High potency	Amcinonide	Cream, lotion, ointment	0.1
	Augmented betamethasone dipropionate	Cream	0.05
	Betamethasone dipropionate	Cream, ointment, foam, solution	0.05
	Desoximetasone	Cream, ointment	0.25
	Desoximetasone	Gel	0.05
	Diflorasone diacetate	Cream	0.05
	Fluocinonide	Cream, ointment, gel, solution	0.05
	Halcinonide	Cream, ointment	0.1
	Mometasone furoate	Ointment	0.1
	Triamcinolone acetonide	Cream, ointment	0.5
III-IV. Medium potency	Betamethasone valerate	Cream, ointment, lotion, foam	0.1
	Clocortolone pivalate	Cream	0.1
	Desoximetasone	Cream	0.05
	Fluocinolone acetonide	Cream, ointment	0.025
	Flurandrenolide	Cream, ointment	0.05
	Fluticasone propionate	Cream	0.05
	Fluticasone propionate	Ointment	0.005
	Mometasone furoate	Cream	0.1
	Triamcinolone acetonide	Cream, ointment	0.1
V. Lower-medium potency	Hydrocortisone butyrate	Cream, ointment, solution	0.1
	Hydrocortisone propritate	Cream	0.1
	Hydrocortisone valerate	Cream, ointment	0.2
	Prednicarbate	Cream	0.1
VI. Low potency	Alclometasone dipropionate	Cream, ointment	0.05
	Desonide	Cream, gel, foam, ointment	0.05
	Fluocinolone acetonide	Cream, solution, oil	0.01
VII. Lowest potency	Dexamethasone	Cream	0.1
	Hydrocortisone	Creams, ointments, lotions, solutions	0.25, 0.5, 1
	Hydrocortisone acetate	Creams, ointments	0.5–1

its chemical formulation. Vasoconstrictor assays reveal that generic formulations tend to vary in their clinical activity and their vehicles may at times contain agents differing from those of brand-name formulations. Thus care must be taken in considering substitution of generic formulations for brand-name corticosteroids. The concentration of each topical corticosteroid is only significant with respect to potency relative to other corticosteroids of the same chemical formulation. Accordingly, hydrocortisone acetate 2.5% is much weaker than triamcinolone acetonide 0.1%, which in turn is weaker than clobetasol propionate 0.05%, even though the concentrations would suggest the opposite. It also should be recognized that hydrocortisone acetate differs chemically from hydrocortisone butyrate, hydrocortisone propritate, and hydrocortisone valerate, which as midpotency steroids are stronger than hydrocortisone acetate. Halogenated steroids are usually stronger than nonhalogenated steroids.

Ointments are the most commonly chosen vehicle for treating AD. Corticosteroid ointments afford the advantage of occlusion, more effective penetration, and in general greater efficacy than equivalent cream or lotion formulations. Ointments are particularly effective in the management of dry, lichenified, or plaque-like areas of dermatitis. Ointment formulations, however, may occlude eccrine ducts, inducing sweat retention and pruritus, and hair follicles, leading to folliculitis. As with emollients, formulations in ointments may not be as well tolerated during the summer months of increased heat, perspiration, and high humidity. Creams often contain additives that may be irritating or sensitizing. Creams and lotions, however, are more cosmetically elegant and afford the advantages of greater convenience and accept-

ability during hot weather and in intertriginous areas. Traditional gels and foams are not well tolerated in individuals with AD, but they may be most effective in the management of acute weeping or vesicular lesions. Topical corticosteroids in emollient-based foam formulations and hydrocolloid gels (in contrast to the alcohol-containing foams and gels) are particularly useful for hairy areas, to avoid occlusion, and for cosmetics. Oil preparations are most commonly used for scalp dermatitis. Best applied to a wet scalp, oil formulations can be shampooed out after at least 1 hour to overnight. A fluocinolone acetonide oil preparation, however, has been shown to be helpful after the bath for children with extensive AD.<sup>160</sup>

Occlusion of treated areas with polyethylene film such as Saran wrap or the use of corticosteroid-impregnated polyethylene film (Cordran tape) enhances the penetration of corticosteroids up to 100-fold. This mode of therapy is particularly effective for short periods (8 to 12 hours a day on successive days) for patients with chronic lichenified or recalcitrant plaques of dermatitic skin. Occlusive techniques, however, are contraindicated for prolonged periods of time and are not recommended in infected or intertriginous areas. Given that the diaper is an occlusive dressing, application of steroids in the diaper area of infants should be avoided or limited to short-term use of low-strength topical steroids.

For sites of severely lichenified dermatitis, salicylic acid can be compounded into preparations with steroids to improve penetration. Tar (liquor carbonis detergens or crude coal tar) can be also be used as an adjunctive therapy in patients with chronic dermatitis in the form of tar baths (e.g., Cutar) or compounded with topical corticosteroids

(e.g., compounding triamcinolone 0.1% with 6% salicylic acid and 5% to 10% liquor carbonis detergents in Aquaphor ointment). The objectionable odor, staining properties, potential for irritation, risk of causing folliculitis, and low potential risk of later carcinogenesis make tar a choice only for only selected patients.

A variety of steroid-free topical anti-inflammatory agents have been introduced to allow patients to decrease their application of topical steroids and thus associated risks. Topical calcineurin inhibitors (tacrolimus ointment 0.03% and pimecrolimus cream 1%) have been approved for the past decade as an alternative therapy for AD in children older than 2 years of age.<sup>161,162</sup> Several studies and anecdotal reports have suggested good efficacy and safety for tacrolimus ointment 0.1% (above 2 years of age) and for tacrolimus 0.03% ointment and pimecrolimus cream in infants under 2 years of age, but their use is off-label.<sup>163,164</sup> Tacrolimus and pimecrolimus prevent the formation of a complex that includes calcineurin, a phosphatase.<sup>165</sup> Without this complex, the phosphate group from the nuclear factor of activated T cells (NF-AT) cannot be cleaved, the NF-AT transcription factor cannot be transported to the nucleus, and production of cytokines associated with T-cell activation is inhibited. Tacrolimus and pimecrolimus also inhibit mediator release from mast cells and basophils and decrease IgE receptor expression on cutaneous Langerhans cells.<sup>166</sup>

To date, the only confirmed safety issue associated with the use of calcineurin inhibitors in children is burning or pruritus with application, described in the minority of affected children, particularly those with active inflammation. This sensation has been shown to result from stimulation of TRPV1 receptors in skin with depletion of substance P.<sup>167</sup> Calcineurin inhibitors do not show the atrophogenic potential of the corticosteroids and can be safely used on the head, neck, and intertriginous areas. Furthermore, no adverse effects on the eyes have been found, allowing safe application in periorbital areas. No increase in cutaneous infections has been noted in children.<sup>168</sup> Tacrolimus ointment shows good efficacy in children with moderate to severe AD<sup>169</sup> the efficacy of the 0.1% ointment is comparable to a midpotency topical corticosteroid,<sup>170</sup> and that of the 0.03% ointment to a low-potency steroid. Pimecrolimus cream is also comparable to a low-potency steroid and is indicated for pediatric patients with mild to moderate AD.<sup>171,172</sup> Assays of systemic absorption of tacrolimus and pimecrolimus have shown transient low levels in the blood, if at all, and no adverse effects on systemic immunity have been demonstrated.<sup>169,173</sup>

In 2006, the US Food and Drug Administration placed a black box warning on the class of calcineurin inhibitors based on the theoretical potential for topical calcineurin inhibitors to cause skin carcinogenesis and lymphoma. This theoretical risk was based on the known risk of malignancy (posttransplant lymphoproliferative disease and non-melanoma skin cancer) in transplant patients who are profoundly immunosuppressed by systemically administered tacrolimus and in animal studies when treated with 26 to 47 times the maximum recommended dosage. However, the number of malignancies and lymphomas is very low in AD children in postmarketing registries,<sup>174</sup> and task forces of the American College of Allergy, Asthma, and Immunology; the American Academy of Allergy, Asthma, and Immunology; and the American Academy of Dermatology found no evidence to support the issuance of a black box warning.<sup>175-178</sup> Nevertheless, pimecrolimus and tacrolimus are best used intermittently in rotation with topical steroids, and patients need to be advised of these potential risks, as well as to practice sun protection while using these agents. Several new nonsteroidal anti-inflammatory medical devices (also known as "barrier-repair agents"; see related text) have also become available for mild to moderate dermatitis and may decrease the need for steroid application.<sup>179</sup> Phosphodiesterase 4 inhibitors (oral apremilast and topical crisaborole) are currently in trials as new nonsteroidal approaches for treating AD.<sup>180</sup>

### Role of Antihistamines

Reduction of the pruritus of AD is best achieved by application of topical anti-inflammatory medications. Sedating antihistamines, such as hydroxyzine, diphenhydramine, and doxepin, may help itchy children fall asleep, although they have little direct effect on the pruritus itself. Nonsedating antihistamines may be valuable as treatment for other atopic conditions such as allergic rhinitis and have been shown

to decrease the risk of urticaria, but their value in decreasing pruritus is unclear, because they are usually nonsedating.<sup>181</sup> Long-term use in young children has not led to behavioral, cognitive, or psychomotor developmental abnormalities.<sup>182</sup> Regardless, many pediatric dermatologists use both sedating and nonsedating antihistamines as part of an overall atopic dermatitis treatment program and attest to their clinical benefit.

### Treatment of Secondary Cutaneous Infections

Antistaphylococcal antibiotics are important in the management of patients with heavy *S. aureus* colonization or infection because of the role of *S. aureus* overgrowth in triggering dermatitis. Topical antibiotics, such as mupirocin, or fusidic acid (not currently available in the United States) can be used for localized impetiginized lesions, but systemic antibiotics are required for more extensive involvement. Despite the increase in community-acquired (CA) MRSA nationally, most atopics still harbor MSSA (84% to 93%).<sup>54,55</sup> As a result, cephalaxin is still used most commonly (and successfully) to empirically treat secondarily infected dermatitis and will cover both staphylococcal and streptococcal organisms.<sup>58</sup> The chronic administration of systemic antistaphylococcal therapy for AD should be avoided in an effort to minimize the risk of development of MRSA in the atopic population.

Dilute sodium hypochlorite (bleach) baths are now standard of care as a maintenance measure for decreasing flares in moderate to severe AD. The addition of ½ cup of 5% to 6% sodium hydroxide per full tub of water (1 mL/L or 4 mL per gallon) markedly reduces the severity and extent of the dermatitis in children with a history of staphylococcal infections.<sup>54,183,184</sup> Even daily maintenance dilute sodium hypochlorite baths are generally well tolerated and may be needed for more severe AD. A washcloth can be used to distribute the bleach-bath water to the head and neck, avoiding the eyes and mouth. If skin erosions from secondary infection make bathing uncomfortable, postponing bleach baths until after the first few days of treatment may be necessary. If a bath is not possible, a 5- to 10-minute wet compress with bleach solution or a shower using a sodium hypochlorite-containing wash (such as CLn) can be used.<sup>185</sup> Intermittent application of mupirocin ointment to the nares and hands of patients and caregivers twice daily for five sequential days each month, and use of gentle antibacterial soaps<sup>186</sup> may also decrease colonization.

Antiviral treatment of cutaneous herpes simplex infections is important in preventing widespread dissemination, which rarely is life-threatening. Administration of oral acyclovir (100 mg tid to qid for children under 6 years of age; 200 mg qid for older children) for a week usually controls the infection. More extensive involvement may require hospitalization and intravenous acyclovir treatment, especially in younger children. For children with recurrent EH, a course of prophylactic administration of oral acyclovir once daily for 6 months or longer effectively suppresses the recurrences. Adjunctive therapies include topical compresses and concurrent administration of topical or systemic antibiotics if bacterial infection is also suspected. In general, topical corticosteroids can be continued during the course of systemic acyclovir therapy without impacting clearance of the viral infection if the dermatitis is problematic. Molluscum infections (see Chapter 15) can be managed by curettage after application of topical anesthetics,<sup>187</sup> or if available, by cantharidin application.<sup>188</sup> Children with molluscum and AD (but not nonatopical) may show improvement in both their dermatitis and the molluscum lesions by treatment with high doses of oral cimetidine (40 mg/kg per day divided twice daily) for a 3-month course.<sup>189,190</sup> Imiquimod has not been found beneficial in double-blind, randomized trials.

### Other Considerations for Atopic Dermatitis that Fails to Respond: Adherence and Alternative Diagnoses

Moderate to severe AD may be recalcitrant to topical corticosteroid and calcineurin therapy. Although secondary staphylococcal infection is a common reason for recalcitrance, several other factors should be considered before initiating systemic immunosuppressive therapy or phototherapy. Poor adherence is a major reason for failure to respond. In one study with electronic-cap monitoring to detect opening of tubes, mean adherence of patients with mild to moderate atopic dermatitis was 32%, increasing on or near office visit days.<sup>191</sup> Shortening the time between prescription of the medication and the

follow-up office visit<sup>192</sup>; prescribing once-a-day treatment; using sticker charts to engage children<sup>193</sup>; providing adequate education about the disease, the use of treatment, and why it is needed; and adapting instruction on medication utilization to existing elements of the family routine (e.g., linking to bathing or brushing the teeth)<sup>194</sup> may be helpful.

Chronic, unresponsive dermatitis, especially involving the eyelids, hands, feet, or vulva may result from ACD,<sup>195</sup> and comprehensive patch testing should be undertaken (see [Contact Dermatitis](#) section). Several other alternative diagnoses that may require different intervention are described (see [Differential Diagnosis](#) section).

### Management of Children with Severe Atopic Dermatitis Requiring Systemic Immunosuppressive Therapy

Systemic immunosuppressive therapy<sup>196,197</sup> or ultraviolet light treatment can be considered for patients with recalcitrant moderate to severe disease. Narrow-band ultraviolet-B light therapy, which avoids intervention with systemic immunosuppressive therapy, has been reported to cause at least moderate improvement in 89% of children and complete clearance in 40% over a median of 3 months.<sup>198</sup> Nevertheless, the requirement for frequent treatments in a medical office (two to three times weekly) and holding still in a hot, enclosed box while wearing protective goggles, as well as the unknown risk of long-term cutaneous damage from ultraviolet light, complicate the use of this form of therapy for most pediatric patients.

Systemic corticosteroid therapy is effective for most patients with AD, but the rapid rebound after discontinuation of therapy and high risk of potential side effects make its use impractical for patients with AD. Systemic administration of nonsteroidal anti-inflammatory medications to children with AD has largely replaced the use of systemic corticosteroids by pediatric dermatologists in the management of more recalcitrant severe AD.

Cyclosporine has the most rapid onset of action and greatest efficacy but also the highest risk of potential side effects. Therapy is initiated with 3 to 5 mg/kg per day (microemulsion for preferred). Response may be seen within 1 to 3 months, but medication should be tapered once significant improvement is achieved; trough levels can be determined in patients without a sufficient response to determine if a higher dosage can be administered. Discontinuation of treatment usually leads to relapse flares, but low-dose continuing treatment or intermittent courses in children can be effective.<sup>199–201</sup> Several experts now recommend initial treatment with cyclosporine to rapidly suppress the severe AD (for 3 months) followed by continued treatment with ultraviolet light treatment or an alternative, safer immunosuppressant such as mycophenolate mofetil or methotrexate. Renal and hepatic function and blood pressure must be carefully monitored during cyclosporine therapy.

Azathioprine (2.5 to 3.5 mg/kg per day) has effectively suppressed severe, recalcitrant AD in 58% to 92% of children during a 3-month trial.<sup>202–204</sup> Pretreatment determination of thiopurine methyltransferase level can predict the risk of developing myelosuppression, and hepatic functions should also be monitored. In one study the thiopurine methyltransferase (TPMT) levels changed unpredictably during treatment in 25% of patients, suggesting that periodic assessment of TPMT levels is warranted to optimize clinical response.<sup>204</sup> Azathioprine should be used with caution, given its recent link of hepatosplenic T-cell lymphoma.

Mycophenolate mofetil has been found to cause at least 60% improvement in 91% of treated children with a dosage of 40 to 50 mg/kg per day for children and 30 to 40 mg/kg per day for adolescents with maximal effects at 8 to 12 weeks.<sup>205</sup> Complete blood counts and liver function testing should be performed.

Methotrexate was found to be effective or very effective in 75% of children with severe AD in a recent retrospective analysis. There were no serious adverse events noted, although 14% experienced minor nausea and 14% had slight elevation in hepatic transaminases. Low-dose therapy (0.3 to 0.5 mg/kg per week)<sup>206</sup> is administered with folate supplementation. The need for a small test dose of methotrexate has not been demonstrated. Complete blood counts should be followed weekly, and hepatic transaminases should be monitored at least monthly.

Interferon- $\gamma$  downregulates Th2 lymphocyte function, and treatment with recombinant interferon- $\gamma$  (50  $\mu$ g/m<sup>2</sup> daily or every other day) has led to improvement in some patients, including pediatric patients.<sup>207–209</sup> Clinical improvement correlates with decreases in peripheral eosinophilia but not IgE levels. Flu-like symptoms are particularly common early in the treatment course. The high price and benefit for only a subset of individuals also limit the use of interferon- $\gamma$  in children who are severely affected with AD.

Biologics to date have not been used for pediatric AD. However, weekly subcutaneous injection of IL-4 receptor antibody (dupilumab) shows very promising results in adult AD, consistent with the important role of Th2 cytokines in AD inflammation.<sup>210</sup> An alternative biologic approach may be treatment with ustekinumab to combat the impact of elevation of downstream Th22 cytokine activation, as has been shown effective in adults and an adolescent with severe AD.<sup>211–213</sup>

### Use of Experimental or Complementary Treatment Approaches

The impact of vitamin D3 levels and potential value of vitamin D3 supplementation remain controversial. Low levels of vitamin D3, including in cord blood,<sup>214,215</sup> have been associated with childhood AD,<sup>216,217</sup> although there is not a relationship with disease severity<sup>218</sup> unless there is allergic sensitization.<sup>219</sup> Vitamin D3 has been shown to upregulate the expression of cathelicidin, including in the skin of individuals with AD, but topically applied vitamin D3 irritates skin affected by AD. Although one small open-label study of oral vitamin D3 supplementation in children who were vitamin-D deficient with AD showed clinical improvement,<sup>220</sup> a small double-blind trial showed improved serum levels of vitamin D3 after 3 weeks but no clinical improvement in AD.<sup>221</sup> At this time there is insufficient evidence to recommend vitamin D3 supplementation for AD.<sup>222</sup>

Probiotics have recently received considerable attention as a means of prevention of AD. Evidence that reduced diversity in the gut microbiota is a risk factor in the development of AD<sup>223–226</sup> provides further rationale for probiotic use. Although there is some evidence of benefit prenatally in prevention (for reviews,<sup>227–230</sup>) there is insufficient evidence to recommend probiotics as part of standard management of infantile AD. Not all lactobacilli are effective, and *Lactobacillus rhamnosus* GG has shown the greatest efficacy; in fact, early administration of *L. acidophilus* did not prevent AD development<sup>230</sup> and increased atopic sensitization.<sup>231</sup> Although early studies suggest some benefit of prebiotics (fiber compounds that stimulate the growth of advantageous organisms) and fatty acids (such as the  $\gamma$ -linolenic acid [GLA] alone or in combination with  $\omega$ -3 fatty acids),<sup>230</sup> there is insufficient evidence to recommend these approaches for either reducing the risk of developing AD or treating AD.

Leukotriene antagonists such as montelukast, which are used extensively in asthma prophylaxis, have largely been ineffective.<sup>232</sup> The benefit from administration of traditional Chinese herbal therapy has been variable.<sup>233–235</sup> Regardless, the demonstration of hepatic toxicity, cardiac adverse events, and idiosyncratic reactions from this therapy has raised concerns; furthermore, the discovery of glucocorticoid contamination in some preparations warns that these alternative agents be used with caution.<sup>236</sup> Massage therapy has been advocated as a means to improve the clinical signs of atopic dermatitis in young children, in addition to improving the psychological well-being of the patients and family members.<sup>237</sup> Psychological counseling, behavioral modification, hypnotherapy, and biofeedback can also be helpful in decreasing scratching.<sup>104</sup> Psychological intervention for families can also be beneficial, because increased parental stress and depression correlate with higher levels of biological markers of inflammation.<sup>238</sup> A form of alternative medicine, particularly herbal remedies and homeopathy, is used in 42.5% to 63.5% of patients with AD.<sup>239,240</sup> More than half reported no improvement but tried the therapies based on recommendation from nonphysicians, concern about the potential risks of topical steroids, and dissatisfaction with conventional treatment. Of concern is that these complementary approaches have potential side effects, have not been adequately tested for safety and efficacy, and require time and effort that might otherwise be directed toward use of physician-prescribed treatment.

## Pityriasis Alba

Pityriasis alba is a common cutaneous disorder characterized by asymptomatic hypopigmented patches, usually on the face, neck, upper trunk, and proximal extremities.<sup>241</sup> Individual lesions vary from 1 cm or more in diameter and may show a fine scale (Fig. 3-33). This disorder is thought to represent a nonspecific dermatitis with residual postinflammatory hypopigmentation and occurs more often in individuals with darker skin types.<sup>242</sup> Histologic evaluation shows normal numbers of melanocytes but decreased epidermal melanosomes and melanocyte degeneration.<sup>243</sup> Most cases appear after sun exposure because of the contrast that results between areas that can show a pigmentary response to ultraviolet light and the pityriasis alba areas that do not.

The differential diagnosis of the hypopigmented macules of pityriasis alba includes tinea versicolor, vitiligo, the white macules seen in association with tuberous sclerosis; nevus depigmentosus; cutaneous T-cell lymphoma; leprosy; postinflammatory hypopigmentation secondary to atopic dermatitis, psoriasis, tinea corporis, or pityriasis rosea; and in light-skinned individuals, nevus anemicus. Application of mild topical corticosteroids or calcineurin inhibitors for a few weeks followed by frequent emollient and protection of the sites and surrounding area from sun exposure appears to diminish the dry skin and fine scaling, allowing repigmentation of involved areas. Patients and parents should be warned that, as with postinflammatory hypopigmentation, repigmentation may take several months to years. Effective moisturization during drier months may help prevent recurrence of the pityriasis alba in subsequent summers.

## Hyperimmunoglobulinemia E Syndrome

HIES is a rare immunodeficiency disorder characterized by very high levels of IgE in association with AD and recurrent cutaneous and sinopulmonary infections.<sup>244,245</sup> The AD is seen in 100% of patients, usually within the first 6 months, and is of variable severity (Fig. 3-34). Most patients have an autosomal dominant form (also called *Job syndrome*), which results from mutations in the gene encoding signal transducer and activator of transcription 3 (*STAT3*).<sup>246,247</sup>

Many neonates or infants with autosomal dominant HIES have pruritic papulopustules, especially on the face, which show eosinophilic folliculitis or eosinophilic dermatitis by biopsy of lesional skin.<sup>248</sup> Infections often begin during the first 3 months of life. Cutaneous candidiasis may also be an early clinical feature (83%). Cutaneous *S. aureus* infections may take the form of excoriated crusted plaques, pustules, furuncles, cellulitis, paronychia, lymphangitis, or abscesses, especially on the neck, scalp, periorbital areas, axillae, and groin (Fig. 3-35).

**Figure 3-33** Pityriasis alba. Circumscribed scaly hypopigmented lesions on the cheek. These patches are thought to represent postinflammatory hypopigmentation and are most easily visible in children with darker skin. Note the concomitant lip-licker's dermatitis.

**3-35). The abscesses are slightly erythematous and tender but not nearly to the degree expected for a normal individual. Although some patients demonstrate cutaneous manifestations only,<sup>249</sup> patients with HIES usually have recurrent bronchitis and pneumonias with resultant empyema, bronchiectasis, and in 77% of patients, pneumatocele formation. The pneumatoceles tend to persist and become the site of further infections with bacteria (*Pseudomonas*) or fungi (*Aspergillus*, *Candida*). Rarely, massive hemoptysis ensues. Other common sites of infection include the ears, oral mucosae, sinuses, and eyes. Visceral infections other than pneumonia are unusual.**

By late childhood and adolescence, patients with HIES begin to develop progressive facial coarseness,<sup>244</sup> perhaps reflecting bony abnormalities and recurrent facial abscesses. Osteopenia is usually detected by adolescence or early adulthood, and patients have an increased risk of bone fractures, often because of unrecognized or minor trauma.<sup>250</sup> Scoliosis occurs in 64% of patients 16 years of age or older, and hyperextensibility of joints has been reported in 70% of patients. Dental abnormalities associated with HIES syndrome include retention of primary teeth, lack of eruption of secondary teeth, and delayed resorption of the roots of primary teeth.<sup>251</sup> Focal brain hyperintensities and an increased incidence of lymphoma are other features. Patients with HIES of intermediate phenotypes that include

**Figure 3-34** HIES with AD of the antecubital area.

**Figure 3-35** Hyperimmunoglobulinemia E syndrome (HIES). In addition to atopic dermatitis, most infants and children with HIES show erythematous, slightly purulent cold abscesses, shown here on the forehead and scalp. (Reprinted with permission from Bologna JL, Jorizzo JL, Rapini RP. Dermatology. Elsevier, 2003.)

staphylococcal and mucocutaneous candidal infections may have STAT3 mosaicism.<sup>252</sup>

The abnormalities in STAT3 signaling impair Th17-cell development, leading to insufficient expression of IL-17 and IL-22, which drive expression of antimicrobial peptides, thus promoting *S. aureus* and candidal infections.<sup>253</sup> The diagnosis of HIES is largely based on clinical findings and the presence of very high levels of IgE. There are no specific tests to confirm the diagnosis other than the finding of HIES-related mutations. Patients have markedly elevated levels of polyclonal IgE. Although levels of more than 2000 IU/mL are needed to consider the diagnosis in older children and adults, the normal levels of IgE in infants (0 to 50 IU/mL) are considerably lower than those in older children. A 10-fold increase in IgE levels above normal levels for age should trigger consideration of HIES, although these levels of IgE are more common in AD without HIES.<sup>254</sup> Affected individuals tend to have IgE antibodies directed against *S. aureus* and candida. Levels of IgE are not related to clinical course and may decrease to normal in affected adults. Approximately 93% of patients have eosinophilia of the blood and sputum. Abnormal polymorphonuclear leukocyte and monocyte chemotaxis has been noted, but is intermittent and not correlated with infection. Cell-mediated immunity (Th1-driven) is often abnormal as well and may manifest as anergy to skin testing, altered responses in mixed leukocyte culture, and impaired blastogenic responses to specific antigens such as *Candida* and tetanus. The decrease in memory (CD27+) B cells is markedly decreased in 80% of patients, in contrast to individuals with AD and high levels of IgE.<sup>255</sup>

Autosomal recessive HIES usually results from loss-of-function mutations in DOCK8 (dedicator of cytokinesis), which regulates the actin cytoskeleton and is less common than the dominant form. Although patients share the cardinal features of high levels of IgE, AD, and infections, patients fail to show the bone, dental, and coarse facial features of the dominant form. Cardinal features that are not part of the STAT3-deficient form include severe viral infections (molluscum, herpes, and life-threatening cytomegalovirus [CMV] infections), early malignancy (cutaneous and mucosal squamous cell carcinomas), neurologic changes (aneurysms and strokes), and an increased risk of autoimmune issues (anemia, thrombocytopenia, and vasculitis).<sup>256,257</sup> One patient with autosomal recessive HIES and homozygous mutations in TYK2 (which activates STAT3) had nontuberculous mycobacterial infections.<sup>258,259</sup> The additional clinical features of recessive HIES have been ascribed to additional abnormalities in IL-12 and interferon- $\alpha/\beta$ -cytokine production.

HIES must be distinguished from a number of other disorders in which IgE levels may be elevated. Most common is AD, which shows similar inflammatory cutaneous features and often very high levels of IgE, especially if severe;<sup>254</sup> the concurrent presence of abscesses, coarse facies, noncutaneous infections, and dental and bony abnormalities in HIES may enable differentiation. WAS can be distinguished by thrombocytopenia with cutaneous petechiae and hemorrhagic episodes. Eosinophilia and elevations of IgE levels with dermatitis can also be seen in patients with DiGeorge syndrome, the Omenn syndrome type of severe combined immunodeficiency, graft-versus-host disease (GVHD), and selective IgA deficiency.

The mainstay of therapy for HIES is antistaphylococcal antibiotics, and patients are usually treated prophylactically with trimethoprim-sulfamethoxazole. When other bacterial or fungal infections develop, infections must be treated with appropriate alternative antibiotics. Recombinant interferon- $\gamma$  has shown inconsistent efficacy. The cutaneous and pulmonary abscesses often require incision and drainage. The pneumatoceles should be removed surgically, especially if present for longer than 6 months, to prevent microbial superinfection. Therapy for AD as discussed in previous sections is also useful for HIES; omalizumab has improved the severe dermatitis of a recalcitrant patient with a relatively low level of IgE.<sup>260</sup> Alendronate sodium may alleviate the osteopenia.<sup>250</sup>

**Figure 3-36** A bleeding diathesis owing to thrombocytopenia and platelet dysfunction, the most common manifestation of patients with Wiskott–Aldrich syndrome (WAS), may manifest as petechiae, ecchymoses, and purpuric patches. The dermatitis of patients with WAS is indistinguishable from atopic dermatitis.

microthrombocytopenia and platelet dysfunction, and recurrent severe pyogenic infections.<sup>261,262</sup> Bleeding is the most common manifestation, but the presence of mild to severe AD distinguishes WAS from X-linked thrombocytopenia and X-linked neutropenia with myelodysplasia, which are both allelic. The majority of patients are male, but full expression has been reported in girls.<sup>263</sup>

The dermatitis usually develops during the first few months of life and fulfills criteria for AD (Fig. 3-36). Excoriated areas commonly have serosanguineous crust and often show petechiae or purpura. IgE-mediated allergic problems such as urticaria, food allergies, and asthma are also seen with increased frequency.

The hemorrhagic diathesis results from both quantitative and qualitative defects in platelets. Platelets from patients with WAS are small and structurally abnormal with a reduced half-life, although megakaryocyte numbers are normal. Epistaxis and bloody diarrhea are often the initial manifestations. Mucocutaneous petechiae and ecchymoses (see Fig. 3-36), spontaneous bleeding from the oral cavity, hematemesis, melena, and hematuria are common, but the severity varies.

Recurrent bacterial infections begin in infancy as placentally transmitted maternal antibody levels diminish and include staphylococcal impetigo, furunculosis, otitis externa and media, pneumonia, pansinusitis, conjunctivitis, meningitis, and septicemia. Infections with encapsulated bacteria such as pneumococcus, *Haemophilus influenzae*, and *Neisseria meningitidis* predominate. With advancing age, T-cell function progressively deteriorates and patients become increasingly susceptible to infections caused by herpes and other viruses and to *Pneumocystis jiroveci*.

Additional clinical features may be hepatosplenomegaly, lymphadenopathy, and autoimmune complications. The most common autoimmune complication is hemolytic anemia, occurring in 36% of patients and usually before 5 years of age.<sup>264</sup> Other autoimmune disorders that clearly seem linked to WAS are autoimmune neutropenia (25%), arthritis (29%), IgA nephropathy, and painful cutaneous vasculitis (22%) that can appear as purplish induration of skin and soft tissues.

The clinical course of WAS is progressive, usually resulting in death by adolescence without transplantation. Overall, 40% of patients die of infection, 21% of hemorrhage (usually intracranial), and 25% of malignant neoplasia. Lymphoreticular malignancies occur overall in 13% to 22% of patients,<sup>265</sup> with an average age of onset of 9.5 years. Non-Hodgkin lymphoma<sup>265,266</sup> is the most common malignancy and is often linked to Epstein–Barr (EBV) infection, and extranodal and brain involvement predominate. Fewer than 5% who develop lymphoma survive more than 2 years.

## Wiskott–Aldrich Syndrome (WAS)

WAS is a rare X-linked recessive disorder, which in its classic form consists of dermatitis that meets criteria for AD, bleeding from

Individuals with WAS have mutations in the gene that encodes WAS protein (WASP), and the extent of WASP depletion correlates with disease severity. WASP, through complexing with other proteins, activates Arp2/3 and ultimately polymerizes the actin cytoskeleton to enable cell movement, dendrite formation, formation of immune synapses, T-cell activation, and B-cell homeostasis. Platelet abnormalities result from defective migration in proplatelet formation, inherent platelet defects increasing fragility, and autoimmunity against platelets. T-regulatory cell dysfunction has been blamed for the increased risk of autoimmune complications. The mechanism for the AD is not defined but could relate to T-cell activation defects and the abnormal interactions of WAS Langerhans cells with T cells after antigenic stimulation.

Laboratory studies show thrombocytopenia in 100% of patients, with platelets below about  $80,000/\text{mm}^3$  and often below  $20,000/\text{mm}^3$ . Platelets tend to be small, and aggregation is sometimes defective. Eosinophilia is common, but lymphopenia is not usually seen until after 6 to 8 years of age. Total serum  $\gamma$ -globulin is usually normal, but levels of IgM are often low, with variable IgG levels and increased levels of IgA, IgE, and IgD. The number of T lymphocytes and response *in vitro* to mitogens may be normal in early life but often decreases with advancing age. Delayed hypersensitivity skin-test reactions are usually absent, and antibody responses to polysaccharide antigens are markedly diminished.

Several conditions may be confused with WAS. Many other immunodeficiencies are characterized by dermatitis, increased susceptibility to infections, and the development of malignancy, but do not share the bleeding diathesis. The clinical findings of hemorrhage, petechiae, and recurrent sinopulmonary infections in WAS help to differentiate WAS from AD.

Bone marrow transplantation with human leukocyte antigen (HLA)-identical marrow is the treatment of choice. Full engraftment results in normal platelet numbers and functions, immunological status, and if T lymphocytes engraft, clearance of the dermatitis.<sup>267</sup> Optimal survival occurs with matched sibling donors and allogeneic transplantation below the age of 5 years (87%). Despite the good result of matched unrelated donors in young children (71%), there is a higher risk of acute GVHD after transplant (56%) versus matched siblings (16%).<sup>268</sup> Mixed chimerism (i.e., engraftment of T cells but not myeloid or B cells) increases greatly the risk of chronic GVHD. If a matched donor is unavailable, infusion of autologous stem cells modified *ex vivo* by gene therapy is an alternative approach.<sup>269</sup>

Appropriate antibiotics and transfusions of platelets and plasma decrease the risk of fatal infections and hemorrhage. Intravenous infusions of  $\gamma$ -globulin are also useful in patients. Topical corticosteroids may improve the dermatitis, and chronic administration of oral acyclovir is appropriate for patients with EH. Splenectomy has been used selectively for patients with severe platelet abnormalities; however, splenectomy increases the risk of infection by encapsulated organisms, markedly increasing the risk of mortality after transplantation. Children with WAS are unable to mount immune responses after administration of vaccines against encapsulated organisms. Rituximab has been used successfully in some children with EBV-induced lymphoma to prolong survival.<sup>270</sup>

## Lichen Simplex Chronicus

Lichen simplex chronicus (circumscribed neurodermatitis) is a localized, chronic pruritic disorder characterized by patches of dermatitis that result from repeated itching, scratching, and rubbing of the involved area. The pruritus may begin in an area of normal-appearing skin or may be initiated in a preexisting lesion of atopic, seborrheic, or contact dermatitis, lichen planus, or psoriasis.

Lesions of lichen simplex chronicus generally occur in adolescents or adults but may be seen in younger children. The disorder may develop at any location on the body, but the most common areas of involvement are those that are easily reached and may be scratched unobtrusively (particularly during periods of tension and concentration). These include the nape or sides of the neck, wrists, ankles, hands, and pretibial areas. Other common sites of involvement include the inner aspects of the thighs, vulva, scrotum, and perianal areas.

**Figure 3-37 (A) and (B)** Lichen simplex chronicus. Localized plaques of dermatitis that result from repeated scratching and rubbing of the involved area.

The clinical features of lichen simplex chronicus include single or multiple oval plaques with a long axis that usually measure up to 15 cm in diameter (Fig. 3-37). During the early stages, the skin is reddened and slightly edematous with exaggerated skin markings. Older, more typical lesions are characterized by well-circumscribed, dry, thickened, scaling, pruritic, often hyperpigmented plaques.

The diagnosis of lichen simplex chronicus is dependent on the presence of pruritic lichenified plaques in the characteristic sites of predilection. Lesions of tinea corporis may be differentiated by a lack of lichenification, by the presence of a scaly border (often with clearing in the center), by demonstration of hyphae on microscopic examination of skin scrapings, and by fungal culture. Psoriatic plaques generally may be differentiated by a characteristic thick, adherent white or silvery scale, their underlying deep red hue, and characteristic areas of involvement. Lesions of AD may be differentiated by history, more poorly demarcated lesions, the presence of atopic stigmata, and a tendency toward involvement in antecubital and popliteal areas.

The successful management of lichen simplex chronicus depends on an appreciation of the itch-scratch-itch cycle and the associated scratching and rubbing that accompany and perpetuate this disorder. Topical application of potent corticosteroids, under occlusion if necessary, and the administration of systemic antihistamines (such as diphenhydramine or hydroxyzine) usually induces remission of the pruritus and the eruption within a period of several weeks. Use of tap water compresses before application of the topical corticosteroid or compounding topical steroid with salicylic acid (e.g., 6% salicylic acid and 0.1% triamcinolone powder in hydrophilic ointment) may increase penetration of the topical anti-inflammatory agent. Other techniques include application overnight of flurandrenolide-impregnated tape, protection from scratching and rubbing by occluding with adhesive dressings, and injection of intralesional triamcinolone acetonide (e.g., 5–10 mg/mL) in tolerant adolescents.

## Seborrheic Dermatitis

*Seborrheic dermatitis* refers to a self-limiting erythematous, scaly, or crusting eruption that occurs primarily in the so-called “seborrheic areas” (those with the highest concentration of sebaceous glands), namely the scalp, face, and postauricular, presternal, and intertriginous areas. Seborrheic dermatitis in the pediatric population is most commonly seen in infants and adolescents. The cause of seborrheic dermatitis is not well understood. Its predilection for areas of high sebaceous gland density and the correlation of activity with increased hormonal levels during the first year of life<sup>271</sup> and adolescence suggests a relation to sebum and sebaceous glands. Seborrheic dermatitis of adolescence and adulthood has been attributed to *Pityrosporum ovale* (*Malassezia ovalis*), a lipophilic yeast normally found in abundance on the human scalp.<sup>272</sup> However, the relationship between seborrheic dermatitis in infants and that of adolescents and adults is controversial. It is unclear if this organism plays an etiologic role in infants.<sup>273,274</sup> Many infantile cases improve with topical ketoconazole, suggesting that overgrowth of yeast may, at least in some instances, play a role in the pathogenesis of this disorder.

Seborrheic dermatitis appears in infancy between the second and tenth week of life (usually the third or fourth) and peaks in incidence at 3 months of age.<sup>275</sup> Infantile seborrheic dermatitis often begins with a noneczematous, erythematous, scaly dermatitis of the scalp (termed *cradle cap*) or the diaper area and is manifested by thin dry scales or sharply defined round or oval patches covered by thick, yellowish brown, greasy crusts. Although the condition is limited to the scalp in most affected infants, it may progress to the forehead, ears, eyebrows, nose, and back of the head (see Figs. 3-2 and 2-22). Erythematous greasy, salmon-colored, sharply marginated scaly patches may also involve the intertriginous and flexural areas of the body, the postauricular areas, the trunk, umbilicus, anogenital areas, and groin (Fig. 3-38). Pruritus is slight or absent, and the lesions usually lack the dry, fine scaling character associated with AD. Overlap of seborrheic dermatitis and AD, however, may occur with the features of AD becoming more prominent as the seborrheic dermatitis subsides. In one study, 49% of infants with AD had a history of infantile seborrheic dermatitis, in contrast to 17% of controls.<sup>276</sup>

The differential diagnosis of seborrheic dermatitis during infancy includes AD, psoriasis, LCH, and immunodeficiency. Lesions of AD are almost always pruritic, are poorly defined, and show dry, fine scaling. In addition, the occluded diaper area is usually spared in AD, in contrast to the common diaper area involvement of seborrheic dermatitis. Psoriasis can be quite difficult to differentiate, because it can present in infants in a fashion very similar to that of seborrheic dermatitis, with sharply marginated, brightly erythematous scaling patches. Psoriasis tends to show a slower response to topical corticosteroid therapy and can be distinguished, if necessary, by skin biopsy. Although LCH

**Figure 3-38** Seborrheic dermatitis. A cause of diaper rash in young infants, seborrheic dermatitis is difficult to distinguish clinically from infantile psoriasis but tends to be less erythematous, to have thinner scaling, and to respond more quickly to topical anti-inflammatory medications.

can at times be mistaken for seborrheic dermatitis, the presence of discrete 1- to 3-mm yellowish to red-brown crusted or eroded papules, purpuric lesions, hepatosplenomegaly, or lymphadenopathy support the diagnosis of LCH; histopathologic and immunohistochemical examination of cutaneous lesions confirms the diagnosis of LCH. When the erythema and scaling of infantile seborrheic dermatitis becomes severe, generalized, and exfoliative, the diagnosis of immunodeficiency must be considered. The lack of constitutional findings (diarrhea, fever, weight loss), alopecia, associated infections, and the spontaneous clearance or rapid response to therapy of seborrheic dermatitis help to distinguish the conditions. Severe generalized seborrheic-like dermatitis in association with failure to thrive, recurrent skin and other infections, and chronic diarrhea (once called *Leiner syndrome*) can be seen in several immunodeficiency disorders, including C3 and C5 complement deficiencies, C5 dysfunction, hyperimmunoglobulinemia E syndrome, severe combined immunodeficiency (especially Omenn syndrome), and X-linked agammaglobulinemia.<sup>277</sup>

Between puberty and middle age, seborrheic dermatitis may appear on the scalp as a dry, fine, flaky desquamation, commonly known as *dandruff*. This seborrhea is an extreme form of normal desquamation in which scales of the scalp become abundant and visible, often overlying inflammation. Erythema and scaling of various degrees may also involve the supraorbital areas between the eyebrows and above the bridge of the nose, nasolabial crease (Fig. 3-39), lips, pinnae, retroauricular areas, and aural canals. Blepharitis is a form of seborrheic dermatitis in which the eyelid margins are red and covered with small, white scales. Seborrheic dermatitis may also involve the sideburns, beard, and mustache areas, with diffuse redness, greasy scaling, and pustulation. The severity and course of seborrheic eruptions of the eyelids and bearded areas are variable and have a tendency to chronicity and recurrence.

**Figure 3-39** Seborrheic dermatitis. (A) Facial seborrheic dermatitis in adolescents typically involves nasolabial folds and may result from overgrowth of lipophilic yeasts of the normal flora. In (B) tinea faciei was considered, but the distribution and bilaterality are atypical for tinea.

Occasionally an adolescent patient may have an eruption that has clinical features of both seborrheic dermatitis and psoriasis. Such eruptions may be termed *sebopsoriasis*. Lesions of seborrheic dermatitis can be differentiated from those of psoriasis by a lack of the characteristic vivid red hue or micaceous scale, a predisposition toward flexural rather than extensor aspects of the extremities, and the fact that lesions of seborrhea generally tend to remain within the confines of the hairline. Lesions of psoriasis (or sebopsoriasis) commonly extend beyond the hairline and in general are more resistant to standard antiseborrheic therapy.

The prognosis of infantile seborrheic dermatitis is excellent. In some patients, the disorder clears within 3 to 4 weeks even without treatment, and most cases clear spontaneously by 8 to 12 months of age. The condition generally does not recur until the onset of puberty, although mild scaling of the scalp, particularly at the vertex, can be seen in some affected children through preschool years. Treatment of infantile scalp seborrheic dermatitis is best managed by frequent shampooing.<sup>278</sup> Although antiseborrheic shampoos including ketoconazole shampoo<sup>279</sup> may be useful, in infants or young children, these products may be drying or irritating to the eyes. A gentle “no-tears” shampoo usually suffices. If the scales are thick and adherent, removal can be facilitated by the thin application of mineral or baby oil followed by gentle scalp massage with a soft toothbrush and then shampooing. Antiseborrheic shampoos are alternatives if therapy with no-tears shampoo is not effective. If there is a significant inflammatory component, a topical corticosteroid lotion, oil, or solution, with or without 3% to 5% precipitated sulfur or salicylic acid, may be applied once to twice daily. For involvement other than the scalp, a low-strength topical corticosteroid or topical antifungal agent is usually effective when applied once to twice daily.

Adolescents with seborrhea of the scalp may try a variety of antiseborrheic shampoos, tar shampoo, ketoconazole shampoo, or 5% tea tree-oil shampoo.<sup>278,280</sup> Antiseborrheic shampoos may contain selenium sulfide (e.g., Sebulex, Exsel, and Selsun), salicylic acid (e.g., T-sal), or zinc pyrithione (e.g., Head and Shoulders and DHS Zinc). If the scale is extremely thick and adherent, it can be loosened by warmed mineral oil massaged into the scalp or by the use of P&S Liquid (Baker Cummins), ideally left on overnight. Scales are then loosened by scrubbing gently with the fingers or a soft brush, and the scalp is shampooed. For patients with associated erythema or pruritus, topical corticosteroid lotions, gels, oils, or foams may be used. Seborrheic dermatitis of the face or intertriginous areas in adolescents usually responds quickly to the application of a mild corticosteroid, calcineurin inhibitor, or antifungal medication. If these are too greasy, a foam preparation of ketoconazole is available.<sup>281</sup>

Blepharitis may be managed by warm-water compresses, gentle cleansing with a dilute solution of a nonirritating or baby shampoo, and mechanical removal of scales when necessary. Topical corticosteroids on the eyelids or eyelid margins should be used with caution, although calcineurin inhibitors (e.g., tacrolimus or pimecrolimus) may be used safely in this area.

Seborrheic dermatitis of the intertriginous or diaper areas occasionally may be complicated by secondary candidal or bacterial infection. Candidal infection is usually seen in the diaper areas as discrete erythematous scaling papules and sometimes pustules, especially at the periphery of the affected area. Secondary bacterial infection is more commonly seen as oozing at the neck fold and other intertriginous sites. In such instances, topical anticandidal and/or antibacterial agents are generally helpful. For patients refractory to topical treatment or for those with significant secondary bacterial infection, bacterial cultures and appropriate systemic antibiotics are necessary.

## Intertrigo

Intertrigo is a superficial inflammatory dermatitis that occurs in areas where the skin is in apposition (Fig. 3-40; see also Fig. 17-38). As a result of friction, heat, and moisture, the affected areas become intensely erythematous in a well-demarcated pattern, macerated, and often secondarily infected by bacteria or *Candida*, or in adolescents by dermatophytes (see Chapter 17). Intertrigo with secondary streptococcal infection often presents with oozing and can be associated with

**Figure 3-40** Intertrigo is a superficial inflammatory dermatitis that occurs at sites of skin apposition. Secondary bacterial or yeast infection is common. Note the weeping of clear fluid.

**Figure 3-41** Pompholyx, or dyshidrotic eczema. An acute recurrent or chronic eruption of the palms, soles, and lateral aspects of the fingers with deep-seated tapioca-like vesicles to large, tense bullae.

bacteremia.<sup>282,283</sup> Treatment is directed toward elimination of the macerated skin. Open wet compresses, dusting powders (such as ZeaSORB), topical corticosteroid lotions, and when indicated, appropriate antibiotics or fungicidal agents may be used.

## Dyshidrotic Eczema

Dyshidrotic eczema (pompholyx) is an acute recurrent or chronic eczematous eruption of the palms, soles, and lateral aspects of the fingers, characterized by deep-seated, variably inflamed lesions that range from tapioca-like vesicles to large, tense bullae (Figs. 3-41 and 3-42).<sup>284</sup> The distribution of lesions generally is bilateral and somewhat symmetrical. Patients complain of considerable pruritus and/or burning. Hyperhidrosis is often associated. Attacks usually last a few weeks, but relapses are frequent, often several times per year.

Dyshidrotic eczema may be confused with contact dermatitis or tinea, disorders commonly unilateral or more localized. ACD (see **Allergic Contact Dermatitis** section) on the feet or hands most commonly results from exposure to potassium dichromate (for tanning leather) or rubber but occasionally is caused by paraphenylenediamine (PPD; in hair dyes and as an additive to henna), nickel, fragrance mix, colophony (in glues and also in violin rosin), and

**Figure 3-42** Pompholyx, or dyshidrotic eczema. Superficial crusting and desquamation often replace the ruptured tiny vesicles of dyshidrotic eczema.

potassium dichromate.<sup>285</sup> Fungal culture and patch testing can be performed to distinguish these disorders from tinea and contact dermatitis, respectively. “Id” reactions and pustular psoriasis must also be considered in the differential diagnosis of this disorder and are most commonly bilateral. Juvenile plantar dermatosis is limited to the feet and tends to be bilateral (Fig. 3-43). A reaction on the palms and soles resembling dyshidrotic eczema has also been described after intravenous immunoglobulin (IVIG), most commonly after the first IVIG treatment in adults with neurological disorders.<sup>286,287</sup> In a minority of these cases, eczematous lesions may be extensive. Severe dyshidrotic eczema may also occur after IVIG therapy for Kawasaki disease<sup>288</sup> or Stevens–Johnson syndrome.<sup>289</sup>

The natural course of dyshidrotic eczema is one of frequent recurrence. Open wet compresses tend to open the vesicles, and application of moderate to potent topical corticosteroids, although not curative, helps to relieve the manifestations of this disorder. Topical tacrolimus 0.1% ointment has been used successfully as an alternative that allows rotational therapy.<sup>289</sup> When infection is present, antibiotics may be administered topically or systemically. Although not a disorder of eccrine glands *per se*, the use of topical aluminum chloride in concentrations of 12% (e.g., Certain Dri) to 20% (e.g., Drysol) may decrease the associated hyperhidrosis and help to control the disorder if not too irritating. Hyperhidrosis can also be controlled by oral administration of glycopyrrolate if topical application of drying agents is ineffective. For adolescents with recalcitrant hyperhidrosis, intradermal injections of botulinum toxin might be considered.<sup>290</sup> Phototherapy with either narrow-band ultraviolet-B light or high doses of ultraviolet A1 light<sup>291</sup> and even short courses of oral corticosteroids with gradual tapering have been used.

## Juvenile Plantar Dermatoses

Juvenile plantar dermatosis (dermatitis plantaris sicca or “sweaty-sock dermatitis”) is a common dermatosis of infancy and childhood, most commonly localized to the distal aspect of the soles and toes, particularly the great toes, but sparing the interdigital spaces. Associated with hyperhidrosis and thought to represent a frictional irritant dermatitis, the disorder is manifested acutely by a symmetrical, smooth, red, glazed, and fine scaling (see Fig. 3-43, A) but can become lichenified with chronicity (see Fig. 3-43, B). Similar changes have also been reported on the fingertips in up to 5% of patients with excessive perspiration. Untreated juvenile plantar dermatosis generally tends to persist for several years, and although there is no seasonal pattern, some patients report slight worsening of the condition during the summer and in cold weather.

The differential diagnosis of juvenile plantar dermatosis includes tinea pedis, palmoplantar psoriasis, pityriasis rubra pilaris, and shoe-contact dermatitis. Tinea pedis can manifest as scaling and erythema

**Figure 3-43** Juvenile plantar dermatosis. (A) Characteristic smooth, glazed dermatosis with scaling on the skin of the toes and distal plantar surfaces of the feet of a child with juvenile plantar dermatosis (“sweaty sock dermatitis”). (B) Scaling, lichenification, and fissuring in association with chronic juvenile plantar dermatitis. This patient also has ichthyosis vulgaris, which explains the hyperlinear soles.

of the plantar foot but is more likely to involve the interdigital spaces. Associated pustulation of tinea may be mistaken for secondary staphylococcal infection. Potassium hydroxide scrapings and culture may be required to distinguish tinea pedis and juvenile plantar dermatosis. The plaques of psoriasis are often thicker and more erythematous. Pityriasis rubra pilaris may closely resemble psoriasis but often shows a salmon-orange coloration on the palms and soles. Both psoriasis and pityriasis rubra pilaris usually show lesions elsewhere. Contact dermatitis owing to a component of shoes is more commonly on the dorsum of the foot, but the plantar foot is occasionally involved (see *Shoe Dermatitis* section).

Although treatment is not always completely successful, children with hyperhidrosis of the feet should wear all-cotton socks and avoid occlusive footwear whenever possible, remove their shoes when indoors, change their socks whenever they are damp, dust an absorbent powder such as ZeaSORB into shoes and hosiery (to help lessen perspiration), and use an emollient cream as soon as the shoes and socks are removed. Use of a medium-strength to potent topical steroid is usually effective in diminishing the associated pruritus and inflammation. Low-strength topical steroids are often not effective, probably owing to the thick overlying stratum corneum of the plantar surface. Topical or systemically administered antistaphylococcal antibiotics

may be needed if patients show crusting or pustulation suggesting secondary infection. Careful application of a cyanoacrylate (Super Glue) to fissured areas often provides relief from the associated discomfort.

## Frictional Lichenoid Dermatitis

Frictional lichenoid dermatitis (frictional lichenoid eruption, juvenile papular dermatitis, recurrent summertime pityriasis of the elbows and knees) is a recurring cutaneous disorder affecting children, especially boys, between 4 and 12 years of age.<sup>292</sup> Most cases are seen in the spring and summer when outdoor activities are common, and many cases have been associated with playing in sandboxes (sandbox dermatitis) or on grass. Approximately half of the affected children have AD, allergic rhinitis, or asthma.<sup>293</sup> The eruption is characterized by aggregates of discrete lichenoid papules, 1 or 2 mm in diameter, which occur primarily on the elbows, knees, and backs of the hands of children in whom such areas are subject to minor frictional trauma without protection of clothing (Fig. 3-44). Lesions may be hypopigmented, and associated pruritus is often severe but may be absent. It tends to occur in children with a predisposition to atopy.

The differential diagnosis of this disorder includes psoriasis, AD, molluscum, flat warts, lichen nitidus, and the papular acrolocated syndrome (Gianotti-Crosti syndrome; see Chapter 16). The management of frictional lichenoid dermatitis includes avoidance of frictional trauma to the involved areas (as might occur with leaning on elbows and knees) and application of topical corticosteroids and emollient, especially to ease any associated pruritus.

## Nummular Dermatitis

Nummular dermatitis is characterized by discoid or coin-shaped plaques. The name is derived from the Latin word *nummulus* ("coin-like"), because of the shape and size of the lesions. The plaques of nummular dermatitis are composed of minute papules and vesicles, which enlarge by peripheral extension to form discrete, round or oval, erythematous, often lichenified and hyperpigmented plaques that measure 1 cm or more in diameter (see Figs. 3-30 and 3-31). They usually occur on the extensor surfaces of the hands, arms, and legs as single or multiple lesions on dry or asteatotic skin. Pruritus is usually associated and may be intense. Occasionally the face and trunk may be involved. The surrounding skin may be xerotic, particularly in children with AD and nummular dermatitis, but in many patients is normal. Secondary staphylococcal infection is common and manifests as crusting and exudation.

Nummular dermatitis must be differentiated from ACD, AD (which may be seen concurrently), psoriasis, and superficial dermatophyte infections of the skin. History of exposure, patch testing if appropriate, fungal culture, and biopsy of lesional skin can help to distinguish these conditions.

Effective therapy requires application of class II to IV topical corticosteroids, preferably in an ointment base or under occlusion. The combination of a refined tar preparation (liquor carbonis detergens 5% to 10%) in a strong corticosteroid used twice daily is an alternative means of treatment. Secondary staphylococcal infection should always be considered, especially in recalcitrant lesions, and commonly requires systemic administration of antibiotic (such as cephalexin). Therapy with a topical corticosteroid can be continued in the face of treated infection.

## Winter Eczema

Winter eczema, also known as asteatotic eczema, eczema craquelé, or xerotic eczema, is a subacute eczematous dermatitis characterized by pruritic scaly erythematous patches, usually associated with dryness and dehydration (asteatosis) of the epidermis. Generally seen on the extremities and occasionally on the trunk, these changes are most common during winter when the humidity is low, particularly in adults and adolescents who bathe or shower often with harsh or

**Figure 3-44** Frictional lichenoid dermatosis. Aggregates of lichenoid papules occur primarily on the elbows, knees (**A**), knuckles, and backs of the hands of children (**B**). Although the somewhat monomorphic appearance of the papules on the hand in this child is suggestive of lichen nitidus (see Chapter 4), the associated pruritus, localization, and concurrent presence of lichenoid papules of various sizes on the elbows allow the diagnosis to be made clinically.

drying soaps. Frequent bathing with incomplete drying and resultant evaporation of moisture causes dehydration of the epidermis, with redness, scaling, and fine cracking that may resemble cracked porcelain (hence the term *eczema craquelé*). Treatment of winter eczema is centered in the maintenance of proper hydration of the stratum corneum and is dependent on the routine use of emollients, limiting the time and temperature of showers, use of mild soaps, and topical therapy with corticosteroids (preferably those in an ointment base) for individual lesions.

## Lichen Striatus

Lichen striatus is a self-limiting inflammatory dermatosis that follows Blaschko lines, the path of ectodermal embryologic development of skin.<sup>294,295</sup> Although not considered contagious or inherited, lichen

**Figure 3-45 (A) and (B)** Lichen striatus. A self-limiting, usually unilateral linear or curvilinear collection of small, erythematous, flat-topped papules that follows one of the Blaschko lines, lines of the embryologic development of skin. Lines on the face tend to be particularly thin.

striatus has been described in more than one family member.<sup>296,297</sup> It has followed viral infections, vaccination (e.g., hepatitis B virus), and trauma, but its cause is unknown. The mean age of onset is 4 years of age, although older children may be affected. Girls appear to be affected two to three times more often than boys. In the largest series to date, 60 of 115 affected children were atopic.<sup>295</sup>

The eruption is usually asymptomatic and reaches its maximum extent within a few weeks to months. Only 6% of affected children show more than one band. Lesions begin as 2- to 4-mm erythematous to hypopigmented, slightly scaling, flat-topped papules that rapidly coalesce to form the curvilinear band. The line of involvement tends to be narrow but can range from several millimeters to 1 or 2 cm in width. Most commonly lichen striatus affects an extremity but occasionally the face (Fig. 3-45),<sup>298</sup> neck, trunk, or buttocks is affected. Nail involvement is seen, typically by extension of an extremity lesion.<sup>299</sup> In dark-skinned or tanned individuals the eruption may appear as slightly scaly (Fig. 3-46) or as a band-like area of hypopigmentation (Fig. 3-47). Although the band is usually continuous, it may occasionally be interrupted by or interspersed with coalescent plaques several centimeters in diameter along a line of Blaschko.

The differential diagnosis of lichen striatus most commonly includes inflammatory linear verrucous epidermal nevus (ILVEN), which tends to be more psoriasiform (Fig. 3-48; see also Chapter 9 and Fig. 9-38) and blaschkitis<sup>300</sup> (more eczematous) (Fig. 3-49). In contrast to lichen

**Figure 3-46** Lichen striatus. Linear collection of papules of lichen striatus, most commonly seen on the extremities. The erythema is more difficult to appreciate on darker skin, but the mild scaling may be more apparent.

striatus, blaschkitis is usually papulovesicular, pruritic, involves multiple bands, tends to last for about a month, recurs often, and tends to respond to topical anti-inflammatory medication. Biopsy of blaschkitis shows pure spongiosis without a lichenoid infiltrate. Other acquired inflammatory lesions distributed along lines of Blaschko can include linear forms of lichen planus, linear lichen nitidus, lichenoid drug eruptions,<sup>301</sup> lichenoid chronic GVHD, lupus erythematosus, AD, and linearly arranged ("Koebnerized") lesions of verruca plana. When the diagnosis remains in doubt, histopathologic examination of a cutaneous biopsy specimen will help exclude other possible linear eruptions.

Lichen striatus usually resolves spontaneously within 3 to 24 months (mean duration, 6 months)<sup>295</sup> but occasionally lasts longer (up to 3.5 years)<sup>302</sup> and often leaves an area of hypopigmentation that subsequently disappears. Recurrences occur in 2% of children. Therapy is generally unnecessary, and topical corticosteroids do not tend to hasten resolution. However, facial lesions have responded to tacrolimus,<sup>303</sup> and the combination of a topical tazarotene and topical steroid have been associated with lesional clearing.<sup>304</sup>

## Contact Dermatitis

*Contact dermatitis* may be defined as an eczematous eruption produced either by local exposure to a primary irritating substance (irritant contact dermatitis) or by an acquired allergic response to a clinically relevant sensitizing substance (allergic contact dermatitis, ACD).<sup>31</sup> A contact allergen can sensitize but does not cause a reaction on first exposure. With continued or repeated exposure, the allergen may trigger a contact dermatitis based on a type IV allergic reaction. An irritant, on the other hand, may be defined as a substance that produces an eczematous response on the basis of irritation rather than by immunologic means and can occur in anyone; allergens only can trigger contact dermatitis in susceptible individuals. Photocontact reactions (see Chapter 19) such as phytophotodermatitis after contact with the juice or rinds of certain lemons and limes occur only when the skin is exposed to ultraviolet light. ACD should be distinguished from contact urticaria, which can be distinguished by the morphology of the lesions (urticarial) and is best treated with antihistamines.<sup>305,306</sup>

### PRIMARY IRRITANT DERMATITIS

Common substances that produce primary irritant dermatitis include harsh soaps, bleaches, detergents, solvents, acids, alkalis, bubble baths, certain foods, saliva, urine, feces, and intestinal secretions. The severity of the dermatitis varies from person to person or from time to time in the same person as a result of the condition of the skin at the

**Figure 3-47 (A) and (B)** Lichen striatus. The streaks of lichen striatus may be hypopigmented macular streaks from onset, and are particularly prominent in children with darker skin types. The stripe of hypopigmentation can be a narrow stripe, but often is a collection of bands or a broad band.

time of exposure, the strength of the irritant, the location of the eruption, the cumulative effect of repeated exposures to the irritating substance, and local factors such as perspiration, maceration, and occlusion.

In children, the lips and adjacent skin commonly become dry and, as a result of a licking habit, inflamed and scaly (lip-licker's dermatitis) (Fig. 3-50). If extensive, lip-licker's dermatitis must be distinguished from ACD (see Fig. 3-54) and perioral granulomatous dermatitis (Fig. 3-51), which is characterized by small erythematous papules of the perioral, and often suborbital, areas and is exacerbated by application of topical corticosteroids (see Chapter 8). Contact dermatitis induced by mango (see *Poison Ivy (Rhus) Dermatitis* section; Fig. 3-55) can also resemble lip-licker's dermatitis. Saliva also commonly becomes trapped between the thumb and mouth of thumbsuckers, and a similar reaction is commonly seen in toddlers who continue to use pacifiers for long periods of time. In infants with AD, saliva is a significant irritant associated with the extensive drooling from teething and contributes to the dermatitis on the cheeks and chin. In the infant and young

**Figure 3-48** Inflammatory verrucous epidermal nevus (ILVEN). Lichen striatus must be differentiated from ILVEN, a persistent mosaic lesion that follows the lines of Blaschko (see Chapter 9). The papules of ILVEN tends to be more erythematous, less discrete, more scaly and more pruritic than those of lichen striatus, but biopsy or observation over 2 to 3 years may be necessary to determine the diagnosis.

**Figure 3-49** Blaschkkitis. Although distributed along a Blaschko line, lesions of blaschkkitis are eczematous, are often multiple, and last for just a few weeks in contrast to those of lichen striatus or ILVEN.

child, circumoral erythema may also represent a contact dermatitis in response to foods such as citrus foods, carrots, shrimp, and spinach. The dermatitis is caused by direct contact with the skin, not from ingestion of the offending food substances, although exposure is aggravated by regurgitation of food particles, dribbling of saliva, and rubbing of the involved areas.

Diaper dermatitis is the most common form of irritant contact dermatitis in infancy (see Chapter 2), with a peak age of incidence of 9

**Figure 3-50** Lip-licker's dermatitis. Chronic contact dermatitis with lichenification and hyperpigmentation in the shape of licking from the tongue and sometimes beyond.

**Figure 3-51** Periorificial granulomatous dermatitis. The discrete, tiny, noneczematous papules are usually seen in a perioral distribution but may be perinasal and/or infraorbital. The morphology and distribution help to distinguish periorificial granulomatous dermatitis from perioral irritant or allergic contact dermatitis.

to 12 months of age. ACD in the diaper area is rare. Irritant diaper dermatitis typically affects the exposed convex surfaces and spares the folds, which are protected. Toddlers and younger children who use “pull-up” diapers at night and children with enuresis not uncommonly show an irritant dermatitis of the buttocks region related to exposure to urine and limited absorbency of the pull-up. Perianal dermatitis is often irritant, related to exposure to stool, but must be distinguished from perianal psoriasis (see Chapter 4) and perianal streptococcal cellulitis (see Chapter 14). Juvenile plantar dermatosis has been linked to exposure to sweat and is more commonly seen in children with plantar hyperhidrosis (see previous discussion). Excessive handwashing, especially during winter months and in compulsive handwashers, is the most common cause of dermatitis on the dorsum of the hands. The increased attention to handwashing as a means to decrease the spread of infectious disease has markedly increased the risk of developing irritant hand dermatitis in school-aged children.

Soccer and hockey shin guards typically trap sweat and cause friction, leading to an irritant contact dermatitis on the anterior aspect of the lower legs of school-aged children that can become lichenified if chronic. Strategies to reduce friction, such as wearing a cotton sock under the guard and coating the area with absorbent powder or petrolatum before using the guards, together with topical

anti-inflammatory therapy for the dermatitis as needed, have been helpful.<sup>307</sup> Should the dermatitis persist or worsen, ACD should also be considered, particularly to the rubber compounds and neoprene components in sporting equipment (Table 3-3). Irritant reactions may also occur from exposure to fiberglass particles attached to clothes after exposure to fiberglass insulation panels or drapes.<sup>308</sup> Because clothes washed in a washing machine in which fiberglass materials have been washed are also capable of inducing this cutaneous reaction, children whose parents have been exposed may also be affected. Fiberglass dermatitis presents as a pruritic, patchy folliculitis or subacute dermatitis. Microscopic examination of skin scrapings from involved areas or suspected articles of clothing may reveal pale, greenish, granular rod-like fibers one to two times the width of a hair. The use of methylphenidate transdermal patches in children with ADHD often leads to irritant reactions confined to the site of patch application; ACD to the patch is rare.<sup>309</sup>

Avoidance of the irritant is key to improvement. Low-potency topical corticosteroids or calcineurin inhibitors are used to treat the dermatitis of face and intertriginous areas; medium-strength topical steroids, or even potent topical steroids for hands and feet, may be required. Moisturizing creams or ointments lubricate and protect the affected areas. The treatment of irritant diaper dermatitis is discussed in Chapter 2.

## ALLERGIC CONTACT DERMATITIS

ACD may account for up to 20% of all dermatitis in childhood and is likely to be underdiagnosed.<sup>80,81,310</sup> Key areas of involvement are the eyelids, neck, hands, axillae, anogenital area, and lower extremities. ACD represents a type IV immunologic (delayed hypersensitivity or cell-mediated) reaction in which antigenic contact with cutaneous Langerhans cells and T-lymphocyte activation are key. Despite their clinical similarity, nickel sensitization involves Th1/Th17 and Th22 lymphocytes, but fragrance allergy and, to a lesser extent, rubber allergy largely involve Th2 lymphocyte activation.<sup>311</sup> After sensitization to the offending allergen, ACD will develop upon reexposure to the sensitizing substance. Sensitization may occur after only a few exposures to the offending substance, or allergy may occur after years of contact. Once the area has become sensitized, however, reexposure to the offending allergen may result in an acute dermatitis within a relatively brief period (generally 8 to 12 hours after exposure to the sensitizing allergen).

Reactions to *Rhus* family of contact allergens (e.g., poison ivy) are the most common triggers in children. Other major sources of clinically relevant ACD in children are metals (especially nickel, chromates, cobalt, and occasionally gold), fragrances and balsam of Peru, lanolin/wool alcohols, topical antibiotics (neomycin and bacitracin), formaldehyde, and rubber products<sup>80,81</sup> (Table 3-3). Girls are at greater risk for developing contact allergy, especially during adolescence and on the face because of their greater exposure to ear piercing (nickel), cosmetics (preservatives and fragrances), and hair products. Initial sensitization to common allergens and occasionally ACD itself may occur during infancy.<sup>312</sup> Of tested children, 23% to 49% have AD, although it is unclear whether this high number represents a referral bias or truly increased risk<sup>77,313-315</sup>; the greatest relevant reactivity in this group is to allergens in the emollients.<sup>78</sup> More recently recognized triggers in children are PPD contaminating henna tattoos,<sup>316</sup> disperse dyes in clothing,<sup>317</sup> cocamidopropyl betaine (CAPB) in “no-tears” shampoos and cleansers,<sup>318</sup> and the preservatives methylchloroisothiazolinone (MCI) and methylisothiazolinone (MI), which are in wet wipes. The diagnosis of ACD is based on the appearance and distribution of skin lesions and aided when possible by a history of contact with an appropriate allergen (Tables 3-3 and 3-4). Appearance on exposed areas only, linearity, and sharp edges are also clues to a reaction to a contactant, although ACD usually expands beyond the contact area in contrast to irritant contact dermatitis. For example, linearly distributed vesicles and bullae overlying erythema are typical of poison-ivy reactions. Dermatitis can appear at a distant site because of allergen transfer from one body site to another or by “recall reactions,” which are flares at sites of prior allergen exposure.

Dermatitis on the eyelids, hands, feet, and legs is most commonly associated with positive reactions on patch testing. Eyelid dermatitis

**Table 3-3** Most Common and/or Relevant Sensitizers in Children and Their Sources\*

Group	Allergen	Sources	Typical Distribution	Other Comments
Plant	Urushiol	Poison ivy, sumac, oak	Extremities in linear streaks; face, genitals	If aerosolized, can be extensive and on face resemble angioedema
Metal	Nickel	Jewelry, snaps, buckles, eyeglasses, keys, coins, cell phones, tablets, laptop computers, orthodontics	Subumbilical, face, eyelids, earlobes, neck, wrists	Detect with glyoxime on objects
Topical antibiotic	Neomycin	Antibiotic-containing ointments	Face, eyelids	Bacitracin can also sensitize
Fragrance and Balsam of Peru	Fragrance mix Balsam of Peru ( <i>Myroxylon pereirae</i> )	Cosmetics, perfumes, sunscreens, toothpaste, flavoring agents in food and drink, lozenges, lip balms, topical healing agents, insect repellents	Face, eyelids, mouth, lips, neck, hands	Cross reacts with eugenol/isoeugenol (essential oils from several spices, such as cloves and cinnamon); vanilla, tiger balm, benzoin, propolis, colophony, citrus peel
Preservative	Thimerosal	Creams, lotions, mascara, vaccines	Torso, face	Largely removed
Metal	Cobalt	Buttons, snaps, jewelry, cement, ceramics, vitamin B <sub>12</sub>	Umbilical, earlobes, neck, hands	Contaminant with nickel
Metal	Chromate	Leather (tanned), cement, paints, matches, green felt	Umbilical, hands, soles	
Metal	Gold	Jewelry, occupational exposure to jewelry, medicinal use; rarely dental gold	Face, eyelids, earlobes, neck wrists, fingers; rarely mucosal	Long-lasting patch reaction
Rubber accelerator	Thiuram	Elastic (waistband, socks), gloves, shoes (soles and insoles), pesticides	Waistline, feet, hands	Washing clothes with bleach causes release
Emollient	Lanolin/wool alcohols	Emollients, lip balms, soaps, aftershave, baby and bath oil, hand sanitizers	Hands, body	Sheep wool products
Preservative	Formaldehyde/formaldehyde releasing	Lotions, cosmetics, shampoo, newsprint, wrinkle-resistant clothes	Hands, face, ears, trunk (sparing axillae)	
Oxidative chemical	Paraphenylenediamine	Hair dyes, printer ink, contaminant in henna tattoos (black)	Hairline, ears, hands, sites of tattoos	
Preservative	Methylchloroisothiazolinone/methylisothiazolinone (MCI/MI)	Many infant products, such as wet wipes, protective creams, liquid soaps, shampoos, household cleaners, paints	Especially hands; can be head and neck, feet, diaper region, generalized	
Surfactant	Cocamidopropyl betaine (CAPB)	Cleansing products for children (such as tear-free formulations)	Face, hands	
Dye	Disperse dyes	Diaper material, colored synthetic garments (school and athletic uniforms)	Areas of high friction, e.g., around the axillae sparing the vault, anterior thighs	
Rubber accelerator and antioxidant	Mixed dialkyl thiourea	Neoprene in computer mouse pads, wetsuits, shoes, athletic braces, shin guards, protective pads	Areas of friction and sweating under athletic equipment	
Adhesives	p-tert-butylphenol formaldehyde	Glues, surface coating and adhesives in shoes, ECG pads, leather goods, upholstery, hobbies	Hands, feet	

ECG, Electrocardiogram.

\*For additional information, see <https://www.truetest.com/global/patientinfo.htm> and choose the specific antigen.

**Table 3-4** Distribution of Dermatitis and Possible Triggers

Localization	Triggers
Eyelids	Cosmetics, emollients (hands), fragrances, hair dyes, metals, nail products
Hairline, postauricular, ear helix	Hair dyes, hair products
Earlobes, neck	Fragrance, metal jewelry
Periaxillary	Textile dyes, formaldehyde and formaldehyde releasers
Axillary vault	Deodorants
Subumbilical	Metal (snaps, belt buckles)
Extremities, linear streaks	Poison ivy and oak, phytophotodermatitis
Plantar aspect of feet	Adhesive, rubber in shoes
Dorsal aspect of feet	Leather (chromates, dyes), rubber, adhesive

**Figure 3-52** Toilet seat dermatitis. This boy's mother used wipes with iodopropynyl butylcarbamates and fragrance to clean the seat. The dermatitis cleared after a switch to dilute bleach water.

often results from preservatives in cosmetics, fragrances, or emollients applied to the hands. Shoe dermatitis (to the leather chromates, rubber, or dyes) should be suspected if lesions occur on the dorsum of the foot. Subumbilical or earlobe dermatitis is typical of nickel contact allergy, and axillary-vault dermatitis should lead to investigation of sensitivity to deodorant or fragrances, whereas axillary dermatitis sparing the vault may relate to clothing dyes. Toilet seat dermatitis (buttock and posterior thighs) could result from ACD to essential oils, lacquer, or paint in a wooden toilet seat but now more commonly is irritant contact dermatitis from detergents or allergic contact dermatitis to a cleansing component (Fig. 3-52) (and responds well to treatment of the dermatitis followed by prevention with the use of toilet seat covers).<sup>319</sup> Occasionally oral lichenoid reactions occur after ingestion of allergens. The histopathologic picture of ACD usually does not allow differentiation from primary irritant dermatitis or AD.

The acute lesions of ACD are characterized by intense erythema accompanied by edema, papules, vesiculation (sometimes bullae), oozing, and a sharp line of demarcation between involved and normal skin. In the subacute phase, vesiculation is less pronounced and is mixed with crusting, scaling, and thickening of the skin. Chronic lesions, conversely, are characterized by lichenification, fissuring, scaling, and little or no vesiculation.

**Figure 3-53** Nickel contact dermatitis with id. (A) Note the characteristic subumbilical (or periumbilical) hyperpigmented plaque of dermatitis in this patient with nickel contact dermatitis. (B) The lichenification and hyperpigmentation indicate a chronic dermatitis. The tiny discrete papules seen around the plaque extend across the entire trunk and represent an id reaction to the dermatitis.

### Autosensitization Dermatitis or Id Reaction

An id reaction (autosensitization dermatitis, autoeczematization) describes a hypersensitivity disorder characterized by the acute onset of small edematous papules or papulovesicles. Id reactions to nickel are found in up to 50% of patients<sup>320</sup> and may appear on the trunk (Fig. 3-53), forearms, flexor aspects of the upper arms, the extensor aspects of the upper arms and thighs, and less commonly, the face. The eruption is nearly always symmetrical but may demonstrate light sensitivity or an isomorphic response (the Koebner phenomenon), in which trauma elicits new lesions. Lesions are generally associated with moderate to severe pruritus. The disorder usually appears acutely over a few days and nearly always is preceded by an exacerbation of the preexisting dermatitis by infection, rubbing, or inappropriate therapy. The acute eruption may subside spontaneously in a few weeks if the primary dermatitis is controlled. Relapses, however, are common, particularly when the initial local lesion flares and is followed by a further disseminated eruption.

The diagnosis of id reaction is made clinically on the basis of a generalized papulovesicular eruption that develops in the wake of pre-existing eczematoid dermatitis. Treatment depends on the use of open wet compresses, antihistamines, and topical corticosteroid preparations. Control of the primary lesion is critical to prevent further or recurrent antigenic stimulation. Although seldom indicated, a 2- to 3-week course of systemic corticosteroids may at times be necessary in cases unresponsive to more conservative therapy.

Id reactions may also be seen in response to infectious agents, particularly in bacterial and dermatophyte infections. The tiny papules of

**Table 3-5** Allergen Components in the Commercially Available TRUE Test Kit

Panel 1.2	Panel 2.2	Panel 3.2
Nickel sulfate	p-tert-Butylphenol formaldehyde resin	Diazolidinyl urea
Wool alcohol (lanolin)	Epoxy resin	Quinoline mix
Neomycin sulfate	Carba mix	Tixocortol pivalate
Potassium dichromate	Black rubber mix	Gold sodium thiosulfate
Caine mix	Cl+ Me-isothiazolinone	Imidazolidinyl urea
Fragrance mix	Quaternium-15	Budesonide
Colophony	Methyldibromo glutaronitrile	Hydrocortisone 17-butrate
Paraben mix	p-Phenylenediamine	Mercaptobenzothiazole
Negative control	Formaldehyde	Bacitracin
Balsam of Peru	Mercapto mix	Parthenolide
Ethylenediamine dihydrochloride	Thimerosal	Disperse Blue 106
Cobalt dichloride	Thiuram mix	Bronopol

TRUE, Thin-Layer Rapid Use Epicutaneous.

the id reaction associated with tinea capitis most commonly are localized to the head and neck. Often, the id reaction of tinea capitis occurs after initiation of treatment with oral antifungal agents and is erroneously considered to be a drug reaction. Recognition of the underlying infection and continuing the antimicrobial treatment is critical for clearance.

### Patch Testing

Patch tests may be used to confirm the diagnosis of ACD if a specific agent is suspected, even in young children.<sup>321</sup> Different panels of antigens for patch testing are available in Europe, the United States, and Japan, which has led to efforts to standardize testing internationally. In the United States, the Thin-Layer Rapid Use Epicutaneous (TRUE) patch test kit (Allerderm; <http://www.truetest.com>) is commercially available and has been expanded to 35 allergens (Table 3-5). Of the most relevant allergens in children,<sup>322</sup> only dialkyl thioureas and CAPB are not found in the latest TRUE test kits. These kits test have allergens for reactivity against the most common contact allergens measured and preloaded onto hypoallergenic tape for easy use; however, the potential allergens are not inclusive and lack flexibility. The North American Contact Dermatitis Group (NACDG) and American Contact Dermatitis Society (ACDS) screening allergen series are more extensive sets of test substances.

When patch testing is performed, patches should be placed on grossly normal, nonhairy skin such as the back or volar forearm.<sup>323</sup> Distraction techniques such as having the child watch a video are very useful, particularly for testing smaller children.<sup>324</sup> Patch testing should be deferred in the presence of extensive active dermatitis; false-positive reactions may be obtained, and a strongly positive patch-test reaction may cause acute exacerbation of the dermatitis. Antihistamines affect type I reactions and not type IV reactions; thus their administration is not a contraindication to patch testing. Systemic corticosteroid and immunosuppressive therapy might mask weak patch-test responses, and it is preferable that oral steroids be discontinued at least 3 weeks before patch testing. Potent topical steroids have also been shown to suppress patch-test reactivity<sup>325</sup> and should be avoided at the site of testing for 1 week before patch testing.

Patch tests generally should be kept in place for 48 hours, and a reading can be made after an interval of 20 to 60 minutes after removal of the patch to allow the skin to recover from the effects of pressure and occlusion (Fig. 3-54). The patch or its removal may

**Figure 3-54** Patch testing. Positive patch test reaction to p-tert-butylphenol formaldehyde resin in a patient with shoe dermatitis because of reactivity to the glue (see Fig. 3-55).

produce mild transient erythema or a temporary blanching effect, resulting in false reactions.

Reactions are graded based on redness, induration, and presence of blistering. Unless testing for weak sensitizers (such as fabrics or cosmetics), a doubtful reaction (faint macular erythema only) is usually of no significance. A 1 plus (1+) reaction is characterized by erythema, infiltration, and possibly papules. The addition of vesicles to this response indicates a 2 plus (2+) reaction, and a bullous reaction is read as 3 plus (3+). A second reading of the patches should be performed at 72 to 96 hours after the patches are placed. This reading distinguishes irritant from allergic reactions, because irritant reactions often resolve after patches are removed, whereas allergic reactions increase in time. Delayed reading at 5 days or beyond may be needed for certain allergens (metals such as nickel, cobalt, potassium dichromate, and gold; topical antibiotics such as neomycin and bacitracin; topical corticosteroids; PPD). In a recent study, 66% of children had a positive reaction at 48 hours, 84% at 72 hours, and 50% between days 7 and 9; 13% only had delayed reactions to offending agents, stressing the need to include the late observation.<sup>326</sup>

Based on the results, families can learn more about specific allergens at <https://www.truetest.com/global/patientinfo.htm>; members of the ACDS have access to the ACDS Contact Allergen Management Program (CAMP), which provides detailed lists of products that patients are able to use. It may also be advisable for patients to test a product on a limited area on the upper inner arm twice a day for 1 week (the repeat open application test [ROAT]).

Occasionally, positive reactions may have no clinical significance. In that case, the reaction is termed *contact allergy* rather than ACD. Similarly, the offending material may not give rise to a positive reaction at the site of the test but may show a positive test if carried out on an area of skin closer to the point of the previously existing dermatitis. The value of patch tests is corroborative and should be used only as a guide in an attempt to confirm a suspected allergen. Scratch and intracutaneous tests are not useful in contact allergic dermatitis.

### Poison Ivy (*Rhus*) Dermatitis

In the United States, poison ivy, poison oak, and poison sumac produce more cases of ACD than all other contactants combined.<sup>327</sup> The plants causing poison ivy dermatitis are included under the botanical term *Rhus* and are *Toxicodendron* species. Poison ivy and poison oak are the principal causes of *Rhus* dermatitis in the United States. Regardless of the specific *Rhus* plant, the clinical appearance of the dermatitis may be identical. The *Rhus* group belongs to the family of plants known as Anacardiaceae, and cross reactions may occur. These include furniture lacquer derived from the Japanese lacquer tree, oil from the shell of the cashew or Brazil nut, the fruit pulp of the gingko tree, and the marking nut tree of India, from which a black "ink" used to mark wearing apparel is produced. The ACD to this ink is termed *dhobi itch*. The rind of the mango also cross reacts, and the possibility of contact dermatitis to *Rhus* should be considered in children with perioral dermatitis after eating mango or on the hands of mango pickers<sup>328</sup> (Fig. 3-55).

**Figure 3-55** Mango dermatitis. Individuals who react to *Rhus* family plants may demonstrate a perioral dermatitis after eating mango but only when in contact with the mango rind, not from the fruit itself.

**Figure 3-56** Poison ivy plant. A member of the *Rhus* family, showing three notched leaflets. (Courtesy of Dr Jon Dyer.)

The poison ivy plant (Fig. 3-56) characteristically shows three leaflets notched at the edge. It grows luxuriantly as a tall shrub or woody rope-like vine in vacant lots, among grasses, and on trees or fences throughout all sections of the United States except the extreme southwest. Poison sumac grows as a shrub or tree, never as a vine. It has 7 to 13 leaflets (arranged in pairs along a central stem), with a single leaflet at the end, is relatively uncommon, grows less abundantly, and is found only in woody or swampy areas primarily east of the Mississippi River. Poison oak, conversely, grows as an upright shrub, is most prominent on the West Coast, and is not a problem in the eastern United States. Although *Rhus* dermatitis is more common in the summer, the eruption may occur at any time of year by direct contact with the sensitizing allergen from the leaves, roots, or twigs of the plants.

The eruption produced by poison ivy and related plants is a delayed contact hypersensitivity reaction to an oleoresin (urushiol) of which the active sensitizing ingredient is a pentadecylcatechol. It is characterized by itching, redness, papules, vesicles, and bullae (Fig. 3-57). Although often irregular and spotty, a linear distribution is highly characteristic because of scratching and transfer of the urushiol oleoresin (Koebner phenomenon). When contact is indirect, such as from a pet that has the oleoresin on its fur, the dermatitis is often diffuse, thus making the diagnosis more difficult unless the true nature of

**Figure 3-57** (A) *Rhus* dermatitis with Koebner phenomenon. (B) A characteristic linear vesicular eruption on the forearms with poison ivy (*Rhus*) dermatitis.

exposure is suspected. In the fall, when brush and leaves are burned, it must be remembered that the sensitizing oil may be vaporized and transmitted by smoke to exposed cutaneous surfaces, often presenting as a diffuse facial dermatitis with periorbital swelling (Fig. 3-58).

*Rhus* dermatitis usually first appears in susceptible, sensitized individuals within 1 to 3 days after contact with the sensitizing oleoresin; in highly sensitive individuals it may occur within 8 hours of exposure. Such temporal differences are probably the result of the degree of exposure, individual susceptibility, and variation in cutaneous reactivity of different body regions.

About 70% of the population of the United States would acquire *Rhus* dermatitis if exposed to the plants or the sensitizing oleoresin contained in its leaves, stems, and roots. The result is an acute eczematous eruption that, barring complications or reexposure to the offending allergen, persists for 1 to 3 weeks. Since the undiluted sap from plants of the *Toxicodendron* species turns black when exposed to dry surfaces and skin, dramatic black lacquer- or enamel-like deposits on the skin ("black spot poison ivy") and clothing of individuals exposed

**Figure 3-58** *Rhus* dermatitis. The entire face may become swollen with *Rhus* dermatitis, especially if the patient was exposed through aerosolization. The fine vesication distinguishes contact dermatitis from angioedema.

**Figure 3-59** *Rhus* dermatitis. The oleoresin may be transmitted by the fingers to other parts of the body, including the male genitalia.

to poison ivy or other urushiol-containing plants may rarely be seen.<sup>329,330</sup> These spots typically cannot be removed with soap and water and may precede the development of typical dermatitis.

The best prophylaxis, as with any type of ACD, is complete avoidance of the offending allergen. Patients should be instructed in how to recognize and avoid members of the poison *Rhus* group. When poison ivy is present in the garden or in children's play areas, chemical destruction or physical removal is indicated. Heavy-duty vinyl gloves should be used if the plants are uprooted, because the urushiol is soluble in rubber and can penetrate latex gloves.<sup>331</sup> No topical measure is totally effective in the prevention of poison ivy dermatitis, but certain commercially available barrier preparations with quaternium-18 bentonite (organoclay) have been shown to diminish reactivity significantly (IvyBlock, StokoGard, Hollister Moisture Barrier, Hydropel).<sup>332</sup> Desensitization to the oleoresin of poison ivy by systemic administration of *Rhus* antigen is unreliable and should be reserved only for extremely sensitive individuals who cannot avoid repeated exposure to the antigen. Systemic reactions are not uncommon with the use of hyposensitization procedures.

In an effort to minimize the degree of dermatitis, individuals with known exposure should wash thoroughly with soap and water as rapidly as possible so that removal of the oil is accomplished, preferably within 5 to 10 minutes of exposure. If the oleoresin is not carefully removed shortly after exposure, the allergen may be transmitted by the fingers to other parts of the body (particularly the face, forearms, or male genitalia) (Fig. 3-59). However, the fluid content of vesicles and bullae is not contagious and does not produce new lesions. Thus unless the sensitizing antigen is still on the skin, the disorder is neither able to be spread on an individual nor contagious from one person to another.

Complete change of clothing is advisable, and whenever possible, contaminated shoes and clothing should be washed with soap and water or cold water mixed with alcohol to remove the urushiol. Harsh soaps and vigorous scrubbing offer no advantage over simple soaking and cool water. Thorough washing may not prevent a severe dermatitis in highly sensitive persons. It may, however, reduce the reaction and prevent spread of the oleoresin. When early washing is not feasible, it is worthwhile to wash at the first opportunity in an effort to remove any oleoresin remaining on the skin or clothing and thus prevent its transfer to other parts of the body.

In the management of mild *Rhus* dermatitis, treatment with an antipruritic "shake" lotion such as calamine lotion is helpful. Topical preparations containing potential sensitizers such as diphenhydramine or benzocaine should be avoided. As in other acute eczematous eruptions, cool compresses with plain tap water or Burow solution are soothing, help remove crusts, and relieve pruritus. Administration of potent topical corticosteroids and systemic use of antihistamines and antipruritic agents are helpful. Because the acutely involved areas tend to be vesicular and weeping, creams and lotion forms of topical steroids are more commonly used than occlusive ointments.

In severe, more generalized cases of *Rhus* dermatitis, short-term systemic corticosteroid treatment may be indicated. Systemic corticosteroid therapy may be initiated with dosages of 1 mg/kg per day of prednisone or its equivalent. Steroids should be tapered gradually over 2 to 3 weeks. Premature termination of systemic corticosteroids may result in a rapid rebound, with return of the dermatitis to its original intensity.

### Metal and Metal Salt Dermatitis

Nickel dermatitis, the most common ACD to metal, is also by far the most common cause of contact allergy in children undergoing patch testing, with a prevalence of 10.3% to 40% in tested children worldwide.<sup>313,322,333</sup> Nickel may be added to other metals to increase metal strength (in chromium or cobalt) or as plating to increase attractiveness and durability (a variety of metals, including gold).

Earlobe dermatitis is a cardinal sign of nickel dermatitis. Ear piercing has repeatedly been shown to be a strong risk factor for both females<sup>334</sup> and males.<sup>335</sup> The current trend toward piercing of additional body areas in both males and females has increased the numbers of nickel-sensitive individuals. A positive family history of nickel ACD appears to be a risk factor.<sup>320</sup> Several studies have shown an increased risk of nickel sensitivity in girls (perhaps because of piercing).<sup>336</sup> Since piercing of ears or other sites is responsible for an increased tendency of sensitization to nickel and nickel products, piercing should be done with a stainless steel needle. Persons undergoing piercing should be advised to wear only stainless steel earrings or titanium earrings until the earlobes (or other sites) are completely healed, usually about 3 weeks. Although stainless steel contains up to 20% nickel, the nickel is bound tightly and usually causes no problems.

Prominent pruritic periumbilical and subumbilical papules should also trigger consideration of contact allergy to nickel from the nickel-containing buttons on pants and belt buckles (see Fig. 3-53) and may

**Figure 3-60** Nickel contact dermatitis. This dermatitis (**A**) represents a reaction to nickel-containing eyeglass frames (**B**).

present as recalcitrant lichenified plaques in children with AD.<sup>337</sup> Circular erythematous scaling patches on the midline trunk of infants may signal reactivity to the metal snaps in baby clothes, and at least 6% of the fasteners in children's clothing have been shown to release nickel ion.<sup>338</sup> Other potential triggers are zippers, clothing hooks, the dorsal eyelets on shoes, nickel-containing eyeglass rims (Fig. 3-60), shoe buckles, musical instruments,<sup>339</sup> razors,<sup>340</sup> gaming systems,<sup>341</sup> laptops,<sup>342</sup> tablets,<sup>343</sup> and cell phones/cell phone accessories.<sup>344,345</sup> Although the concentration of nickel in orthodontic appliances is low and has not been found to sensitize against nickel, patients who are already nickel sensitive, usually from exposure through ear piercing, may rarely show gingival reactions induced by the appliance<sup>346</sup>, the prevalence of reactions to orthodontic appliances is approximately 0.03%.<sup>347</sup> Students should be aware of the presence of nickel in seats with metal studs, which may lead to patches on the posterior thighs,<sup>348</sup> and metal ballet balance bars may lead to hand dermatitis. Hand dermatitis may also be associated with nickel allergy, because nickel may be present in the metal handles of scissors, keys, doorknobs, and the wheels of skateboards. Nickel coins in the United States no longer contain nickel, but small amounts are present in coins from other countries, and reactions to coin rolling or after coin ingestion by young children have been described.<sup>349</sup> Patch testing for nickel sensitivity can be performed, but false negatives are not uncommon, and repeated testing may be helpful. If a substance is suspected of containing free nickel, application of a test solution of dimethylglyoxine in a 10% aqueous solution of ammonia (Allerderm Ni kit) to the suspected item will usually cause the suspected metal to turn pink.

Once the presence of hypersensitivity to nickel has been established, the hypersensitivity usually lasts for years. Patients must therefore be taught how to avoid contact with nickel objects through the use of proper substitutes. If possible, wearing clothes with nickel should be avoided, and substitution of pants with elasticized waists for jeans

with metal snaps and leather for metal belt buckles should be considered. Periodic coating of the offending metal with clear nail polish (including after each washing if laundered) may prevent loss of nickel, but sewing cloth over the nickel snap is not effective because sweating encourages nickel to leach through the fabric into contact with skin. In general, watches with stainless steel backs should be worn; application of an adhesive moleskin on the back of a watch may be helpful. Sterling silver or platinum jewelry is usually tolerated. Nickel-free eyeglass frames are available. The majority of inexpensive earrings contain some nickel,<sup>350</sup> so that individuals with the allergy should wear only surgical stainless steel earrings, "hypoallergenic" earrings with titanium (which looks like platinum), or earrings with plastic casings (Blomdahl, Simply Whispers). Vinyl gloves can be worn by patients who are sensitive to nickel in order to avoid hand contact with nickel. Midstrength to potent topical steroids can be used to treat a reaction, but avoidance of nickel is required for full efficacy. Dietary avoidance of nickel is difficult but has been recommended by some authors in patients with severe nickel-induced hand ACD and those with systemic contact dermatitis who do not respond to avoidance. Foods with high nickel content include canned foods, chocolate, cocoa, soy beans, cashews, almonds, oatmeal, legumes, and several fish and shellfish.

Chromates are an ingredient in the manufacture of many products such as cement, mortar, leather, paints, and anticorrosives. They are used in the dye of the green felt fabric used for pool tables and the yellow-green pigment of tattoos and cosmetics. Dichromates are used to toughen the collagen in leather and allow it to resist wear, water, and changes because of heat. Most contact reactions in children that are caused by chromates manifest as shoe dermatitis (see *Shoe Dermatitis* section).

Cobalt blue pigment is found in glass and pottery and used in the blue and green of watercolor paints and crayons. It is inextricably linked to nickel in metal-plated objects and costume jewelry, and it can be found in cosmetics, joint replacements, and cement. Oral administration of vitamin B<sub>12</sub>, which also contains cobalt, can cause intractable hand eczema, and injection may lead to dermatitis at the injection site in individuals who are sensitive to cobalt.

Allergic reactions to aluminum are probably not rare and develop most often from vaccination with Al-adsorbed vaccines, including those for diphtheria, tetanus, and pertussis; *Haemophilus influenza*; pneumococcus; hepatitis A and B; and human papillomavirus.<sup>351,352</sup> Children most commonly present with intensely itchy subcutaneous nodules or indurations localized to the site on the anterolateral thigh from 3 weeks to 4 years after the vaccination. Exacerbation of the itching may occur with intercurrent upper respiratory or GI tract infections, sometimes as a prodromal sign. These itchy indurated areas persist for a median duration of 4.6 years. In one study patch testing with aluminum showed reactivity in 95% of those affected, and almost 20% of these reported ACD after exposure to Al-containing deodorants, cosmetics, sunscreens, emollients, and buttons.<sup>352</sup> Other contactants that contain aluminum are Al-precipitated pollen extracts used for allergen-specific immunotherapy, ear drops, and pigments used in tattooing. More than 90% of children with these reactive lesions had milder reactions after vaccines beyond infancy, suggesting that the value of continued vaccination outweighs the risk of avoidance of Al-adsorbed vaccines.

### Shoe Dermatitis

Shoe dermatitis is an extremely common form of contact dermatitis in childhood that usually results from rubber products, especially given the increasing trend for athletic shoes. It is commonly misdiagnosed as tinea pedis, a disorder that occurs uncommonly in children before puberty. In one study, more than 50% of children with foot dermatitis showed reactivity to suspected contact allergens.<sup>353</sup>

Shoe dermatitis usually begins on the dorsal surface of the base of the great toe. It may remain localized or spread to involve the dorsal surfaces of the feet and other toes. The thick skin of the plantar surfaces is generally more resistant but may demonstrate dermatitis over the sole, ventral surface of the toes, instep, or even the entire plantar surface that may be confused with juvenile plantar dermatosis or psoriasis. Erythema, lichenification, and in severe cases, weeping and crusting are typical, but the interdigital spaces usually are spared. In

contrast, maceration, scaling, and occasional vesiculation of the interdigital webs, particularly between the fourth and fifth toes, are usually seen with *tinea pedis*. Irritant dermatitis from friction and ill-fitting shoes may also sharply localize to the dorsal aspects of the toes.

Rubber components are the principal allergens<sup>354</sup>; these include accelerators (most commonly mercaptobenzothiazole but also thiuram, carbamate, and diphenylguanidine) and rubber antioxidants. Rubber accelerators facilitate the transformation of liquid rubber to solid. Several components of the approved patch-test kit in the United States test for rubber, including the carba mix, the black rubber mix, mercaptobenzothiazole, mercapto mix, and the thiuram mix (Table 3-5); however, additional testing should be performed if shoe dermatitis is suspected but an agent is not found in this standard kit, because it is not fully inclusive. Rubber is a common component of the insoles of shoes and particularly of box toes. Rubber cement may be used in joining show uppers, outer leather, and linings.

Individuals with rubber sensitivity may also react to exposure to pacifiers (perioral); wearing latex gloves or handling rubber bands or balloons (hand dermatitis); wearing underwear, swimwear and socks with elastic (especially if clothes are bleached; waist and inguinal areas); handling rubber handle grips (sweaty hands)<sup>355</sup>; wearing swim goggles (periorbital); using cosmetic applicators (face); and wearing adhesive bandages. In adolescent boys, penile contact dermatitis may result from wearing rubber condoms.

Neoprene is a form of rubber in which dialkyl thioureas are used to speed up vulcanization, making it tougher and more pliable for shaping. It is now widely used in sporting equipment, mouse pads and computer cases, wetsuits, athletic shoes, shin guards and other protective pads, orthopedic braces, leggings, and Halloween masks. Components of neoprene-containing items that cause ACD are diethyl thiourea (a dialkyl-thiourea that is not in the TRUE test) and p-tertiary (tert)-butylphenol formaldehyde resin in adhesive.<sup>356</sup>

Less commonly, chromates in leather and adhesives (colophony and p-tert-butylphenol formaldehyde resin) can cause foot dermatitis (Fig. 3-61). p-Tert-butylphenol formaldehyde resin has also recently been implicated in ACD from the foam padding of a bra.<sup>357</sup> The nickel in eyelets and arch supports should also be considered. Iatrogenic ACD also often occurs on the foot, particularly because of neomycin or bacitracin in topical antibiotics.<sup>358</sup> Hyperhidrosis and wearing of occlusive hosiery and shoes contribute to shoe-contact allergy by leaching out allergens and increasing their percutaneous penetration.

Patients with shoe sensitivity should avoid the offending allergen and control associated hyperhidrosis. Use of shoe substitutes depends on whether the reactivity is to rubber, chromates, or adhesives. Vegetable-tanned footwear is a substitute if reactivity is to chromates.

**Figure 3-61** Shoe dermatitis. The recalcitrance of this patient's dermatitis to potent topical steroids led to patch testing, which showed reactivity to p-tert-butylphenol formaldehyde resin (see Fig. 3-54), a component of the glue used in shoes. More commonly, shoe dermatitis is seen on the dorsal aspect of the feet and results from rubber products in shoes or chromates used to tan the leather.

Open sandals, unlined sewn leather moccasins (such as from L.L. Bean), wooden clogs, or plastic "jelly" sandals are other alternatives. In addition, polyvinyl shoes, although they increase the tendency to perspiration, commonly lack many of the potential sensitizers seen in regular shoes; Bass Weejuns loafers and vinyl tennis shoes may also be acceptable substitutes. Since the inner sole is a common source of contact sensitization, removal and replacement with cork insoles, Dr. Scholl's Air Foam pads, or Johnson's Odor-Eaters held in place with a non-rubber adhesive such as Elmer's glue, are often helpful.

The management of active shoe dermatitis, as in other eczematous disorders, is aided by the use of open wet compresses, topical corticosteroids, and antipruritic agents. Since hyperhidrosis is usually responsible for the "leaching" out of potential sensitizing agents, utilization of measures that minimize excessive perspiration of the feet is advisable. Athletic equipment can be lined with water-repellent canvas as an adjunct to the use of a protective sock or sleeve. The topical use of aluminum chloride, available as Drysol or Certain Dri, or tannic acid soaks (two teabags in 1 quart of water) once or twice weekly, often assist in the control of hyperhidrosis. Noncaking agents such as ZeaSORB powder dusted freely into shoes and hosiery not only tend to lessen perspiration but also may act as a mechanical barrier, thus limiting contact with potential allergens and irritants. When painful fissures are present, soaking the foot in water for 20 minutes at bedtime followed by the careful application of superglue or liquid adhesive into the fissured areas, the use of topical corticosteroids and emollient creams, and occlusion at night with plastic wrap or small plastic bags will hasten resolution and lessen discomfort. Barrier socks (Microair), which have three layers of fabric that provide a physical barrier and are breathable, have been helpful in decreasing reactions if exposure cannot be avoided.<sup>359</sup> Individuals with rubber allergy should wear vinyl rather than rubber gloves, and avoid bleaching clothes with elastic, and using rubber swim goggles, rubber headphones, and latex condoms.

### Dermatitis to Cosmetics and Topical Medications

The most common cosmetic agents causing ACD are lipsticks, antiperspirants, hair dyes with PPD, substances in commercial and home permanent wave formulations, lanolins, acrylics, nail lacquers, benzalkonium and ascorbic acid in contact-lens solutions, fragrances (perfumes), sunscreen components (particularly benzophenone and increasingly octocrylene), and a number of preservatives used in cosmetics and shampoos. These allergens are the most common triggers of ACD of the hands.<sup>360</sup> Because early use of cosmetics abets this problem, it is recommended that cosmetics be avoided in young children. Even "toy" cosmetics contain fragrance, particularly cinnamic aldehyde.<sup>361</sup> In many instances, the eyelids are affected not by cosmetics applied to the lids and lashes but by preparations applied to the scalp, face, and nails. Exposure to peppermint oil most commonly leads to perioral dermatitis.<sup>362</sup> Peppermint oil is found in cosmeceuticals, personal hygiene products (mouthwashes, toothpastes, and bath preparation), topical medications (cooling sensation), and food.

ACD is increasingly blamed on preservatives and vehicle components.<sup>363</sup> Methylchloroisothiazolinone/methylisothiazolinone (MCI/MI; Kathon CG)<sup>364</sup> or MI alone<sup>364</sup> is a preservative in baby shampoos, soaps, wet wipes, and protective creams. The dermatitis usually manifests on the face, perianal/buttock area, and/or hands and resists topical and oral antibiotics and corticosteroids. One study found that MCI/MI ranked third in positive patch-testing results in pediatric patients.<sup>365,366</sup> Lesions from MCI/MI on the buttock may be confused with baboon syndrome, which is characterized by well-defined symmetric erythema on the buttocks and sometimes on the upper thighs and axillae and usually related to oral drug ingestion.<sup>367</sup> Recent studies found that testing to higher concentrations of MCI/MI as well as to MI alone is necessary to detect ACD to MCI or MI.<sup>368</sup> However, the TRUE test tests for only the MCI/MI mix at lower concentration.

Another common cause of fingertip and facial dermatitis is CAPB, a surfactant contained in many no-tears shampoos and soaps, contact-lens solutions, and moist baby and facial wipes. CAPB reactivity has been found in 11.3% children who have undergone patch testing.<sup>322,369</sup>

Formaldehyde and formaldehyde releasers (such as quaternium-15, diazolidinyl or imidazolidinyl urea, bromonitropropanediol/bronopol,

and dimethylol dimethyl [DMDM] hydantoin<sup>363</sup> are other preservatives that may trigger contact allergy. A reaction to tosylamide/formaldehyde resin in nail polish is seen largely in female patients who paint their nails<sup>370</sup> but has been described in boys, including from application to the nails as a deterrent to nail biting.<sup>371</sup> Dermatitis tends to occur on the eyelids, cheeks, lips, chin and neck, rather than on the nails themselves. Although the incidence of lanolin sensitivity from emollients is low, lanolin and its derivatives may be present under many different names (e.g., wool wax, wool grease, and wool fat). Lanolin sensitivity should be suspected in children with AD who tolerate application of petrolatum but not the application of lanolin-containing emollients, such as Aquaphor or Eucerin.

In the United States, parabens (compounds containing p-hydroxybenzoic acid) are often added in low concentrations to creams, lotions, and cosmetics in an attempt to retard microbial growth; although possible allergens, they are weaker than other preservatives such as MCI/MI, CAPB, and formaldehyde/formaldehyde releasers. Thimerosal is an organic mercurial compound used as a preservative. It has largely been removed from vaccines but can be found in cosmetics, eye drops, and contact-lens solutions. Although positive patch testing to thimerosal may occur, reactivity is unlikely to be clinically relevant, and rates of sensitization will likely decline with the removal of thimerosal from many vaccines.<sup>372</sup> Although still in the TRUE test kit, the NACDG has removed thimerosal from their standard testing trays because of its low clinical relevance.

More than 5000 different fragrances are in use today, and the ingredient "fragrance" on a label represents a mixture of many. Reactivity to fragrance has been shown to increase with age.<sup>373</sup> Use of perfumes in adolescent girls has been associated with the "atomizer sign," the presence of primary dermatitis at the Adam's apple where the perfume is sprayed.<sup>374</sup> Deodorants can be triggers for ACD in the axillary vault and generally cause an eczematous dermatitis (see **Metal and Metal Salt Dermatitis** section); antiperspirants containing zirconium may produce allergic granulomatous reactions. If near the axillary area but not in the vault clothing and disperse dye is the most like cause of the reactivity (see **Clothing Dermatitis** section). Even baby washes and shampoos have fragrance as a component. "Unscented" or "fragrance-free" means that the product has no perceptible odor but does not necessarily mean devoid of fragrance chemicals, because it may just reflect the addition of masking agents. Furthermore, manufacturers are not required in the United States to list specific fragrances and often do not list essential oils and fragrances used for reasons other than aroma (e.g., preservatives, bisabolol, citrus oil). Testing to both fragrance mix and balsam of Peru captures 70% to 80% of fragrance allergies. True fragrance-free products are available.<sup>375</sup>

The most common allergy-containing fragrances are cinnamic alcohol and cinnamic aldehyde, which are among the eight components of the fragrance mix used in contact allergy testing. Cinnamic alcohol and cinnamic aldehyde are components of chewing gums, toothpaste, mouthwash, flavored lip balms, chewable vitamins,<sup>376</sup> detergents, soaps, and deodorants.<sup>377</sup> Other fragrances are used in perfumes, aftershaves, colognes, and even food flavorings. Reactions to fragrance mix were noted in 18% of 500 children in a recent study in the United Kingdom.<sup>314</sup>

Balsam of Peru (*Myroxylon pereirae* tree extract) is an oleoresin that may contain some of the fragrances in the fragrance mix as well as a range of other components (such as citrus peel, tea tree oil, benzoic acid, and others). Individuals who react to balsam of Peru may react to beeswax, colophony, various spices, turpentine, and coumarin. Balsam of Peru is found in many body washes, shampoos, and diaper-area salves. Its presence as a flavoring in citrus peel and spices (e.g., cinnamon, cloves, vanilla, nutmeg, paprika, and curry) has led to systemic contact dermatitis reactions to citrus products, spices, pickles, chocolate, wine, and colas<sup>378</sup>; avoidance of ketchup in affected children can lead to marked clearance of widespread, recalcitrant dermatitis.<sup>379</sup>

A variety of topical prescription and over-the-counter formulations are capable of producing contact and (at times) systemic contact reactions. Of these, ethylenediamine, benzocaine and its derivatives, topical antibiotics, and topical preparations with diphenhydramine are the most common. Topical application of diphenhydramine (such as in Caladryl) is generally frowned upon, because it reportedly could

cause sensitization and lead to a generalized reaction after systemic administration of diphenhydramine, but occurrence is exceedingly rare. In addition, application of over-the-counter topical antibiotics may cause contact dermatitis and may lead to worsening of cutaneous inflammation despite appropriate use. Neomycin sulfate has long been considered the most allergenic of the topical antibiotics, but bacitracin allergy is increasing in prevalence, and anaphylactic reactions to topical application of bacitracin have been described<sup>380</sup>; both are ingredients in "triple antibiotic" formulations. Although neomycin and bacitracin are not chemically related, both bacitracin and neomycin cosensitization may occur concurrently when topical antibiotics with both are applied. Fusidic acid is an antibiotic used topically outside the United States that can cause both ACD and anaphylaxis after topical application.<sup>381</sup> Recently, ACD to potassium peroxymonosulfate, used as a chemical shock treatment for hot tubs and swimming pools to clear the water, has been described.<sup>382</sup>

Ethylenediamine, a compound stabilizer seen in various topical creams, including with nystatin cream, cross reacts with certain antihistamines, among them hydroxyzine and promethazine hydrochloride. Ingestion of a cross-reacting oral antihistamine in an ethylenediamine-sensitive individual can cause generalized dermatitis<sup>383</sup>; systemic contact dermatitis may also occur from administration of hydroxyzine but without reactivity to ethylenediamine.

The trend of adolescents to hair streaking and dyeing and to henna tattoos has increased the exposure to dyes containing PPD. In addition to typical contact allergic dermatitis, these reactions to PPD may resemble erythema multiforme or vesicular erythema multiforme.<sup>384</sup> Because of the tendency to use PPD in the mixture to darken and increase the precision of design of the temporary henna tattoo, children may show ACD to PPD at any site of henna tattooing.<sup>317,385</sup> Henna itself is rarely a sensitizer. Concentrations of PPD as high as 17.5% have been found in henna-tattoo preparations despite the limit of 6% PPD allowed in hair dyes. Once sensitized to PPD after a henna tattoo, children not only have a lifelong potential reactivity to permanent oxidative hair dye<sup>386</sup> but also may show systemic contact dermatitis to components that cross react with PPD such as hydrochlorothiazide, sulfonamide medications, and ester anesthetics such as benzocaine.<sup>387</sup> PPD may also be a component of fur dyes, dark-colored cosmetics, inks, rubber products, and photographic supplies. PPD reactions in children may also occur because of "connubial dermatitis," in which a child is sensitized through contact with the product on a parent.<sup>322</sup>

ACD from topical corticosteroids has been increasing in incidence and should be considered when patients with dermatitis are worsening despite the application of topical steroids.<sup>388</sup> Sensitization can also occur from ophthalmic solutions and aerosolized inhaled corticosteroids.<sup>389</sup> Reactions to topical steroids can be anywhere, but typically those from ophthalmic solutions involve the conjunctivae, eyelids, and periorbital areas whereas ACD to inhaled steroids is usually on the face, sometimes with extension. Generalized eruptions may occur after systemic exposure to a cross-reacting steroid. Five groups of corticosteroids have been classified based on their chemical structures (A, B, C, D1, and D2) (Table 3-6). Sensitization to group A steroids (in over-the-counter hydrocortisone and oral prednisone) is highest (overall 5.72%).<sup>390</sup> Topical steroids can be screened by the ROAT on the forearm. Tixocortol pivalate, budesonide, and hydrocortisone 17-butyrate are used to test for allergy to topical corticosteroids, although the combination of tixocortol pivalate and budesonide detect almost 90% of the patients with corticosteroid allergies. Positive reactions to topical steroids may not be detectable until 5 days or more after patching. The majority of individuals who test positive to topical steroids have other positive patch tests as well, and it should be remembered that ACD may result from the excipient (e.g., preservative or penetration enhancer) or even the nickel from the tube, rather than the steroid itself.

### Adhesive Tape Dermatitis

Although most cutaneous reactions related to the wearing of adhesive tape are of a mechanical rather than contact sensitivity type, allergic reactions may be caused by the rubber compounds (rubber accelerators or antioxidants) that have been incorporated into the adhesive or the vinyl backing of the adhesive (Fig. 3-62). Dermicel (Johnson

**Table 3-6** Classification of Topical Corticosteroids Based on Chemical Structure and Cross Reactivity

Group A	Group B	Group C	Group D1	Group D2
Hydrocortisone acetate	Amcinonide	Desoxymethasone	Alclometasone	Difluoprednate
Methylprednisolone	Budesonide*	Dexamethasone	Beclomethasone	Hydrocortisone 17-butyrate*
Prednisolone	Desonide	Diflucortolone	Betamethasone dipropionate	Prednicarbate
Tixocortal pivalate*	Fluocinolone Fluocinonide Halcinonide Triamcinolone	Fluocortolone Halometasone	Betamethasone 17-valerate Clobetasol Diflorasone Fluticasone Mometasone	

\*Used to test reactivity.

**Figure 3-62** Tape contact dermatitis. Note that this patient did not react to the cloth Band-Aid (left), but rather to the larger tape (right).

& Johnson), Steri-Strips, or Micropore surgical tape (3M Company), nonrubber acrylate, and spray-on Band-Aids are helpful for those individuals allergic to or irritated by ordinary adhesive tapes.

### Clothing Dermatitis

Although nonspecific irritation from fabrics, rubber, dyes, and cleaning solutions is not uncommon, ACD caused by true sensitization to fabrics is occasionally seen in childhood. Permanent press and crease-resistant fabrics have been responsible for many cases of contact dermatitis because of the use of formaldehydes and formaldehyde-releasing preservatives. Of textiles, blended cottons, corduroy, silk, and rayon have the highest concentrations of formaldehyde, whereas polyester has the least. In a recent survey of 65 children suspected of having contact dermatitis, 7.5% reacted to formaldehyde and 3.8% to each of the listed formaldehyde-releasing preservatives.<sup>322</sup> This type of dermatitis is more likely to occur in individuals whose clothes are tight-fitting and close to the skin. The inner thighs, axillary lines, and popliteal fossae are particularly susceptible.

Dermatitis attributable to dyes in wearing apparel such as school and athletic uniforms is increased from clothing dyed black or dark blue (because the concentration of dyes in dark clothing is much

higher than that of dyes in light-colored clothing, and dark colors tend to bleed more readily than dyes of lighter hue). Disperse dyes may be used in patch testing, but the garment can also be directly applied for patch testing. Children may also react to the epoxy resin in the adhesive holding a knee patch onto jeans and elastic or rubber waist bands in underwear in which the rubber components are leached out after exposure to bleach.

### Compositae Dermatitis

Compositae is one of the largest plant families (10% of the world's flowering plants) and includes among its members chrysanthemum, ragweed, artichoke, sunflower, lettuce, spinach, chamomile, gingko, feverfew, parthenium, and dandelions. Contact allergy to compositae is well recognized in florists, gardeners, and farmers but only occasionally occurs in children.<sup>391</sup> Bisabolol, a compositae derivative, is a component of moisturizers and has been implicated in pediatric ACD.<sup>392</sup>

# Papulosquamous and Related Disorders

## Childhood Psoriasis

Psoriasis is a relatively common immune-mediated disorder that accounts for 4% of all dermatoses seen in children under 16 years of age and occurs overall in 0.5% to 0.8% of pediatric patients with a linear increase in prevalence by age from 0.2% at 2 years to 1.2% at 18 years.<sup>1-5</sup> Psoriasis rarely is present at birth.<sup>6</sup> Approximately one-third of adults with psoriasis noted the onset during the first 2 decades of life. As in the adult population, psoriasis occurs most often in Caucasian children.<sup>4</sup> The severity of the condition may vary from a life-threatening neonatal pustular or exfoliative dermatosis to a mild, localized disorder that causes no distress. Psoriasis usually follows an irregularly chronic course marked by remissions and exacerbations of unpredictable onset and duration.

Both complex genetic and environmental factors participate in the risk of psoriasis. Approximately 30% of pediatric patients have an immediate family history of psoriasis,<sup>7</sup> and the risk of occurrence in monozygotic twins is two to three times that of dizygotic twins.<sup>8</sup> The major genetic determinant is *PSOR1* (35% to 50% of patients), which is within the major histocompatibility complex on chromosome 6.<sup>9</sup> Early-onset psoriasis has been linked to human leukocyte antigen (HLA) antigen Cw6, and 73.7% of patients with guttate psoriasis show HLA Cw6 antigen, in contrast to a rate of 7.4% in the general population. Autosomal dominant mutations in caspase recruitment domain family member 14 (*CARD14*) or *PSOR2* also lead to a psoriatic<sup>10</sup> (or pityriasis rubra pilaris [PRP]) phenotype. At least 35 additional susceptibility loci for psoriasis have subsequently been identified at other chromosomal locations, among them genes regulating T-cell function, especially interleukin (IL)-23 function, tumor necrosis factor (TNF) activation, nuclear factor (NF)-κB signaling, T-helper (Th) 2 cytokines, interferon (IFN)-mediated antiviral responses, and macrophage activation.<sup>11</sup>

Evidence that psoriasis is an immune-mediated disorder is also based on the success of targeted therapy, such as cyclosporine and inhibitors of TNF; IL-12, -23, and -17; and their receptors. The majority of T cells in psoriatic plaques are CD45RO+ memory-effector T cells that migrate into skin exposed to an antigenic trigger. Th1 and Th17 cytokines predominate, in contrast to the largely Th2 cytokine response of the acute lesions of atopic dermatitis.<sup>12</sup> The innate immune system plays a key role in psoriasis, initiating a cascade that involves activation of myeloid dendritic cells by TNF-α, IFN-γ, IL-6 and IL-1β. The activated dendritic cells express IL-12 and IL-23, leading to Th1 and Th17 cell expression of TNF-α/IFN-γ and of IL-17/IL-22, respectively. These cytokines stimulate the keratinocytes to produce more IL-1β and IL-6, TNF-α, chemokines, and antimicrobial peptides, further contributing to immune activation and cutaneous inflammation.<sup>13</sup> Skin injury and streptococcal infections<sup>14,15</sup> are well-known environmental triggers, but the occurrence of psoriasis has also been linked to *Staphylococcus aureus* infection<sup>16</sup> and Kawasaki disease,<sup>17</sup> suggesting a role for superantigens. Psoriasis has been triggered by administration of growth hormone therapy, IFN (e.g., for chronic hepatitis), and other drugs (particularly, lithium, β blockers, antimalarials, and sodium valproate).<sup>18</sup> Flares of psoriasis have also clearly been linked to psychological and physical stress.

## CLINICAL MANIFESTATIONS

Classic lesions of psoriasis consist of round, brightly erythematous, well-margined plaques covered by a characteristic grayish or

silvery-white (mica-like, or “micaceous”) scale.<sup>19-21</sup> Psoriatic papules coalesce to form plaques that measure 1 cm or more in diameter (Figs. 4-1, 4-2, and 4-3). The disorder may present as solitary lesions or countless plaques in a generalized distribution. Lesions are usually bilaterally symmetrical with a distinct predilection for the scalp, elbows, knees, and lumbosacral and anogenital regions. However, lesions may also be found in a flexural distribution with involvement of the axillae, groin, perineum, central chest, and umbilical region. This variant, termed *inverse psoriasis* (Figs. 4-4 and 4-5), may be seen without any extensor surface involvement in 2.8% to 6.0% of patients or in association with only regional involvement in 30% of patients. Lesions may also be limited to the palms (Fig. 4-6) and soles (Fig. 4-7, A).<sup>22</sup> A peripheral white ring is often the first sign of involution (termed a *Woronoff ring*). However, when the central portions of the plaques resolve, the involuting lesions may appear nummular (small circles), annular (central clearing) (Fig. 4-7, B), gyrate, or arcuate (semicircular). A linear variant that courses along the Blaschko lines has also been described<sup>23</sup> and may be associated with psoriatic arthritis.<sup>24</sup>

The hallmark of psoriasis is the micaceous scale that is generally attached at the center rather than the periphery of lesions. Removal of this scale results in fine punctate bleeding points. This phenomenon (termed the *Auspitz sign*) is highly characteristic and relates to rupture of capillaries high in the papillary dermis of lesions. The Koebner phenomenon (an isomorphic response) is commonly seen in psoriasis (Fig. 4-8) but also in verrucae, *Rhus* dermatitis, lichen planus, lichen nitidus, Darier disease, and PRP. This valuable diagnostic sign of psoriasis describes the occurrence of skin lesions at sites of local injury such as after irritation (a scratch or sunburn) (Fig. 4-9), a surgical scar, or a preexisting disease such as seborrheic or atopic dermatitis. The Koebner phenomenon likely is responsible for psoriasis of the diaper region and around enteral feeding tubes.<sup>25</sup>

## Facial Psoriasis

Facial psoriasis is more common in children than in adults and occurs without other involvement in 4% to 5% of patients. Involvement of the periorbital area is most typical (Fig. 4-10), and lesions may be subtle, leading to confusion with atopic dermatitis (Fig. 4-11). The plaques of psoriasis tend to be more clearly delineated than patches of atopic dermatitis, are less pruritic, and may show an annular configuration. It should be noted, however, that approximately 5% of pediatric patients show an eczema/psoriasis overlap, either showing typical lesions of both atopic dermatitis and psoriasis or lesions that are intermediate (e.g., nummular and psoriasisiform).<sup>26</sup> Almost all patients with the overlap have a family history of both atopic disease and psoriasis. Although mucosae do not tend to be affected in psoriasis, geographic tongue is an often unrecognized feature of psoriasis in many children (Fig. 4-12).

## Guttate Psoriasis

Seen in up to 44% of pediatric patients, guttate psoriasis generally occurs in children and young adults and is often the first manifestation of psoriasis.<sup>8</sup> Lesions are drop-like (guttate), round or oval, measure from 2 mm to 6 mm in diameter (Figs. 4-13 and 4-14), and generally occur in a symmetrical distribution over the trunk and proximal aspects of the extremities (occasionally the face, scalp, ears, and distal aspects of the extremities). Guttate psoriasis is often, but not necessarily, triggered by group A streptococcal infection of the oropharynx or perianal area.<sup>20,27</sup> Two-thirds of patients with guttate psoriasis give a history of an upper respiratory tract infection 1 to 3 weeks before the

**Figure 4-1** Psoriasis. Typical plaques of psoriasis with thick, micaceous scale overlying erythema.

**Figure 4-3** Psoriasis. Psoriasis often involves the forehead, particularly contiguous to the scalp. Note the eyelid and brow involvement. Given the yellowish scaling, this has been called "sebopsoriasis."

**Figure 4-2** Psoriasis. Variably sized erythematous plaques with moderately thick overlying scale.

onset of an acute flare of the disorder.<sup>28</sup> Although guttate psoriasis may clear spontaneously (Fig. 4-15), 40% of affected children progress to the plaque type,<sup>29</sup> which may ultimately be more severe psoriasis than in children with plaque disease initially.<sup>20</sup>

### Scalp Psoriasis

The scalp is commonly the initial site of psoriatic involvement (20% to 40%), and scalp psoriasis occurs more often in affected girls than boys,<sup>20</sup> perhaps because the Koebner phenomenon associated with combing, brushing, and vigorous shampooing. Most typical are well-demarcated erythematous plaques with thick, adherent silvery scales similar in appearance to those on other parts of the body (Fig. 4-16). However, psoriatic lesions of the scalp, eyebrows, and ears (the superior and postauricular folds and external auditory meatus) may instead be greasy and more salmon-colored, suggesting a diagnosis of seborrheic dermatitis. In this variant, often termed *sebopsoriasis*, lesions may present with features of both seborrhea and psoriasis. Whereas lesions of seborrheic dermatitis generally remain within the hairline, lesions of psoriasis often extend beyond the confines of the hairline onto the forehead (see Fig. 4-3), preauricular, postauricular, and nuchal regions. Rapid response to therapy further distinguishes seborrhea from psoriasis. Another scaling disorder of the scalp that may be a variant of psoriasis is pityriasis amiantacea (asbestos-like) (Fig. 4-17)<sup>30</sup>; the alternative term, *tinea amiantacea*, should be abandoned, because the disorder is unrelated to dermatophyte infection. The disorder more commonly occurs in pediatric patients without other signs of psoriasis and is characterized by large plates of scale

**Figure 4-4** Psoriasis. Discrete, brightly erythematous plaques of inverse psoriasis in a 3-year-old boy. Note that the scaling tends to be thinner in an intertriginous area.

**Figure 4-5** Psoriasis. In contrast to the relative sparing of the glans in the toddler in Figure 4-4, this boy's psoriasis of the genital region involved only the glans.

**Figure 4-6** Psoriasis. Annular plaques on the elbow. Note the central clearing, leaving hyperpigmentation.

firmly adherent to the hair and scalp. Focal hair loss and secondary infection may be associated. Pityriasis amiantacea usually begins in school-aged children and adolescents and progresses to more typical psoriasis in 2% to 15% of pediatric patients. Pretreatment of affected scalp areas with fluocinolone 0.01% oil daily and then shampooing with a keratolytic shampoo is usually effective.

### Diaper-Area Psoriasis

Psoriatic diaper rash (see Fig. 2-27) with or without dissemination is the presenting manifestation in 13% and 4% of patients, respectively.<sup>26</sup> This form of psoriasis must be differentiated from infantile seborrheic dermatitis (see Chapter 3) and, when localized to the diaper area, other forms of diaper dermatitis (see Chapter 2). The sharply defined plaques, bright-red coloration, shininess, and larger, drier scales of psoriasis help to differentiate it from seborrheic dermatitis. Many infants with diaper-area psoriasis also show psoriasisiform lesions elsewhere (Fig. 4-18). Because of the increased moisture of the occluded diaper region, scale may not be visible clinically but can be revealed by scraping the area gently. The incidence of psoriasis in the diaper area during infancy probably reflects the Koebner phenomenon, triggered by trauma from exposure to stool and urine, and resolves when toilet trained. Nevertheless, boys and girls out of diapers may also show genital area involvement. Of prepubertal girls with a genital region complaint, 17% had psoriasis<sup>31</sup> particularly involving the vulva, perineum, and natal cleft.

### Nail Involvement

Although statistics vary, the nails appear to be affected in 25% to 50% of pediatric patients with psoriasis, more commonly during the second decade of life and in males<sup>20</sup> (Figs. 4-19, 4-20, and 4-21). Pitting is most characteristic, manifesting as small, irregularly spaced depressions measuring less than 1 mm in diameter. Larger depressions or punched-out areas of the nail plate may also be noted. These pits are thought to represent small intermittent psoriatic lesions in the nail matrix region that forms the superficial layers of the nail plate. Psoriatic pitting may be indistinguishable from nail pitting seen in alopecia areata (see Chapter 7) and atopic dermatitis (see Chapter 3), although other features assist in differentiating these disorders. Discoloration, onycholysis (separation of the distal and lateral nail plate edges), and subungual hyperkeratosis (lifting of the nail plate with nail thickening) (see Fig. 4-21) are also commonly seen. Secondary bacterial, candidal, and occasionally dermatophyte infections occur with increased incidence.

### Other Forms of Psoriasis

Pustular psoriasis and erythrodermic (exfoliative) psoriasis are the most severe variants of childhood psoriasis<sup>32,33</sup> but occur in only approximately 1% of pediatric patients with the disease.<sup>8</sup> Pustular psoriasis has been described as early as the first week of life.<sup>34,35</sup> It usually occurs as generalized pustular psoriasis, but can be limited to the palms and soles (pustulosis palmaris et plantaris) or to fold areas.<sup>36</sup>

**Figure 4-7** Psoriasis. Involvement of the psoriasis on the palms (**A**) and soles (**B**).

On previously quiescent psoriatic plaques or normal skin, erythematous halos develop and rapidly become studded with superficial pinpoint-sized up to 2- or 3-mm pustules (Fig. 4-22). The lesions of generalized pustular psoriasis in children show an annular morphology in 60% of patients (Fig. 4-23).<sup>34,37</sup> Sheets of erythema and pustulation can involve the flexures, genital regions, webs of the fingers, and periungual areas.<sup>38</sup> The cutaneous inflammation typically progresses in an explosive manner from discrete sterile pustules to crusts and ultimately to generalized exfoliative dermatitis. More than 90% of the skin shows intense erythema, massive exfoliation, and associated abnormalities of temperature and cardiovascular regulation. The nails often become thickened or separated by subungual lakes of pus. Mucous membrane lesions in the mouth and tongue are not uncommon. Fever, malaise, and anorexia are typically associated with

**Figure 4-8** Psoriasis. This patient shows the Koebner phenomenon, with development of a linear plaque of psoriasis after trauma to the arm.

**Figure 4-9** Psoriasis. Sunburn on the upper chest and neck led to a flare in an adolescent previously in excellent control.

**Figure 4-10** Psoriasis. Eyelid involvement is often mistaken for atopic or contact dermatitis.

generalized pustular psoriasis. Affected children may show failure to thrive. Patients with extensive pustular or erythrodermic psoriasis usually require hospitalization, and courses are not uncommonly complicated by cutaneous infection and bacterial septicemia. The disease is cyclic and associated with complete clearance of the pustular phase and unexplained exacerbations that span decades. Relapses are common and become progressively more severe, often with a poor prognosis. In contrast to the occurrence of pustular psoriasis in adults known to have psoriasis, pustular psoriasis is often the first manifestation of psoriasis in affected infants and children. The predominant histologic feature on biopsy is the large intraepidermal unilocular pustule containing polymorphonuclear leukocytes (the spongiform

**Figure 4-11** Psoriasis. Facial psoriasis most commonly involves the periorbital area, but more extensive facial involvement can occur.

**Figure 4-12** Psoriasis. Geographic tongue can be seen as the most common mucosal manifestation of patients with psoriasis.

**Figure 4-13** Guttate psoriasis. Tiny guttate (tear-drop) plaques after a streptococcal infection.

pustules of Kogoj) with little if any surrounding spongiosis or inflammation. Although staphylococcal infection may at times occur as a secondary complication, lesions are usually sterile.

Pustular psoriasis with its onset during infancy may be localized to the neck fold.<sup>36</sup> The disorder is often misdiagnosed as dermatitis

**Figure 4-14** Guttate psoriasis. Erythematous, scaling plaques on the leg that measure less than 1 cm in diameter.

**Figure 4-16** Scalp psoriasis. Thick, discrete scaling overlying erythema on the scalp.

**Figure 4-15** Guttate psoriasis. These small hypopigmented macules are the postinflammatory residual lesions of guttate psoriasis.

**Figure 4-17** Pityriasis (tinea) amiantacea. In this severe form of psoriasis of the scalp the scales are strongly adherent (asbestos-like).

**Figure 4-18** Psoriasis in an infant. In addition to diaper area involvement, this infant showed disseminated plaques of typical psoriasis.

caused by bacterial or candidal infection (Fig. 4-24). Biopsy facilitates making the diagnosis, particularly given that many lesions clinically appear more papular than pustular. Other fold areas may be affected, and dissemination to generalized pustular psoriasis is not uncommon.

Pustulosis palmaris et plantaris (pustulosis of the palms and soles) is a bilaterally symmetric, chronic pustular eruption on the palms and soles characterized by deep-seated 2- to 4-mm sterile pustules that develop within areas of erythema and scaling. Plaque or pustular psoriasis may be seen elsewhere on the body. Within several days the pustules resolve and leave a yellow-brown scale that is generally shed

**Figure 4-19** Nail psoriasis. Several fingers show severe onycholysis with oil spots and nail pitting, accentuated where the pits trapped old nail polish. Having just a few nails involved is common.

**Figure 4-20** Nail psoriasis. Note the trachyonychia or rough longitudinal striations, sometimes called "sandpapered" nails (see Chapter 7).

**Figure 4-21** Nail psoriasis. Extensive subungual hyperkeratosis in a teenager. Note the isolated small plaque on one finger.

within 1 or 2 weeks. Phases of quiescence and exacerbation are characteristic, and exfoliating crusted lesions may be seen concurrently with newly developing pustules.

Psoriasis-like pustules during the neonatal period or in infancy, often in association with sterile multifocal osteomyelitis or periostitis,

**Figure 4-22** Pustular psoriasis. Collections of small pustules, some with an annular configuration, overlying bright erythema.

**Figure 4-23** Pustular psoriasis. Note the annular configuration of the pustules.

**Figure 4-24** Localized pustular psoriasis in an infant. In infants, pustular psoriasis may be localized to intertriginous areas, particularly the neck fold, and be confused with dermatitis or infection. This form is difficult to treat and may eventuate in generalized pustular psoriasis.

should raise the possibility of inappropriate activation of IL-1 family cytokines (IL-1 and IL-36) from biallelic mutations in IL-1 or IL-36 receptor antagonists. Pustules may be widespread or grouped and more localized. Deficiency of IL-1 receptor antagonist (DIRA) also may feature joint swelling and pain, oral stomatitis, and pyoderma

gangrenosum, especially during childhood.<sup>38–40</sup> Most neonates with DIRA are born prematurely. Deficiency of IL-36 receptor antagonist (DITRA) is the major cause of generalized pustular psoriasis in patients without common psoriasis.<sup>41–43</sup> DITRA has been described in babies and is characterized by irritability, tender skin, diarrhea, dysphagia, and failure to thrive in association with their pustular psoriasis and/or exfoliative erythroderma. Neutrophilia and thrombocytosis are common, but other organs are not involved.<sup>44</sup> The early onset, and poor response to standard therapy are clues to diagnosis. Skin biopsies in DIRA and DITRA show features similar to those seen in pustular psoriasis.<sup>45</sup> Pediatric patients often respond rapidly to subcutaneous administrations of anakinra 2 to 4 mg/kg per day.<sup>44</sup>

Pustules overlying erythroderma can also be a feature of patients with mutations in *CARD14*, which typically has its onset during infancy or early childhood. More commonly, however, patients with *CARD14* mutations often show signs of recalcitrant plaque-type psoriasis or PRP (see Pityriasis Rubra Pilaris section) and respond rapidly to ustekinumab.

Pustular psoriasis may also present after infancy in association with sterile lytic lesions of bone (sometimes called *chronic recurrent multifocal osteomyelitis* [CRMO]) as part of several syndromes.<sup>46</sup> CRMO in association with congenital dyserythropoietic anemia and neutrophilic dermatoses comprises Majeed syndrome, an autosomal recessive disorder caused by mutations in *LPIN2*.<sup>47</sup> Synovitis, acne, pustulosis, hyperostosis, osteitis (SAPHO) syndrome (see Chapter 8) describes the constellation of synovitis, acne, palmoplantar pustulosis and psoriasis, hyperostosis, and osteitis and usually affects the bones of the lower limb, pelvis, and clavicle.<sup>48,49</sup> The bone and joint lesions can severely impact quality of life but may respond to immunosuppressive medications such as methotrexate and aggressive intervention for the acne with isotretinoin.<sup>50</sup>

## Comorbidities

The most common comorbidity of pediatric psoriasis, as in affected adults, is obesity, which tends to precede the onset of psoriasis by at least 2 years in the majority of affected children.<sup>51,52</sup> Several studies have confirmed the association of pediatric psoriasis and obesity.<sup>53–56</sup> Being overweight (“excess adiposity,” between the 85th and 95th percentiles in body mass index [BMI]) or obese (95th percentile or greater BMI) occurs in pediatric psoriasis with an odds ratio (OR) of 2.65 (95% confidence interval [CI], 1.70 to 4.15) globally and OR of 4.22 (CI, 2.05 to 8.67) in the United States,<sup>7</sup> and the association with excess adiposity is seen regardless of psoriasis severity. However, waist circumference percentile and waist-to-height ratio, which are both better indicators of metabolic risk than BMI percentile, are only increased in children with moderate to severe psoriasis.<sup>7</sup> Early evidence suggests that aggressive therapy for psoriasis does not lead to weight or waist circumference reductions.<sup>7</sup>

Increasing evidence suggests an association with early cardiovascular disease in affected children, as has been noted in adult psoriasis. Pediatric psoriasis is associated with approximately two to four times the rate of comorbidity from hyperlipidemia, hypertension, and diabetes than unaffected children and adolescents.<sup>55</sup> In a study of 20 US children with psoriasis, metabolic syndrome (as defined by having at least three of the following: high triglycerides, high density lipoprotein cholesterol, fasting blood glucose, waist circumference percentile, and blood pressure) occurred in 30% with psoriasis but 5% of the control group ( $p < .05$ ).<sup>57,58</sup> These data suggest that early intervention with lifestyle modification and possibly systemic anti-inflammatory therapy may decrease the long-term metabolic risk for these children. Although results have been controversial, a recent study showed significant improvement in the psoriasis and quality of life in overweight adult psoriasis patients on a low-calorie weight loss diet for 8 weeks.<sup>59</sup>

Joint pain has been described in approximately 10% of US children with moderate to severe psoriasis,<sup>7,53</sup> suggesting that inquiry about pain, joint swelling, or limping, as well as examination of the joints for arthritis should be part of the routine evaluation. Psoriatic arthritis is now considered a form of juvenile idiopathic arthritis, and criteria have been established by the International League of Associations for Rheumatology (ILAR).<sup>60–63</sup> These include arthritis with psoriasis or arthritis and: (1) a family history of confirmed psoriasis in a parent or sibling; (2) dactylitis;<sup>64</sup> or (3) nail pitting or onycholysis.<sup>64</sup> The

diagnosis is excluded if the patient has a positive rheumatoid factor titer or signs of systemic disease (daily fever, evanescent erythematous eruption, generalized adenopathy, hepatomegaly or splenomegaly, or serositis). The occurrence of pediatric psoriatic arthritis is biphasic. Younger children affected by psoriatic arthritis tend to be female with dactylitis and small-joint involvement that is more likely to progress and persist. The swelling often includes the juxtaarticular tissue, resulting in a blunt “sausage-shaped” appearance of the involved fingers or toes. Progression to polyarthritis occurs in 30%, leading to flexure deformities and severe bone destruction (osteoporosis, shortening and tapering of the involved distal phalanx) with longstanding disease. On radiologic examination, this resembles a sharpened pencil (the so-called “pencil-in-cup” or “pencil-and-goblet” deformity) at the metatarsophalangeal and metacarpophalangeal joints. Arthritis in older children is characterized by more enthesitis and axial joint disease.<sup>60</sup> Psoriatic skin lesions occur in approximately 60% of children with psoriatic arthritis, are identical to those seen in patients who do not manifest joint disease, and are not related in severity to that of the joint disease. Either skin disease or arthritis may develop initially, and in most patients flares of joint and skin disease do not correlate.

Pediatric patients with moderate to severe plaque psoriasis have demonstrated significantly impaired physical, emotional, social, and school functioning in comparison to healthy children<sup>65</sup> on par with children who have arthritis or asthma and to a greater extent than children with diabetes.<sup>66</sup> In one study, 65% of children with psoriasis experienced stigmatization and 43% complained about fatigue.<sup>67</sup> Pediatric patients with psoriasis have a higher risk of developing psychiatric disorders, especially depression<sup>68</sup> and anxiety.<sup>69</sup>

The risk of developing Crohn disease (but not ulcerative colitis) is also higher in pediatric psoriasis.<sup>55</sup> Asymmetric anterior uveitis of psoriasis has been described in 14% to 17% of children with juvenile psoriatic arthritis. The cutaneous lesions of psoriasis may develop several years after the onset of persisting uveitis.<sup>70</sup>

## DIAGNOSIS OF PSORIASIS

The diagnosis of psoriasis can usually be made clinically, although biopsy can be performed if the diagnosis is in question. Biopsy sections show epidermal thickening (acanthosis with elongation of the rete ridges), retention of nuclei in the stratum corneum (parakeratosis), and a mononuclear infiltrate. Focal collections of neutrophils in the stratum corneum or subcorneal layer (Munro’s microabscesses) are an additional feature in biopsies from patients with pustular psoriasis.

## COURSE

Most patients have long-term mild to moderate disease, often with plaques confined to areas of frictional trauma such as the elbows, knees, buttocks, and scalp. The course of psoriasis, however, is unpredictable, ranging from spontaneous remissions to frequent exacerbations without an evident trigger. Although sunlight generally is beneficial and often leads to improvement during the summer, sunburns can elicit the Koebner phenomenon and lead to exacerbation. With appropriate therapy, satisfactory control of the disease is possible in a majority of patients.

## DIFFERENTIAL DIAGNOSIS

Guttate psoriasis and plaque psoriasis are most commonly confused with dermatitis as well as other papulosquamous disorders described in this chapter, especially pityriasis rosea or pityriasis lichenoides chronica (PLC) (Box 4-1). PRP is the hardest to differentiate, especially when involved areas are largely the palms, soles, elbows, and knees. The follicular accentuation, focal areas of sparing, and sometimes more salmon coloration of PRP can help to distinguish the conditions clinically; biopsy sections of PRP may show perifollicular inflammation. A plaque-type psoriasisform eruption and less often a generalized or annular pustular psoriatic eruption may follow Kawasaki disease (see Chapter 21).<sup>71–73</sup> Generalized and localized forms of pustular psoriasis can be differentiated from infectious causes of pustulosis by cultures and from noninfectious conditions such as eosinophilic

### Box 4-1 Differential Diagnosis of Psoriasis

#### Guttate and Plaque Psoriasis

Pityriasis rubra pilaris  
Pityriasis rosea  
Pityriasis lichenoides chronica  
Psoriasisform dermatitis  
Lichen planus  
Drug eruptions  
Widespread dermatophytosis

#### Facial Psoriasis

Discoid lupus erythematosus  
Seborrheic dermatitis

#### Scalp Psoriasis

Tinea capitis  
Seborrheic dermatitis

#### Nail Psoriasis

Trauma  
Onychomycosis  
Lichen planus

#### Diaper Area Psoriasis

Seborrheic dermatitis  
Irritant dermatitis  
Candidal diaper dermatitis

#### Pustular Psoriasis

Staphylococcal pustulosis  
Candidal pustulosis  
Herpes simplex infection  
Acute generalized exanthematous pustulosis (viral, drug)  
Extensive eosinophilic folliculitis  
Interleukin-1 receptor antagonist deficiency  
Palmpoplantar pustular psoriasis  
Candidiasis  
Infantile acropustulosis

#### Erythrodermic Psoriasis

Extensive pityriasis rubra pilaris  
Congenital ichthyosiform erythroderma  
Erythrokeratoderma variabilis

folliculitis or infantile acropustulosis by biopsy. Psoriasisform dermatitis may also be seen in boys with immune dysregulation, polyendocrinopathy, enteropathy, or X-linked (IPEX) syndrome (see Chapter 3). Atypical cases of psoriatic arthritis must be differentiated from other types of juvenile idiopathic arthritis or systemic lupus erythematosus.

### Therapy of Pediatric Psoriasis

Education is a key component of psoriasis therapy. Patients and parents must understand the chronicity of the disorder and the tendency in 38% of pediatric patients for spontaneous remissions lasting for variable periods.<sup>74</sup> Most patients respond well to available therapies, but the response is slower than with dermatitis.<sup>75-81</sup> The therapeutic approach should be simplified and tailored to the individual patient to optimize compliance, because therapy is time consuming. Patients and family members of the patient should understand the rationale for treatment and any potential risks. Older children and adolescents should be empowered to maintain their own therapeutic routine with parental guidance. The concept that injury to skin may exacerbate psoriasis (Koebner phenomenon or isomorphic response) should also be explained (Table 4-1). Removal of potential trigger factors, including medications and rapid intervention for streptococcal infection should be explored.

#### Topical Therapy

The topical therapies most commonly used in children include topical corticosteroids, topical calcineurin inhibitors, vitamin D<sub>3</sub> analogues

**Table 4-1** Prevention of Psoriasis in Pediatric Patients

Site of Potential Psoriasis	Preventative Behavior
Creases and folds	Minimize friction by maintaining appropriate weight Avoid irritating underarm deodorants
Face	Avoid irritating soaps and burning from exposure to ultraviolet light
Genital and perianal regions	Avoid irritation from tight garments and exposure to accumulated feces and urine
Hands and feet	Minimize excessive sweating and exposure to irritants such as harsh soaps Avoid tight shoes
Nails	Avoid long fingernails or toenails, trauma to nails in play situations, excessive use of nail polish and remover, and wearing tight shoes Hydrate nails before trimming and avoid manipulation of cuticles
Scalp	Avoid vigorous brushing, combing, or scratching of scalp

**Table 4-2** Topical Treatments for Psoriasis in Children

Medication	Use in Children	Potential Side Effects and Comments
Emollients	Useful in mild disease; adjunct	None
Topical steroids	First-line therapy	Local side effects: atrophy, striae Systemic side effects: impaired growth, adrenal suppression, cataracts, tachyphylaxis
Tar	Thicker plaques	Irritation, staining, folliculitis
Salicylic acid	Thicker plaques; usually compounded with steroids ± tar	Irritation
Anthralin	Short contact application	Irritation; less staining than tar
Calcitriol or calcipotriene	Usually adjunct with steroids	Irritation
Tazarotene gel	Usually adjunct with steroids	Irritation
Tacrolimus/pimecrolimus	Face, intertriginous areas	Burning with initial applications

(calcipotriene and calcitriol), tar preparations, and anthralin (also called *dithranol*; short-contact therapy) (Table 4-2). Emollients are important adjunctive measures to decrease associated scaling and dryness but do not replace medications that treat inflammation. The mainstay of treatment for plaque psoriasis remains topical corticosteroids (see Chapter 3, Table 3-2), which often produce dramatic resolution of lesions as monotherapy. Application up to twice daily of class II–IV (potent to midpotency) topical steroids is required to improve lesions on the trunk and extremities. Ointments tend to penetrate the psoriatic scale better and are preferred. If individual thick plaques fail to respond, a course of ultrapotent topical steroid ointment (such as clobetasol, halobetasol, or augmented betamethasone) can be initiated but should be restricted to 2 weeks of application because of the risk for developing striae (especially in the preadolescent/adolescent

population) and local atrophy with continued use. "Weekend therapy" regimens combine class I steroids (used on weekend days only) and topical calcipotriene/calcitriol and should be administered by a dermatologist familiar with the use of these regimens.<sup>82</sup> Keratolytic agents to enhance penetration, such as 6% salicylic acid, are often compounded into steroid ointment with or without tar. The keratolytic applied alone (e.g., Keralyt gel), occlusion, or steroid-impregnated tapes are alternative treatments for more hyperkeratotic, resistant lesions. Use of halogenated midpotent to potent steroids should be avoided in the diaper area, intertriginous areas, and on the face. Topical calcipotriene/calcitriol and tacrolimus ointment, combined or as monotherapy, are steroid-sparing alternatives. Once the acute lesions are under control, treatment can be tapered to lower potency steroids and/or emollients.

Tar is a time-honored and effective adjunct to the topical treatment of psoriasis that is both anti-inflammatory and antiproliferative. Tar (in the form of 1% to 10% crude coal tar or 5% to 10% liquor carbonis detergents) can be compounded into preparations with topical steroids and/or salicylic acid and applied overnight or before ultraviolet light exposure. Tar as a single agent is available in several over-the-counter preparations (e.g., Estar gel, Fototar). Tar preparations, however, stain skin and clothing, have an odor that is often objectionable to children and adolescents, and increase the risk of developing folliculitis. Tar may also be administered in the form of a tar bath (e.g., Cutar bath oil, Doak Oil Forte, Balnetar) or foam.

An alternative to tar therapy is short-contact anthralin therapy, formulated in a temperature-sensitive vehicle that releases the active medication at skin-surface temperature.<sup>83,84</sup> Anthralin, also called *dithranol*, is applied for 5 minutes initially with gradually increasing times of exposure as tolerated and needed for efficacy. Discoloration of skin or clothing is significantly less than that with tar therapy. Contact with the face, eyes, and mucous membranes should be avoided.

Calcipotriene (cream, ointment or solution) and calcitriol (ointment) are most effective when combined with topical steroids but serve as steroid-sparing agents that may be efficacious in children as monotherapy as well.<sup>85,86</sup> These vitamin-D<sub>3</sub> analogues are best applied twice daily, but the onset of action is slow (often 6 to 8 weeks). Combination therapy of betamethasone (0.064%) and calcipotriene (0.005%) ointment is also available.<sup>87</sup> Irritant dermatitis, particularly on the face and intertriginous areas, occurs in up to 20% of patients.

The topical retinoid tazarotene is available in 0.05% and 0.1% strength creams and gels. Tazarotene is best applied once a day in combination with once-daily application of a medium to potent topical steroid, but even with the topical steroid it is often too irritating for use in childhood psoriasis.

Calcinurin inhibitors, particularly tacrolimus ointment 0.1%, are useful with twice-daily application for 1 to 2 months for facial and intertriginous psoriasis.<sup>88</sup> Although not found to be useful outside of the facial and intertriginous areas in double-blind trials in adults, topical tacrolimus ointment is sometimes useful outside of these areas for childhood psoriasis.

### Treatment of Scalp Lesions

Psoriatic scalp lesions are a frustrating and sometimes recalcitrant component of psoriasis. Topical corticosteroids may be applied in the form of oils, solutions, or foams, and calcipotriene solution may be steroid-sparing. Clobetasol and fluocinolone shampoos are also available. Removal of scales can be facilitated by softening scales through application of oil-based medications. For example, fluocinolone 0.01% oil under shower cap occlusion can be applied for 1 hour to overnight to the wet, affected scalp and should be followed by washing with shampoos containing tar, steroid (0.01% fluocinolone or clobetasol), zinc, or keratolytic agents. Alternatively, a phenol and saline (Baker Cummins P&S) solution with a shower cap for occlusion can be applied overnight. In the morning, the patient can shampoo and then apply a steroid foam or solution if needed. Many patients will apply a second shampoo after the medicated shampoo and use a conditioner after shampooing.

### Treatment of Nail Psoriasis

Psoriatic nails are extremely distressing to the patient, respond slowly to therapy, and are difficult to treat topically because of the failure of

topical agents to penetrate the nail plate. Instillation of class-I steroid solutions into the subproximal nailfold area can be successful, especially applied under occlusive tape at night, but application nightly of flurandrenolide-impregnated tape (Cordran) to the base of the nail for approximately 6 months tends to yield better results. Injections of triamcinolone suspension (10 mg/mL) into the nailfold of the abnormal nail with a 30-gauge needle every 4 to 6 weeks is painful, even with the use of topical anesthetic creams and should be reserved for the motivated older child or adolescent who fails to respond to topical application. Nightly application of tazarotene 0.05% or 0.1% gel under occlusion, if tolerated, has been shown to cause improvement.<sup>89</sup> Use of topical indigo naturalis oil extract has recently been described.<sup>90</sup> Disfiguring nail psoriasis that is unresponsive to topical measures may respond to systemic intervention (generally methotrexate or a biologic medication), but the decision to start a systemic medication must be carefully weighed.

### Compresses for Pustular Psoriasis

Local applications of wet dressings with Burow solution 1:40 or potassium permanganate 1:5000 (one crushed 65 mg tablet into 250 mL of water) often help relieve acute flares of the pustular aspect of palmoplantar or generalized pustular psoriasis.

### Ultraviolet Light

Most patients with psoriasis benefit from exposure to sunlight and accordingly are often better during the summer months. However, sunburn precautions must be taken with sunscreens, avoidance during hours of most intense sunlight, and sun-protective clothing, because sudden overexposure may result in sufficient epidermal injury to cause exacerbation of the disorder. For those who can arrange exposure to sunlight on a regular basis, this can be an important aspect of therapy alone or in combination with topical therapies. Although natural sunlight is easier for children and less aggressive than artificial ultraviolet therapy, ultraviolet treatments under professional supervision may also be used as therapy,<sup>91-96</sup> especially when psoriasis involves more than 10% to 20% body-surface area, involves the palms and soles, and/or is recalcitrant to topical therapy.<sup>93</sup> Response to phototherapy is enhanced by preexposure application of oil or ointment.<sup>92</sup> Narrow-band ultraviolet B (nbUVB) ( $\approx$ 311 nm) has a higher ratio of therapeutic-to-toxic wavelengths than broadband UVB light (290 to 320 nm) and is considered at least as efficacious. More than 90% of children treated with nbUVB improve by more than 75%.<sup>97-99</sup>

The UVB light is best initiated in a light box at a dermatology office as outpatient therapy. Once patients and parents know how to increase the doses of ultraviolet light gradually, judge the effects of the daily treatment, and practice preventive eye care, home light-box therapy can be initiated. Home light boxes are ultimately less invasive to the mainstream activities of a family and may be more cost-effective than in-office therapy, although careful monitoring is required. In general, ultraviolet light therapy is started at 70% to 75% of the minimal erythema dose and increased by about 10% to 20% with each treatment as tolerated. A minimum of three treatments per week is required to clear psoriasis. Although rarely used in young children, phototherapy may be administered to young children who are accompanied by parents in the light unit. Tricks such as use of singing together or listening to a radio or compact disc (CD) player with earphones can be used to distract the child during treatment. Acutely, UVB therapy is associated with skin darkening, a chance of skin burning, and, not uncommonly, early pruritus. Although long-term data are lacking in children with psoriasis, recurrent exposure to UVB light could theoretically increase the long-term risk of the development of skin cancer and premature aging.

The excimer laser ( $\approx$ 308 nm) is fiber-optically targeted UVB light that can treat localized plaques of psoriasis without exposing normal skin to unnecessary radiation. Although its use in children has been limited,<sup>93,100</sup> it is painless and offers safety advantages over nbUVB therapy.<sup>101,102</sup> Psoralens and ultraviolet A (PUVA) light (320 to 400 nm) are used rarely in children because of the ocular toxicity, generalized photosensitivity, and the risk of later development of actinic changes and cutaneous carcinomas<sup>103</sup>; topical application of the psoriasis with UVA is a safer alternative but rarely needed.

Protective eyewear must be worn for 24 hours after each PUVA exposure because of the risk of cataract development. The use of topical PUVA light in a hand/foot box has proven effective in adolescents and older children with psoriasis of the hands and feet.

### Systemic Therapy

Oral medications for treating psoriasis have potentially harmful side effects and should be reserved for children with erythrodermic and pustular forms of psoriasis or for those with moderate to severe plaque-type psoriasis recalcitrant to topical therapies.<sup>104,105</sup> In general, systemic corticosteroids should be avoided. Although occasionally effective, steroids are often ineffective or lead to flares of psoriasis when withdrawn, including triggering of pustular psoriasis. Especially in guttate psoriasis, examination for the possibility of pharyngitis or perianal cellulitis should be performed, and culture for β-hemolytic streptococci obtained as appropriate. Antibiotics should be prescribed if the culture is positive, although recurrent positive cultures may signal a carrier state. Although important for treating streptococcal infections, trials of antibiotic therapy are usually not helpful.<sup>106</sup> Some pediatric patients with refractory psoriasis have been shown to improve after tonsillectomy for the treatment of chronic and recurring streptococcal infection.<sup>15,107–109</sup> A recent study showed that 86% of adult patients who underwent tonsillectomy showed sustained improvement (30% to 90%) 2 years after the procedure in contrast to the unchanged status of control patients. Clinical improvement correlated with reduction in circulating keratin peptide-reactive skin-homing (CLA+) T cells (which also recognize cross-reacting streptococcal M proteins), suggesting that the tonsils generate the T cells recognizing these determinants.<sup>15</sup>

The various systemic medications that are available for treating moderate to severe psoriasis are shown in Table 4-3. Methotrexate is indicated for severe unresponsive psoriasis, exfoliative erythrodermas, pustular psoriasis,<sup>93,110</sup> nail psoriasis, and psoriatic arthritis. It is occasionally used for nail psoriasis if nonsystemic agents are ineffective. Methotrexate has antimitotic, antichemotactic, and anti-inflammatory activities. After appropriate screening tests (blood

counts, hepatic testing, purified protein derivative [PPD] or Quantiferon gold for tuberculosis) and testing for pregnancy in female patients of childbearing age, oral methotrexate is initiated at an oral dosage of 0.3 mg/kg per week, and can be increased to 0.6 mg/kg per week if needed for efficacy.<sup>104,111,112</sup> The upper limit in children is usually 20 mg/week. If methotrexate is not efficacious orally, a trial of subcutaneous weekly administration can be undertaken, especially in obese children requiring higher dosing. Methotrexate assays can be performed to determine if a dosage increase is needed in children who respond inadequately after 12 weeks.<sup>113</sup>

The most common side effects are nausea, abdominal discomfort, fatigue, headaches, and anorexia. The most significant side effect is bone marrow suppression. Administration of folic acid diminishes the risk of nausea, mucosal ulcerations, and macrocytic anemia.<sup>114</sup> The dosage is 1 mg/day (may skip the day of methotrexate administration) or 5 mg/week (day after methotrexate). Switching to subcutaneous administration also reduces gastrointestinal complaints. In young children, one chewable multivitamin contains about 400 µg folic acid. Although optimal dosing of folic acid has not been determined, a common practice is to administer the folic acid on the 6 days when methotrexate is not given, because it antagonizes the efficacy of the methotrexate. Liver and bone marrow function should be monitored by blood testing, but testing should not be in the 72 hours after methotrexate administration when transaminases may be transiently elevated. Obese children may have hepatic steatosis and a higher risk of transaminase abnormalities. Liver biopsy is unnecessary in children, and overall hepatic toxicity is rare. Live vaccines such as measles, mumps, and rubella (MMR), poliovirus, and intranasal influenza vaccines may not be given to a child taking weekly methotrexate. Sulfa drugs, including trimethoprim/sulfamethoxazole (Bactrim), should be avoided while taking methotrexate. Improvement is sometimes seen by as little as 3 weeks after initiation of treatment but more commonly requires 10 weeks. Once clearing is achieved, the methotrexate should be gradually lowered (e.g., 2.5 mg/month) during the subsequent months.

Cyclosporine has been used in young patients with severe unresponsive psoriasis, exfoliative erythrodermas, or pustular psoriasis.<sup>104,115</sup> Its

**Table 4-3** Treatment of Pediatric Psoriasis with Phototherapy and Systemic Agents

Intervention	Baseline Labs	Dosing	Follow-Up Tests	Potential Side Effects and Comments*
Methotrexate	CBC, LFTs; TB testing	0.3–0.6 mg/kg/wk	Monthly CBCs, LFTs for first 6 months and then every 3 months; annual TB testing	GI toxicity, fatigue most common; bone marrow suppression and hepatotoxicity
Cyclosporine	CBC, LFTs, BUN, Cr, Mg <sup>++</sup> ; TB testing	3–5 mg/kg/d; can go higher based on drug trough levels	BP checks; monthly CBCs, LFTs for first 6 months and then every 3 months; annual TB testing	Renal and hepatic toxicity, hypertension, hypertrichosis, immunosuppression, UVB-induced skin cancer
Acitretin	CBC, LFTs, fasting lipids	0.5–1 mg/kg/d	CBC, LFTs, fasting lipid levels; pregnancy testing as appropriate	Cheilitis, hyperlipidemia, musculoskeletal pain, hair loss, skin fragility, bone toxicity if used long-term, teratogenicity
TNF inhibitor: etanercept	TB testing required; optional CBC, LFTs	0.8 mg/kg sc injection weekly (max 50 mg)	Annual TB testing; other testing controversial	Increased risk of mycobacterial infection and possibly lymphoma
TNF inhibitor: adalimumab	TB testing required; optional CBC, LFTs	24 mg/m <sup>2</sup> sc every 2 weeks	Annual TB testing; other testing controversial	Increased risk of mycobacterial infection and possibly lymphoma
TNF inhibitor: infliximab	TB testing required; LFTs; optional CBC	3.3–5 mg/kg IV at 0, 2, 6, then every 7–8 wks	Annual TB testing; LFTs every 3 months	Increased risk of mycobacterial infection and possibly lymphoma; rarely used for psoriasis unless need very rapid intervention
Ustekinumab	TB testing required; optional CBC, LFTs	0.75 mg/kg baseline, 4 wks, every 12 weeks; usually 45 or 90 mg	Annual TB testing; other testing controversial	Increased risk of mycobacterial/ <i>Salmonella</i> infection and possibly lymphoma

BP, Blood pressure; BUN, blood urea nitrogen; CBC, complete blood count; Cr, creatinine; GI, gastrointestinal; HIV, human immunodeficiency virus; IV, intravenous; LFTs, liver function tests; Mg, magnesium; MMR, measles, mumps, and rubella; sc, subcutaneous; TB, tuberculosis; TNF, tumor necrosis factor-alpha; UVB, ultraviolet B.

\*All interventions below other than phototherapy and acitretin are immunosuppressive. If suggested by history or examination, undertake baseline hepatitis A/B/C and/or HIV testing. Before starting any immunosuppressive agent, vaccinations should be up-to-date. Live and live attenuated vaccines should be avoided; among common ones are varicella, MMR, intranasal influenza. Systemic medications are all potential teratogens. See text for more details.

mechanism of action involves inhibition of cytokine production by T lymphocytes. Cyclosporine is usually initiated orally at a dosage of 4 to 5 mg/kg per day (and 3 mg/kg per day if microemulsion) and maintained for 3 to 4 months followed by gradual downward titration and discontinuation within a year of initiation. The dosing can be increased if trough cyclosporine levels prove to be low. The potential complications are hypertension, renal and hepatic toxicity, and hypertrichosis; however, concerns about future leukemias, lymphomas, cutaneous carcinomas, and other oncogenic risks are heightened with childhood use. Live vaccines (e.g., MMR and poliovirus) cannot be used in patients receiving cyclosporine therapy. Patients must also avoid macrolide family medications (e.g., azithromycin) because they can markedly increase cyclosporine levels.

Retinoids tend to be less effective than methotrexate or cyclosporine as a single agent for treating plaque-type psoriasis but can be quite effective for exfoliative erythrodermas and for pustular psoriasis that does not respond to compresses and topical corticosteroids alone.<sup>116</sup> Oral retinoids are often used more successfully in combination with topical ointments, ultraviolet light treatment, methotrexate, or cyclosporine. Acitretin normalizes epidermal differentiation and has an anti-inflammatory effect. The usual regimen is oral administration at a dosage of 0.5 to 1 mg/kg per day, although the dosage can be titrated depending on patient response and laboratory results.<sup>82</sup> Complications related to retinoid usage are most commonly dryness of the skin and mucous membranes and elevation of serum triglyceride levels. The potential for skeletal toxicity (premature epiphyseal closure and hyperostosis), although rare, must be monitored clinically and if appropriate radiographically during infancy, childhood, and puberty in patients who receive retinoids long term. Screening tests include blood counts, fasting lipid profiles, and hepatic studies. Retinoids cause severe teratogenicity and should be used with caution in adolescent girls. Isotretinoin may be an alternative retinoid for female adolescents with pustular psoriasis because of its much more rapid clearance but generally it is not as effective as acitretin.

Dimethylfumarate, a fumaric acid ester, is an immunosuppressant available outside of the United States for treating moderate to severe psoriasis. In a retrospective study of 14 pediatric patients (median age at onset, 15 years), only 36% of patients were nonresponders and 36% showed complete clearance.<sup>117</sup> Severe diarrhea and flushing were the causes of discontinuation in two patients, although transient mild elevation in liver function testing or leukopenia were noted in 36% of the children.

Biologic agents are highly effective, but as with all systemic immunosuppressant medications, are not currently approved by the US Food and Drug Administration (FDA) for pediatric psoriasis (although etanercept is approved for use in pediatric psoriasis in several other countries). Currently available biologic agents inhibit either TNF- $\alpha$  (adalimumab, etanercept, infliximab) or IL-12/IL-23 (ustekinumab).<sup>118</sup> Most of the use of biologic agents for psoriasis in pediatric patients has involved TNF inhibitors. Of the TNF inhibitors, etanercept has been used the most in children, including in infants.<sup>119–123</sup> Etanercept is also the only agent tested in a double-blind, randomized trial in US children.<sup>53,124</sup> In this trial of 211 pediatric patients with moderate to severe plaque type psoriasis, 57% achieved 75% improvement by 12 weeks of therapy with 0.8 mg/kg etanercept; only 11% of patients treated with the vehicle control achieved this degree of improvement. However, etanercept is given weekly, whereas adalimumab requires dosing every other week and has been shown to be more efficacious than etanercept in adults, leading to the pediatric use of adalimumab by many physicians, especially in adolescents. Ustekinumab administration has only been described in a few anecdotal reports for treating severe pediatric psoriasis<sup>125,126</sup> but may be the optimal therapy for CARD14-related psoriasis and PRP.

Weighted average psoriasis area and severity index (PASI)-75 scores in adults with moderate to severe psoriasis after 12 weeks of treatment in placebo-controlled studies were 78.6% for infliximab, 72.1% for ustekinumab, 70.5% for adalimumab, 48.1% for etanercept, and 21% for alefacept,<sup>127</sup> suggesting greater efficacy for adalimumab and ustekinumab than etanercept. Similarly, a meta-analysis showed adalimumab and ustekinumab to have similar efficacy and also greater efficacy than etanercept, cyclosporine, methotrexate, and fumaric acid.<sup>128</sup> Nevertheless, multiple factors need to be considered in making

the choice of systemic agent, including patient preference, cost, tolerance, adverse effects, dosing schedule, and mode of administration. Of importance, biologic agents are also considerably more costly than methotrexate, which is a major deterrent to their use. The mean annual cost for TNF inhibitors for adults in the United States is approximately \$15,000 for etanercept, \$18,000 for adalimumab, and \$24,000 for infliximab.<sup>129</sup> Although primarily used for plaque psoriasis, TNF inhibitors have led to improvement for recalcitrant palmoplantar pustulart<sup>130</sup> and erythrodermic<sup>131</sup> psoriasis. TNF inhibitors can show loss of efficacy with time; in adults the 4-year drug survival for etanercept or adalimumab is approximately 40%.<sup>132</sup> Should a TNF inhibitor lose its efficacy, switching to an alternative TNF inhibitor (or a different class of medication) can significantly improve psoriasis severity.<sup>133</sup>

The long-term risks of biologic therapy in children are unknown, although to date serious acute adverse events are rare. Patients may be at risk for mycobacterial and *Salmonella* infections<sup>134</sup> and baseline intermediate strength purified protein derivative (PPD) or quantiferon gold with annual reevaluation is recommended; the need to obtain baseline and follow-up levels of other laboratory tests (e.g., blood counts and liver function tests) in children is controversial. Adverse effects on the development of the immune system in young children and an increased risk of lymphoma are theoretical concerns.

### Development of Psoriasis and Psoriasiform Dermatitis During Administration of Tumor Necrosis Factor Inhibitors

Just as psoriatic arthritis can develop in children with psoriasis who are administered a TNF inhibitor, children taking biologic agents for indications other than psoriasis can develop psoriasis or psoriasiform dermatitis.<sup>135–137</sup> Occurring most often in children treated for Crohn disease, this seemingly paradoxical inflammatory cutaneous response has also been described in children with juvenile idiopathic arthritis, hidradenitis suppurativa, or Behcet syndrome. The psoriasis from TNF inhibitors favors the scalp, periorificial skin, nails, dorsal aspect of hands and feet (Fig. 4-25), and often the palms and soles, where it can be pustular. Lesions are not uncommonly secondarily infected with *S. aureus*. The eruptions are described after a wide range of duration of treatment, ranging from one dose to up to 63 months. Its occurrence in no way affects the response to the biologic agent for the original indication, and the risk of occurrence is not reduced by concurrent administration of methotrexate. The mechanism for the development of psoriasis despite suppression by TNF inhibition remains unclear. Cytokine imbalance with increased expression of IFN, known to increase risk of psoriasis in chronic active hepatitis, has been proposed.<sup>138</sup> Patients with Crohn disease who developed psoriasis on infliximab were more likely to have homozygous *IL-23R* polymorphisms, suggesting a genetic tendency.<sup>135</sup> An infectious trigger, particularly streptococcal or staphylococcal infection, has been suggested as well.

**Figure 4-25** Psoriasiform eruption induced by tumor necrosis factor (TNF) inhibitor on the dorsal aspect of the hands.

Optimal management has not been assessed for children. The literature largely describes affected adults, approximately half of whom respond to discontinuation of the original TNF inhibitor. However, the original indication is usually good control for children taking these TNF inhibitors, so families resist the idea of changing therapy. Trying topical therapy alone is warranted before considering an alternative systemic regimen. Initiation of methotrexate<sup>139</sup> or ustekinumab<sup>140</sup> are other therapeutic options.

### THERAPY FOR PSORIATIC ARTHRITIS

Many patients with psoriatic arthritis require only nonsteroidal anti-inflammatory drugs, maintenance of joint position, functional splinting, and physiotherapy. The combination of methotrexate and a biologic agent is now most commonly used for more recalcitrant cases. Occasionally arthroscopic synovectomy or joint replacement is required.

### PSYCHOSOCIAL AND EDUCATIONAL SUPPORT

Psoriasis affects the family as well as the child. Caregivers of the children often experience anxiety and/or depression related to the child's psoriasis.<sup>141</sup> The National Psoriasis Foundation ([www.psoriasis.org](http://www.psoriasis.org)) is available as a support group for patients and families of patients and provides superb educational material about psoriasis.

## Reactive Arthritis

Reactive arthritis (formerly called *Reiter syndrome*) most commonly occurs in young men between 20 and 40 years of age<sup>142</sup> but has been described in children as young as 9 months of age. It has been reported in almost 100 children, usually boys.<sup>143</sup> In affected adults, reactive arthritis usually occurs after sexually transmitted infection, particularly *Chlamydia*, or gastrointestinal infection and has been associated with human immunodeficiency virus (HIV) infection.<sup>142</sup> In children, it usually develops after an acute enteric infection, particularly one caused by *Shigella flexneri*, *Salmonella typhimurium*, or *Yersinia*. Diarrhea is initially present in 90% of affected children but in only one-third of adults with this disorder. Fever, anorexia, weight loss, and malaise may be other early signs. Several weeks may pass between the onset of fever and diarrhea and the clinical findings of reactive arthritis.

The classic triad of reactive arthritis includes nonbacterial conjunctivitis, urethritis, and arthritis. However, the complete triad is rarely seen at onset, may take several weeks to develop, and is incomplete in the majority of affected children. Conjunctivitis is the most common ocular manifestation and occurs overall in 50% of children. It tends to be bilateral, is self-limited with clearance in weeks, and ranges in severity from mild injection to mucopurulent inflammation. Acute, painful anterior uveitis, iritis, keratitis, corneal ulceration, and optic neuritis have rarely been described. The arthritis typically is asymmetric and involves more than one joint, most commonly large weight-bearing joints, such as the hip, knee, and ankle. However, other large or small joints can be affected, and involvement occasionally is symmetric. In contrast to the pattern in affected adults, the sacroiliac joint is rarely involved in pediatric cases. Many children also show enthesitis, a typical feature of reactive arthritis characterized by focal tenderness at sites where ligament and tendon insert into bone. The arthritis and enthesitis tend to resolve after a few months but occasionally persist or recur. The urethritis in children is usually asymptomatic, and detection of sterile pyuria may be the only evidence of urethral inflammation. Less commonly, inflammation of the meatus may be clinically detectable or urethral discharge may be noted.

The cutaneous manifestations of reactive arthritis may develop in association with, or independently of, the other features of the disorder. Most classic are the circinate balanitis/vulvitis and keratoderma blennorrhagica. The circinate balanitis/vulvitis occurs in 15% to 75% of affected children<sup>144,145</sup> and presents as well-defined erosions on the glans penis in uncircumcised males and on the vulva in females; circumcised male patients often show inflamed hyperkeratotic plaques on the shaft and scrotum. The keratoderma blennorrhagica occurs in

**Figure 4-26** Keratoderma blennorrhagicum, showing thickened, psoriasisiform papules and plaques on the foot of a patient with reactive arthritis. (Reprinted with permission from Schachner LA, Hansen RC, editors. Pediatric dermatology. Edinburgh: Mosby; 2003: Fig. 15.16.)

8% to 25% of children<sup>143,144</sup> and appears as psoriasisiform scaling, inflammatory papules, pustules, and plaques on pressure or weight-bearing areas of the palms and soles (Fig. 4-26).

Psoriasisiform papules and plaques have also been described on the extensor surfaces of the extremities and the dorsal aspects of the feet and hands. Oral lesions consist of painless erythema, shallow erosions, and small pustules that may occur on the buccal mucosa, gums, lips, palate, and tongue. Oral lesions generally resolve spontaneously after a period of several days. Lesions on the tongue, particularly when thickly coated, may simulate a geographic tongue. Nail changes resembling psoriasis have also been seen.<sup>146</sup>

Diagnosis of the disorder is made based on the constellation of clinical features and is supported by nonspecific laboratory findings. Rheumatoid factor is negative, but most affected children show HLA-B27 antigen. Sterile pyuria and significant elevation of erythrocyte sedimentation rate are usually found. Mild anemia with leukocytosis may be present as well. If performed early, stool cultures may yield the triggering bacterial organism. Although biopsy of the skin lesions may be helpful, it does not distinguish the cutaneous lesions of reactive arthritis from those of psoriasis. Reactive arthritis must be differentiated from other seronegative arthropathies, including psoriatic arthritis,<sup>147</sup> juvenile idiopathic arthritis, infectious arthropathies (especially gonococcal and Lyme disease), Kawasaki disease,<sup>148</sup> Behcet syndrome, and rheumatic fever.

Reactive arthritis is almost always self-limiting in children and clears without sequelae. A few children have died, but the prognosis in children is considered much better than that in adults.<sup>144</sup> A minority of children show recurrent or chronic arthritis. Treatment consists primarily of bed rest and administration of nonsteroidal anti-inflammatory drugs. The cutaneous lesions may respond to topical corticosteroids. Ophthalmologic consultation is appropriate for patients with ocular manifestations. Occasionally, intraarticular injection of corticosteroids or administration of systemic medication is required. Sulfasalazine, methotrexate, acitretin, cyclosporine, and infliximab<sup>149</sup> have been used for patients with severe, unresponsive disease.

## Pityriasis Rubra Pilaris

Pityriasis rubra pilaris (PRP) is a chronic skin disorder characterized by small follicular papules, disseminated yellowish-pink scaly plaques surrounding islands of normal skin, and hyperkeratosis of the palms and soles (Figs. 4-27 through 4-31). Small, follicular-based keratotic papules are an important diagnostic feature but are not always present. Although most pediatric cases are acquired without a family history of the disorder,<sup>150</sup> autosomal dominant PRP has been described in families<sup>151</sup> and is now known to result from activating mutations in *CARD14* (*PSORS2*), which encodes caspase recruitment domain family, member 14. *CARD14* is expressed by keratinocytes and activates NF- $\kappa$ B signaling.<sup>152</sup> Whereas the hereditary form tends to have an earlier onset and be persistent,<sup>151</sup> the sporadic forms of PRP show *CARD14* activation without mutation<sup>153</sup> and may be indistinguishable

**Figure 4-27** Pityriasis rubra pilaris. Symmetric, diffuse, well-circumscribed salmon-colored plaques representing the coalescence of follicular-based papules. The discrete papules can be seen at the borders. Note the “skip areas.”

**Figure 4-29** The keratodermic sandal of a patient with type IV pityriasis rubra pilaris.

**Figure 4-28** Pityriasis rubra pilaris. Note the well-circumscribed palmar erythema and keratoderma.

**Figure 4-30** Pityriasis rubra pilaris. Follicular scaling papules on the knee, a common site.

clinically and histologically from the hereditary form. Involvement of the cheeks and patterned lesions on the trunk are a feature sometimes seen with *CARD14* mutations (see Fig. 4-31).

PRP must be distinguished from psoriasis and disorders of cornification, especially the erythrokeratodermias; it is a rare manifestation of dermatomyositis.<sup>154</sup> Keratoderma of the palms and soles develops in the majority of affected children and can be present before or after the appearance of other features.<sup>155</sup> When seen on the soles, this has been referred to as a “keratodermic sandal” (see Fig. 4-29). The keratoderma shows a sharply demarcated border, sometimes extending to involve the dorsum of the hands and feet. The salmon color and associated edema help to distinguish the keratoderma from psoriasis, ichthyosis, hereditary palmoplantar keratoderma, and erythrokeratodermias (see Chapter 5). Thickening of the elbows, knees (see Fig. 4-30), ankles, and Achilles tendon (see Fig. 4-29) is seen in most

affected children.<sup>156</sup> The most characteristic clinical feature is the 1-mm follicular papule with a central keratotic plug that is often surrounded by salmon-colored erythema (see edges of coalescent scale, Fig. 4-27). Initially discrete, the papules usually coalesce into hyperkeratotic plaques with sharply marginated patches and thickened psoriasiform plaques with a coarse texture similar to the surface of a nutmeg grater. The plaques are generally symmetrical and diffuse and contrast sharply with islands of normal skin that occur within the affected areas. Despite their frequency in affected adults, the distinct follicular-based papules on the dorsal aspect of the fingers are found in a minority of affected children.<sup>155</sup>

More than 40% of pediatric patients show cephalic involvement, often extending from the face to the neck and onto the upper trunk in a cape-like configuration with sharp borders (see Fig. 4-27). Scalp

scaling may be extensive, with large, adhesive scales and underlying salmon-colored erythema. Although perioral and periorbital areas may show the keratotic papules and erythema, the mucosae are spared. Ectropion has been described in children with extensive PRP.

The nails are dystrophic in 13% of patients and can show thickening, onycholysis, transverse striations, and subungual debris (Fig. 4-32). The characteristic pitting of nails seen in psoriasis, however, is not a feature of this disorder. The Koebner phenomenon, a hallmark

**Figure 4-31** Individuals with mutations in *CARD14* may show changes of pityriasis rubra pilaris, sometimes with unusual patterning on the trunk.

**Figure 4-32** Unusual nail changes in a girl with extensive pityriasis rubra pilaris (PRP). Note the onycholysis and splinter hemorrhages. Her skin disease was more typical of PRP than psoriasis.

of psoriasis, has been described in approximately 10% of children with PRP. Pruritus is only occasionally a feature but may occur in children with diffuse disease.

The onset of PRP in children may be acute, as is more typical of adults, appearing and spreading during a few days. Alternatively, the eruption may begin on the scalp and forehead and extend gradually. Exfoliative, rapidly progressive dermatitis with associated malaise, chills, and fever is rarely described in children. Biopsy of a follicular-based papule can aid in diagnosis if it shows the characteristic follicular keratosis, as well as epidermal parakeratosis and dermal mononuclear infiltrates, particularly surrounding the hair follicle.

The disorder has been classified into five types based on the age of onset (types I and II in adults; types III–V in children) and clinical features (Table 4-4).<sup>157</sup> Of these, type IV PRP (juvenile circumscribed type) is the most common type in pediatric patients.<sup>158</sup> However, many pediatric cases cannot easily be fit into any of these classifications because of overlap. In addition, children may originally exhibit characteristics of one type that then evolve into another type. An alternative system of classification of five types has been proposed based on the presentation and courses in 104 children. This newer classification adds a new type I that shows only palmoplantar keratoderma without follicular plugging (20% of children), but combines Griffiths' types I and III into a single classification that includes all ages.<sup>155</sup>

The clinical course of PRP is variable. In a review of 29 pediatric cases, 52% showed clearance within 6 months (mean 2.7 months), and an additional 11% were symptom-free by 1 year after onset.<sup>158</sup> In another study of 30 children, 43% showed 90% to 100% clearing, an additional 23% showed at least 30% clearing, and 17% showed a poor outcome.<sup>159</sup> However, in a more recent study of 28 patients, two-thirds of patients with type III and IV juvenile PRP (i.e., most of the patients) had a protracted course lasting longer than 3 years.<sup>160</sup> The prognosis does not correlate with acute versus gradual onset or extent of involvement. The course at times is characterized by spontaneous remissions and exacerbations; some children have disease that evolves into a phenotype more typical of psoriasis than PRP.

Patients with PRP may respond to emollients, topical corticosteroids, tazarotene<sup>161</sup> and keratolytic agents (e.g., formulations containing urea, salicylic acids, or  $\alpha$ -hydroxy acid), particularly those with milder disease. Calcineurin inhibitor therapy may clear facial lesions.<sup>162</sup>

Nonresponders with more extensive disease are best treated with systemic retinoid therapy, which has been shown to be more effective in children than UVB light, methotrexate, cyclosporine, or azathioprine.<sup>159</sup> Adequate therapeutic trials of retinoids require at least 4 to 6 months and careful monitoring. Extensive extraspinal hyperostosis has been described in a child with PRP after long-term administration of oral retinoid therapy.<sup>163</sup> Given the self-limited nature of the disorder in many affected children, retinoids should be tapered and discontinued as tolerated after several months of continuous therapy. TNF inhibitors with or without retinoids have also been helpful in many patients.<sup>164,165</sup> Treatment with ustekinumab has also proven very effective for patients with recalcitrant PRP,<sup>166</sup> and given that IL-23 is an intermediate in the *CARD14*-induced NF- $\kappa$ B signaling pathway, may be the best choice for treatment of patients with *CARD14* activation.

**Table 4-4** Classification of Pityriasis Rubra Pilaris in Adults and Children

Type	Incidence	Clinical Features
I Classic adult	Most adults	Follicular keratotic papules, first on face and extending caudally; progresses to generalized keratoderma with islands of sparing; palms and soles usually involved; generally clears within 3 years
II Atypical adult	Rare	More ichthyosiform scaling; coarse palmoplantar keratoderma; long duration
III Classic juvenile	14% to 35% of children	Same as type I
IV Circumscribed juvenile	Most common type in children	Thick plaques on knees, elbows; palms, and soles involved
V Atypical juvenile	Rare, familial; onset in first years of life	"Sclerodermatos" changes on palms and soles; follicular hyperkeratosis

**Figure 4-33** Pityriasis lichenoides et varioliformis acuta. Symmetrical oval and round reddish brown macular, papular, necrotic, and crusted lesions on the chest of a 9-year-old boy.

## Pityriasis Lichenoides

Pityriasis lichenoides (formerly called *parapsoriasis*) is a spectrum of cutaneous eruptions that has been subdivided into two forms<sup>167</sup>: (1) an acute form, pityriasis lichenoides et varioliformis acuta (PLEVA, Mucha–Habermann disease); and (2) a chronic form, PLC. Overall, 19% to 38% of cases occur in pediatric patients,<sup>168,169</sup> occasionally during the first decade of life and even at birth.<sup>170</sup> Some children show clinical and/or histological features of both the acute and chronic forms, suggesting considerable overlap and confirming the concept that these groups represent a spectrum of disease. As a result, a newer classification is based on distribution into diffuse, central (neck, trunk, and extremities), and peripheral (acral) forms, rather than the morphology of lesions.<sup>171</sup> Acral involvement, including of the face, is more common in children than in adults, and the disorder persists longer before spontaneous remission in children as well.<sup>172</sup>

PLEVA is a polymorphous eruption that usually begins as asymptomatic to pruritic symmetrical 2- to 3-mm, oval or round, reddish-brown macules and papules. The papules occur in successive crops and rapidly evolve into vesicular, necrotic, and sometimes purpuric lesions (Fig. 4-33). These develop a fine crust and gradually resolve with or without a varioliform scar. Lesions may involve the entire body but are often most pronounced on the trunk, proximal thighs, and upper arms, especially the flexor surfaces. The face, scalp, mucous membranes, palms, and soles are often spared or may be involved to a lesser degree. Transient hypopigmentation or hyperpigmentation may result. The course usually lasts for periods of a few weeks to several months. Patients occasionally have associated fever and constitutional symptoms. A rare variant, the febrile ulceronecrotic form, is characterized by large, coalescing, ulceronecrotic nodules and plaques associated with high fever and arthralgias<sup>173,174</sup>; 50% of reported cases have been in children.<sup>175</sup> Febrile ulceronecrotic PLEVA may be associated with gastrointestinal, pulmonary,<sup>176</sup> and central nervous system<sup>177</sup> involvement.

PLC may begin *de novo* or may evolve from PLEVA; overall it affects 37.5% of pediatric patients with pityriasis lichenoides. The course of PLC is variable and may last for 6 months to several years. Lesions characteristically appear as scaling papules and plaques (Figs. 4-34 and 4-35) that resolve with dyspigmentation but no scarring.

In the early stages, pityriasis lichenoides may be mistaken for chickenpox, arthropod bites, impetigo, vesicular pityriasis rosea, vasculitis, or scabies; chronic forms may be confused with psoriasis, lichen planus, pityriasis rosea, and secondary syphilis. The duration of the eruption (often in crops), the presence of macules and papules interspersed with vesicular, crusted, or hemorrhagic lesions with or without varioliform scarring, and subsequent hypopigmentation or hyperpigmentation help to differentiate pityriasis lichenoides from other conditions. When the diagnosis remains in doubt, histopatho-

**Figure 4-34** Pityriasis lichenoides chronica. Small, erythematous papules with numerous residual macules of postinflammatory hypopigmentation.

**Figure 4-35** Pityriasis lichenoides chronica. Annular scaling plaques with associated hyperpigmentation in an African-American patient.

logic examination of a skin biopsy specimen will often substantiate the proper diagnosis, showing heavy mononuclear cell perivascular infiltration and, in more acute lesions, erythrocyte extravasation into the dermis, intraepidermal vesicle formation, and epidermal necrosis.

The cause of pityriasis lichenoides is unknown. However, studies demonstrating T-cell clonality<sup>178,179</sup> suggest that pityriasis lichenoides is a benign lymphoproliferative process in which a vigorous host immune reaction prevents the condition from evolving into lymphoma. The common temporal association of preceding exposure to viral infection, especially to parvovirus or human herpesvirus (HHV)-8,<sup>174,180,181</sup> or immunization, especially to MMR,<sup>182</sup> implicates an abnormal immune response to a viral antigenic trigger. These results

are consistent with rare reports of cutaneous T-cell lymphoma occurring in patients with clinical manifestations or a history of PLEVA or PLC.<sup>183–185</sup> CD30+ T cells in the biopsy specimens of a few patients with pityriasis lichenoides<sup>186</sup> shows overlap with lymphomatoid papulosis (see Lymphomatoid Papulosis section)<sup>180</sup> and suggests a spectrum of lymphoproliferative disorders from benign (PLEVA, PLC) to lymphomatoid papulosis to T-cell lymphoma.

Pityriasis lichenoides does not tend to improve with topical corticosteroids or oral antihistamines, although the associated pruritus may decrease. Children often show a partial to full response to administration of systemic antibiotics,<sup>168</sup> particularly erythromycin, azithromycin,<sup>187</sup> or tetracyclines. A recent study found a good response in 64% of children after 1 month but in 73% of patients by 2 months and 83% in 3 months, suggesting that a 3-month trial is appropriate.<sup>188</sup> If successful, antibiotics can be tapered, but continued administration at low to full dosage may be required for sustained clearance. Tetracyclines should not be administered to children younger than 8 years of age (depending on the status of eruption of secondary teeth) or to pregnant women. Ultraviolet light is the most effective therapy,<sup>189</sup> and most children show clearance in sun-exposed areas.<sup>190</sup> The improvement from exposure to ultraviolet light may also explain the common onset during autumn or winter months. Narrow-band ultraviolet light exposure is highly effective for pediatric patients who are unresponsive to antibiotics, do not have exposure to natural sunlight, and are significantly bothered by the pityriasis lichenoides.<sup>191,192</sup> Methotrexate,<sup>193</sup> cyclosporine,<sup>194</sup> and cyclophosphamide<sup>177</sup> have resulted in improvement in persistent cases but are only appropriate to consider for severely affected children such as those with the febrile ulcerocro-necrotic form.

## Lymphomatoid Papulosis

Lymphomatoid papulosis is a benign, recurrent, self-healing dermatosis with histologic features suggesting lymphoma.<sup>195–197</sup> It is considered to be within the spectrum of lymphoproliferative disorders that ranges from pityriasis lichenoides to cutaneous T-cell lymphoma and has been included as a separate group in classifications of lymphomas.<sup>198</sup>

The disorder is manifested by numerous reddish-brown papules or, less commonly, vesiculopustules that are most often noted on the trunk and proximal extremities but occasionally on the hands and feet, scalp, and genitalia (Fig. 4-36).<sup>199</sup> Regional distribution has been described in children, although more generalized spread may occur after several years.<sup>200</sup> Lesions characteristically develop hemorrhagic necrotic centers and crusting and gradually involute with residual hyperpigmentation or hypopigmentation. Occasionally, varioliform scars or large ulcerating nodules (Fig. 4-37), plaques, or nonulcerating papules occur. Although individual lesions evolve over a period of several weeks to 1 month or more, tend to appear in crops, and sometimes disappear spontaneously within a few weeks to months, the entire course of the disorder may be prolonged and last for years. The disorder is generally asymptomatic.

Lymphomatoid papulosis must be distinguished clinically and histopathologically from arthropod bites, PLEVA, pseudolymphoma, and lymphoma.<sup>201</sup>

The classic histopathologic picture of lymphomatoid papulosis in children is characterized by a heavy infiltrate of scattered large CD30+ CD15- cells that resembles Hodgkin disease in a background of inflammatory cells (type A), although variants resembling mycosis fungoides (type B), anaplastic large T-cell lymphoma (type C), and mixtures of these lymphomas have been described.

In 10% to 20% of adult patients, malignant lymphoma develops, and adults with lymphomatoid papulosis are also at increased risk for developing nonlymphoid malignancies.<sup>202,203</sup> In a report of 35 pediatric patients with lymphomatoid papulosis, 9% of them developed non-Hodgkin lymphoma during a mean follow-up period of 9 years,<sup>197</sup> emphasizing the need for long-term surveillance. Treatment is generally unnecessary except for cosmetic reasons because of the asymptomatic nature and tendency toward spontaneous clearance. The sometimes aggressive nature of lymphomatoid papulosis may lead to the misdiagnosis of lymphoma and chemotherapeutic treatment.<sup>198</sup>

**Figure 4-36** Lymphomatoid papulosis. Reddish-brown papules, most commonly noted on the proximal extremities and trunk. This picture shows lesions in different stages of evolution from development of necrotic centers and crusting to resolution.

**Figure 4-37** Lymphomatoid papulosis. Ulcerating nodule.

Application of ultrapotent topical corticosteroids twice daily for 2 to 3 weeks followed by weekly pulses has resulted in near clearance.<sup>204</sup> Other described therapies in children have included systemic steroids, systemic antibiotics, and PUVA and UVB light, although none have led to sustained complete remission.

## Pityriasis Rosea

Pityriasis rosea is an acute, benign, self-limiting disorder that affects male and female patients equally.<sup>205,206</sup> Approximately 50% of cases occur before 20 years of age, especially in adolescents. Only 4% of cases occur before 4 years of age. Most patients are otherwise well; however, a prodrome of headache, malaise, pharyngitis, lymphadenopathy and mild constitutional symptoms is present in approximately 5% of affected patients, particularly in association with more florid involvement. The etiology of pityriasis rosea remains controversial. A viral disorder is suggested by the occasional presence of prodromal symptoms, the course of the disease, epidemics with seasonal cluster, occasional reports of simultaneous occurrence in closely associated individuals, and a tendency to lifelong immunity in 98% of

**Figure 4-38** Herald patch (pityriasis rosea). Oval lesion with finely scaled elevated border, occasionally misdiagnosed as tinea corporis.

**Figure 4-39** Pityriasis rosea. The collarette of scale can be subtle.

cases. There is evidence both to support and refute the idea that pityriasis rosea is a reaction to HHV-6 and/or -7.<sup>207</sup>

Some 70% of cases start with a single isolated lesion, the so-called “herald patch” (Fig. 4-38), which is found most commonly on the trunk, upper arm, neck, or thigh. This characteristic initial lesion presents as a sharply defined oval area of scaly dermatitis (2 to 5 cm in diameter) with a finely scaled, slightly elevated border that gradually expands. After an interval of 2 to 21 days, a secondary generalized eruption of smaller papules (0.2 to 1 cm) appears in crops, characteristically sparing the face (in 85% of individuals), scalp, and distal extremities. In about 25% of cases, itching, particularly of secondary lesions, may be noted. The orientation of the long axis of these lesions is most characteristic. The typically ovoid lesions run parallel to the lines of skin cleavage, leading to a pattern resembling a “Christmas tree” on the back, wrapping around the trunk horizontally at the axillary area and suprapubic areas, and following inguinal folds. The smaller lesions also show a “collarette of scale” that surrounds the lesions (Figs. 4-38 and 4-39). Although the truncal distribution is most common, some patients, particularly children, show an inverse distribution of lesions on the face, axillae, and groin (Figs. 4-40 and 4-41). This atypical form of pityriasis rosea may be particularly difficult to diagnose if there is no history of a herald patch and if the characteristic morphology of lesions goes unrecognized. The face and neck are more often involved in children than in adults, particularly in African-American children. Pityriasis rosea has also been found to be more extensive, more often papular (34%), and associated with residual dyspigmentation in affected African-American children.<sup>208</sup>

Occasionally, lesions may be predominantly round and papular, particularly in young children and African-Americans (Fig. 4-42). Vesicular, pustular, urticarial, and hemorrhagic variants have also been described. The herald patch occasionally is the only manifestation.

**Figure 4-40** Pityriasis rosea. Inverse pattern showing the distribution along skin lines. Scaling may be more difficult to appreciate in intertriginous areas.

**Figure 4-41** Pityriasis rosea. The axillary area is a good site to look for orientation along skin lines that facilitates the diagnosis.

Involvement of the oral mucous membranes occurs in up to 16% of patients as asymptomatic erythematous patches that rarely appear erosive, hemorrhagic, or bullous.

The secondary eruption peaks within a few days to a week. Clearance usually occurs within 6 weeks, initially in the lesions that appeared earliest, but may require as long as 5 months. The disorder is rarely recurrent.<sup>207</sup> Postinflammatory hypopigmentation or hyperpigmentation may commonly be noted, particularly in dark-skinned individuals, and may persist for weeks to months after clearance of the pityriasis rosea.

**Figure 4-42** Pityriasis rosea. Truncal involvement with larger plaques and predominantly round papular lesions, most commonly seen in young children and African-Americans. Note the peripheral scale and distribution along skin lines.

The diagnosis of pityriasis rosea depends on recognition of the distribution of lesions and the characteristic appearance of the oval lesions with their fine peripheral or collarette scales. The histologic features of pityriasis rosea are not diagnostic and resemble those of a subacute or chronic dermatitis. The herald patch may be mistaken for tinea corporis, and the full-blown eruption must be differentiated from widespread tinea infection, drug eruption, PLEVA, seborrheic dermatitis, nummular eczema, psoriasis (particularly the guttate variety), and importantly, secondary syphilis. The latter must be considered in sexually active individuals who show involvement of the palms and soles, an unusual (but occasional) site for lesions of pityriasis rosea. The hemorrhagic form of pityriasis rosea must also be distinguished from vasculitis, including Henoch-Schönlein purpura, and viral disorders with thrombocytopenia.

Most patients require no treatment beyond reassurance as to the nature and prognosis of the disorder. Pruritus, if present, usually responds to topical antipruritics (calamine lotion, lotions containing menthol and/or camphor, lotions with pramoxine), oral antihistamines, colloidal starch or oatmeal baths, and mild topical corticosteroid formulations. Exposure to ultraviolet light or sunshine tends to hasten resolution of lesions, and in the summertime it is not uncommon to see patients with pityriasis rosea under covered areas with little to no evidence of the eruption on sun-exposed regions.<sup>209</sup>

## Lichen Planus

Lichen planus is a disorder primarily of adults, but 2% to 11% of reported cases occur in children and adolescents,<sup>210</sup> including as those young as 3 weeks of age. The etiology of lichen planus is unknown, but evidence suggests a cell-mediated autoimmune response. Familial cases are rare<sup>211</sup> but have an earlier age at onset, increased severity, a greater likelihood of chronicity, and an increased incidence of erosive, linear, ulcerative, and hypertrophic forms. Several cases in children have been described after hepatitis B vaccination.<sup>212-214</sup> The association of lichen planus with hepatitis C, as seen in adults,<sup>215</sup> has not been noted in children.<sup>212,216</sup> Lesions resembling lichen planus are a common manifestation of chronic graft-versus-host disease (see Chapter 25).

The primary lesion is a small, shiny, flat-topped polygonal, reddish or violaceous papule (Figs. 4-43 and 4-44).<sup>217</sup> Individual papules vary from 2 mm to 1 cm or more and may be closely aggregated or widely dispersed. Lichen planus is generally mildly to intensely pruritic in adults but is not uncommonly asymptomatic in affected children.<sup>210</sup>

**Figure 4-43** Lichen planus. The shiny flat-topped polygonal violaceous papules of lichen planus may be linear in orientation, suggesting the Koebner phenomenon after scratching. Note the intense residual hyperpigmentation and subtle overlying reticulated scaling.

**Figure 4-44** Typical violaceous lesions of lichen planus on the penile shaft, a common site.

The disorder is usually limited to a few areas with the lower legs the most common site<sup>212</sup>; lichen planus also often affects the flexural surfaces of the ankles and wrists, the genitalia (Fig. 4-45), and the lower back. Involvement of the face (Fig. 4-46), palms, and soles is unusual.<sup>203</sup>

At times, one may detect characteristic small grayish puncta or streaks that form a network over the surface of papules. These delicate white lines, termed *Wickham striae*, become more visible under magnification with a hand lens or by wetting the lesion with an alcohol swab or a drop of oil, which renders the horny layers of lesions more

**Figure 4-45** The shiny flat-topped polygonal violaceous papules of lichen planus. Note the Wickham striae (linear whitish-gray streaks) on the surface.

**Figure 4-48** Oral lichen planus. Wickham striae on the buccal mucosa.

**Figure 4-46** Mildly pruritic violaceous lesions on the eyelids with postinflammatory intense hyperpigmentation; biopsy confirmed lichen planus.

**Figure 4-49** Lichen planus of the nails. Anonychia and pterygium formation.

**Figure 4-47** Lichen planus. Note the linearity of lesions from scratching and the Koebner phenomenon.

transparent. Occasionally, lesions may coalesce to form plaques or a linear configuration (the Koebner phenomenon) at sites of minor trauma, such as scratch marks (Fig. 4-47).

Mucous membrane involvement is seen in up to 40% of pediatric patients<sup>218</sup> and is much less common than in adult patients (50% to 70% of adult patients).<sup>210,213</sup> When present, lesions usually appear as pinhead-sized white papules forming annular or linear lace-like patterns on the inner aspects of the cheeks (Fig. 4-48).<sup>219,220</sup> Lesions on

the palate, lips, and tongue are less characteristic and except for their reticulated appearance may easily be mistaken for areas of leukoplakia. On the lips the papules are more often annular, sometimes with adherent scaling reminiscent of that seen in lupus erythematosus. Although the typical reticulated mucosal lesions of lichen planus are asymptomatic, painful ulcerative lesions have been found on the tongue, oral mucous membranes, and mucosal surfaces of the pharynx, esophagus, gastrointestinal tract, vulva, and vagina.

Up to 10% of adult patients with lichen planus demonstrate involvement of one to all nails, but nail involvement appears to be less common in affected children; one study, however, noted nail involvement in 19% of 100 children.<sup>210,212</sup> Violaceous lines or papules in the nailbed may occasionally be seen through the nail plate. The nail dystrophy consists of loss of luster, thinning of the nail plate, longitudinal ridging or striation, splitting or nicking of the nail margin, atrophy, overlapping skin folds (pterygia), marked subungual hyperkeratosis, lifting of the distal nail plate, red or brown discoloration, and at times complete and permanent loss of the nail (Fig. 4-49).<sup>221</sup> Some children with 20-nail dystrophy (trachyonychia, see Chapter 7) may have lichen planus, but biopsy of the nail matrix would be needed to confirm the diagnosis in the absence of cutaneous changes.<sup>222</sup>

Although lichen planus is considered to be papulosquamous, many variations in morphology and configuration may be noted. These

variations include vesicular, bullous, actinic, annular, hypertrophic (Fig. 4-50), atrophic, linear,<sup>223</sup> erythematous, and follicular forms (Table 4-5).<sup>223-225</sup> Lichen planus pemphigoides is a rare autoimmune blistering disease in which the typical lichen planus lesions evolve into bullous lesions with a mean lag time of 8 weeks (see Chapter 13).<sup>224</sup> The extremities are most commonly involved, and approximately half

**Figure 4-50** Lichen planus. The plaques of lichen planus may be hypertrophic but show the characteristic violaceous coloration and intense hyperpigmentation.

**Table 4-5** Variants of Lichen Planus

Variant Type	Characteristics
Bullous <sup>225</sup>	Bullae develop on existent LP lesions
LP pemphigoides <sup>224</sup>	LP + bullous pemphigoid with autoimmune reactivity, usually against type XVII collagen (bullous pemphigoid 180 antigen)
Actinic	Onset during spring, summer; primarily sun-exposed surfaces (face, neck, dorsum of arms and hands); often annular configuration; most commonly in children and young adults
Annular	Occur in 10% of patients, often scattered amid typical lesions of LP
Hypertrophic	Pruritic, thick hyperkeratotic plaques, especially on the legs and dorsal regions of the feet; persistent
Atrophic	May represent a resolving phase in which larger plaques become centrally depressed with residual hyperpigmentation
Hemorrhagic/purpuric	Shows nonblanching component on diascopy
Linear <sup>223</sup>	LP occurring spontaneously along the lines of Blaschko; presumably reflects somatic mosaicism
Erosive/ulcerative	Intensely painful ulcerations on the palms and soles; chronic lesions may evolve into squamous cell carcinoma; erosive lesions may occur on mucosal surfaces
LP/lupus erythematosus	Overlapping features of lupus and LP; lesions are usually acral and patients may show high titers of ANA
Lichen planopilaris	Follicular LP; keratotic plugs surrounded by violaceous erythema, especially on scalp but can affect any hair-bearing area; usually results in cicatricial alopecia

ANA, Anti-nuclear antibodies; LP, lichen planus.

of the affected children show palmoplantar lesions. Direct and indirect immunofluorescence shows the presence of circulating antibodies, and patients often respond to topical corticosteroid and oral dapsone therapy, but systemically administered steroid may be required.

Many drugs may produce an eruption that resembles lichen planus (lichenoid drug eruption). Most commonly implicated are antihypertensives (captopril, enalapril, labetalol, and propranolol), diuretics (especially hydrochlorothiazide), antimicrobials (especially hydroxychloroquine and quinidine), metals (especially gold salts), and penicillamine. Among other agents rarely implicated but used often in children and adolescents, are griseofulvin, tetracycline, carbamazepine, phenytoin, and nonsteroidal anti-inflammatory drugs. In contrast to other drug eruptions, in which the latent period between introduction of the drug and the reaction is within 1 month, the latent period with lichenoid drug eruptions is typically several months to years after initiation of a medication. Similarly, the time to clearance after discontinuation of the medication is also prolonged and can take several weeks to months. The lichenoid lesions of lichenoid drug eruptions tend to be more eczematous, psoriasiform, or pityriasis rosea-like than the typical papules of lichen planus. Lesions occur much less commonly on oral mucosae than on skin.<sup>226</sup> In addition, they uncommonly show Wickham striae and are often photodistributed, particularly on the extensor forearms. The histologic picture resembles lichen planus, but shows more eosinophils.

The diagnosis of lichen planus depends on the recognition of the typical purple, polygonal, pruritic papules and plaques. When the diagnosis is in doubt, histopathologic examination of a cutaneous lesion can confirm the proper diagnosis. Characteristic changes are destruction of the basal cell layer (liquefactive degeneration), saw-toothing of the rete pegs, and a band-like lymphocytic infiltrate that hugs and invades the lower epidermis. Although cases of lichen planus occasionally clear in a few weeks, two-thirds of affected individuals with acute forms display spontaneous resolution within 8 to 15 months. In most patients, the lesions tend to flatten but are often replaced by an area of intense hyperpigmentation that may persist for months or years (Fig. 4-51). Occasionally, lichen planus itself may persist for years, and 10% to 20% of patients suffer one or more recurrences of their disorder.

The standard therapy for lichen planus in pediatric patients involves administration of class II–IV topical steroids and oral antihistamines.

**Figure 4-51** Lichen planus. Intense residual postinflammatory hyperpigmentation.

**Figure 4-52** Lichen nitidus. Sharply demarcated, pinpoint- to pinhead-sized monomorphic, round, usually flesh-colored lesions. Lesions may be distributed in a linear configuration after trauma to the site (Koebner phenomenon).

**Figure 4-53** Lichen nitidus. Note the even distribution of these pinpoint- to pinhead-sized round lesions on the dorsal aspect of the hand.

Pruritus may require 3 weeks of therapy to subside and the lesions themselves 6 weeks to begin to flatten.<sup>212</sup> Topical tacrolimus has been effective in cases recalcitrant to topical steroids.<sup>227</sup> For more extensive or recalcitrant cases, the addition of a 2- to 6-week course of systemic corticosteroids (1 mg/kg per day) is usually helpful in ameliorating the associated pruritus and hastening clearance.<sup>228</sup> Acitretin has also been effective for lichen planus, especially if hypertrophic.<sup>229</sup> Hypertrophic lichen planus lesions may also respond to application of class I topical steroids under occlusion, flurandrenolide-impregnated tape, or intralesional injections of triamcinolone. When traditional forms of therapy fail, metronidazole,<sup>230</sup> griseofulvin,<sup>231</sup> dapsone,<sup>210</sup> PUVA or UVB light therapy,<sup>210</sup> oral retinoids,<sup>228</sup> cyclosporine,<sup>232</sup> and thalidomide<sup>233</sup> have been shown to be effective in selected cases.

If drug-induced lichen planus is considered, medications should be discontinued whenever possible. Mucous-membrane lesions should be treated if symptomatic, eroded, or ulcerated. Topical anesthetics such as diphenhydramine elixir, viscous lidocaine, topical corticosteroids (such as Kenalog in Orabase), or topical tacrolimus ointment<sup>234</sup> may be beneficial. Since erosive forms of oral lichen planus may have an increased risk of malignant transformation, patients with oral lesions should avoid carcinogenic factors (such as tobacco) and receive periodic follow-up examinations and biopsy of suspicious lesions.<sup>235</sup> Nails may respond to administration of systemic corticosteroids, but local application of potent steroids under occlusion or flurandrenolide-impregnated tape at the nail base can be used if the disorder is largely limited to the nail.<sup>221</sup>

## Lichen Nitidus

Lichen nitidus is a relatively uncommon benign dermatosis that affects individuals of all ages but is most commonly seen in children of preschool and school age. Although the etiology remains unknown, association with lichen planus has been reported,<sup>236</sup> and some authorities consider lichen nitidus to be a variant of lichen planus. Familial cases have rarely been described.<sup>237,238</sup> Lichen nitidus has been seen in association with Down syndrome,<sup>239</sup> Niemann–Pick disease<sup>240</sup> and Russell–Silver syndrome.<sup>241</sup>

The individual papules of lichen nitidus are sharply demarcated, pinpoint to pinhead sized, round or polygonal, and usually flesh-colored (Figs. 4-52 and 4-53). The surface of each lesion is flat, shiny, and slightly elevated, sometimes with a central depression. The eruption is arranged in groups, primarily located on the trunk, genitalia, abdomen, and forearms of affected individuals but may be generalized.<sup>242</sup> Linear lesions in lines of trauma (Koebner reaction) are common. Minute, grayish, flat papules on the buccal mucous membrane and nail changes (thickening, ridging, pitting, onycholysis) have

occasionally been noted.<sup>243</sup> A rare variant is spinous follicular lichen nitidus, which may be localized or generalized and is often associated with perifollicular granulomas.<sup>244</sup> Lichen nitidus occasionally clears spontaneously after a period of several weeks to months but more often lasts much longer (occasionally years) with little or no response to treatment. As with lichen planus, significant postinflammatory pigmentary changes may persist.

Biopsy can confirm the diagnosis and characteristically shows claw-like projections of the rete ridges encircling an inflammatory infiltrate of lymphocytes, histiocytes, and occasionally giant cells, resembling a hand clutching a ball. Topical corticosteroids or calcineurin inhibitors occasionally clear the lesions but more often are not effective. Narrow-band UVB phototherapy has cleared generalized lichen nitidus.<sup>245</sup> The usually asymptomatic nature and tendency for spontaneous healing, however, make intervention less critical.

## Keratosis Lichenoides Chronica

Keratosis lichenoides chronica is a rare, chronic, progressive dermatosis that is much more common in adults than in pediatric patients.<sup>246–248</sup> Lesions may be present from birth or appear during infancy and are sometimes pruritic in children.<sup>249</sup> Familial occurrence (probably autosomal recessive) is more common in pediatric cases than in adults. The characteristic erythematous lichenoid papules and scaling verrucous lesions show a linear or reticulated pattern. The eruption tends to be symmetric, particularly on the limbs and less commonly the abdomen and buttock. Pediatric patients often have facial involvement, with well-defined scaling erythematous papules that may appear purpuric or resemble seborrheic dermatitis. Alopecia of the anterior scalp (receding frontal hairline), eyebrows and eyelashes may be noted. The palms and soles may show keratoderma, and nails may be discolored with thickening and longitudinal ridging. Occasionally, mucosae are affected; painful ulcerations or keratoses of the oropharyngeal or genital mucosae, hoarseness, and keratoconjunctivitis have been described. Biopsy sections resemble those of lichen planus.

Keratosis lichenoides chronica may persist for decades and is unresponsive to topical corticosteroid therapy, although one reported patient improved with the application of topical tacrolimus ointment.<sup>250</sup> Ultraviolet light exposure, PUVA therapy, and oral administration of retinoids, alone or in combination, may at times be beneficial.

The hereditary disorders of cornification, or the ichthyoses, are characterized by impairment in desquamation with hyperkeratosis and/or scaling.<sup>1,2</sup> The ichthyoses are largely distinguished by their clinical and in some cases, histologic and ultrastructural features. The discovery of the underlying molecular basis of most of the forms of ichthyosis has not only further refined classification,<sup>2</sup> but has also facilitated understanding of the interactions among epidermal proteins and the role of epidermal lipids in normal epidermal function. Desquamation is the end result of proteolytic degradation of corneodesmosomes (the intercellular junctions within the stratum corneum) and is abetted by friction and cell hydration. Desquamation requires normal epidermal differentiation and depends on a gradient of pH, the presence of protease inhibitors, and the generation of hygroscopic molecules within the stratum corneum cells. Abnormalities in desquamation and differentiation usually result from abnormal corneocyte shedding (retention hyperkeratosis) or from increased epidermal cell proliferation (epidermal hyperplasia).

The epidermal barrier consists of stacked corneocytes (cells of the stratum corneum) and surrounding highly hydrophobic lipid layers (lamellae) formed by the secretion of lamellar body contents at the interface of the stratum granulosum and the stratum corneum. Most of the mutations that lead to ichthyosis affect lipid metabolism or epidermal proteins, leading to barrier dysfunction and resulting in increased transepidermal water loss and decreased water-holding capacity.<sup>3,4</sup> Many of the features of ichthyosis are thought to be continuous compensatory attempts to restore the barrier (e.g., upregulated epidermal lipid synthesis, epidermal hyperproliferation, and inflammation). This homeostatic response likely allows survival of affected individuals.

## Nonsyndromic Forms of Ichthyosis

Four major forms of nonsyndromic ichthyosis<sup>5</sup> have been delineated, based largely on clinical and genetic characteristics. These are the most common forms of ichthyosis:

1. Ichthyosis vulgaris, the most common ichthyosis, transmitted as an autosomal semi-dominant trait
2. Recessive X-linked ichthyosis (RXLI), expressed only in males and transmitted as an X-linked recessive trait
3. Keratinopathic ichthyosis, an autosomal dominant trait (most common is epidermolytic ichthyosis [EI])
4. Autosomal recessive congenital ichthyosis (ARCI) (most collodion babies; the lamellar ichthyosis [LI]/congenital ichthyosiform erythroderma [CIE] spectrum).

## ICHTHYOSIS VULGARIS

Ichthyosis vulgaris is by far the most common genetic form of ichthyosis, and the majority of individuals affected by the disorder are undiagnosed (Table 5-1) either because of the minimal clinical manifestations or because the condition is dismissed as dry skin. This disorder, which is not present at birth, may be noted after the first 2 to 3 months of life and often not until later in childhood. Ichthyosis vulgaris generally improves with age, in summer, and in warm moist environments. Scales are most prominent on the extensor surfaces of the extremities and are most severe in cold and dry weather. Scales on the pretibial and lateral aspects of the lower leg are large and plate-like, resembling fish scales (Fig. 5-1, A); the flexural areas are characteristically spared. In other areas, small, white, bran-like scales may

be seen. Scales tend to be darker on dark-skinned individuals. Scaling of the forehead and cheeks, common during childhood, generally diminishes and clears with age, but hyperlinearity and mild to moderate thickening of the palms and soles is characteristic (Fig. 5-1, B). Discrete hyperkeratosis may occur on the elbows, knees, and ankles.

Patients with ichthyosis vulgaris often reveal an atopic background with a tendency toward atopic dermatitis, asthma, and/or allergic rhinitis.<sup>6</sup> The diagnosis of ichthyosis vulgaris should be considered in patients with atopic dermatitis who show large scales, particularly on the extensor aspects of the extremities; examination of the palms and soles shows the hyperlinearity. The presence in a parent of hyperlinear palms and dry skin, especially on the lower extremities, may be helpful in confirming this diagnosis. Keratosis pilaris, which is commonly associated with ichthyosis vulgaris and atopy<sup>7</sup> (see Chapter 3, and Chapter 7, Figs. 7-24 and 7-25), is most predominant on the upper arms, buttocks, and thighs.

A reduced or absent granular layer in skin sections may help to differentiate ichthyosis vulgaris from other forms of ichthyosis. Given that filaggrin is the major protein of the granular layer, it is not surprising that mutations in the gene encoding for profilaggrin, the precursor of filaggrin, are responsible.<sup>8</sup> In fact, *FLG* mutations are observed in 7.7% of Europeans and 3.0% of Asians, although not all manifest with ichthyosis vulgaris, given the dependence on environmental factors of its phenotype.<sup>7-9</sup> *FLG* mutations are uncommon in darker-skinned populations, even with ichthyosis vulgaris.<sup>10</sup> Ichthyosis vulgaris is now known to be a semi-dominant condition, in contrast to the previous assumption of dominant inheritance (i.e., manifestations are seen with a mutation on one allele in 1:12 Europeans but are worse if null mutations are on both alleles (probability, 1:576). The cleaved product of profilaggrin, filaggrin, plays an important role in linking a protein (involucrin) and lipids (ceramides) in the corneocyte envelope (see Chapter 3). In addition, filaggrin breaks down to amino acid metabolites that increase skin hydration (natural moisturizing factor). Without filaggrin, the epidermis cannot provide normal barrier function; transepidermal water loss is increased, leading to xerosis; and the ingress of foreign substances (such as allergens and pathogens) occurs more readily, thereby increasing the risk of exposure to triggers of atopy. In fact, mutations in profilaggrin are strongly linked to the risk of atopic dermatitis and secondary asthma, regardless of the ethnicity or specific profilaggrin mutation. The risk is highest in individuals with two mutated alleles. Overall up to 30% of patients of a Northern European background with atopic dermatitis and more than 20% of Japanese with atopic dermatitis<sup>11,12</sup> have *FLG* mutations. Signs of atopic dermatitis may be seen before other clinical signs of ichthyosis vulgaris, and most individuals with ichthyosis vulgaris never show evidence of atopic dermatitis. However, reduction of filaggrin expression, including in absence of *FLG* mutation, is a feature of autosomal dominance, because the inflammation itself and exogenous stressors suppress the expression of *FLG* and other important differentiation proteins, even in nonlesional skin.<sup>13,14</sup> Emollients may improve dry skin but do not normalize the epidermal gene expression profile of filaggrin.<sup>15</sup>

Individuals with *FLG* mutations have a generally altered risk of developing common diseases, even beyond atopic disorders. Mechanistic studies have shown increased penetration of allergens and chemicals in filaggrin-deficient skin, and epidemiological studies have found higher levels of hand eczema, irritant contact dermatitis, nickel sensitization, and serum vitamin-D levels.

Excessive exposure to factors that decrease skin barrier functions and increase the risk of atopic dermatitis should be avoided. Individuals with ichthyosis vulgaris should be protected against neonatal

**Table 5-1** Comparison of the Most Common Types of Ichthyosis

	<b>Ichthyosis Vulgaris</b>	<b>X-Linked Recessive Ichthyosis</b>	<b>Keratinopathic Ichthyosis,* Epidermolytic Ichthyosis</b>	<b>ARCI: Classic Lamellar Ichthyosis</b>	<b>ARCI: Classic Congenital Ichthyosiform Erythroderma</b>
Prevalence	1:100	1:4000 males	1:300,000	1:300,000	1:300,000
Inheritance	Autosomal semi-dominant	X-linked recessive	Usually autosomal dominant	Usually autosomal recessive	Autosomal recessive
Onset	2 months and beyond	17% at birth; 83% by 1 year	Birth, with superficial blistering	Birth, as collodion baby	Birth, as collodion baby
Character of scales	Fine, white to larger scales, esp. on legs	Large, brown	Verrucous scale, superficial blisters	Large, plate-like scales	Fine white scaling overlying erythema
Localization	Can be generalized; relative sparing of flexures; hyperlinear palms	Accentuation at neck and behind ears; relative sparing of flexures	Generalized; especially at flexures and overlying joints	Generalized; ectropion, occasional alopecia, nail dystrophy	Generalized; ectropion; occasional alopecia
Distinct histologic features	Often shows decreased granular layer	None	Epidermolytic hyperkeratosis	Massive orthokeratosis; moderate acanthosis	More acanthosis
Molecular basis	Mutations in profilaggrin ( <i>FLG</i> ); worse if both alleles	Deletions in <i>ARSC1</i> (arylsulfatase C)	Mutations in <i>KRT1</i> and <i>KRT10</i> ; superficial form with mutations in <i>KRT2</i>	Most commonly mutations in <i>TGM1</i> ; rarely other types (see CIE)	Mutations in <i>TGM1</i> ; <i>ALOXE3</i> ; <i>ALOX12B</i> ; <i>NIPAL4</i> ; <i>ABCA12</i> ; <i>CYP4F22</i> ; <i>PNPLA1</i> ; <i>LIPN</i> ; <i>CerS3</i>
Comments	Increased risk of atopic dermatitis and keratosis pilaris	Accumulation of cholesterol sulfate; FISH analysis to detect deletion; genital abnormalities rare; asymptomatic corneal opacities; contiguous gene deletion: with retardation, anosmia (Kallman syndrome) and/or chondrodysplasia punctata	Superficial form shows more superficial blistering and much less thickening; secondary <i>Staphylococcus aureus</i> infection	Transglutaminase activity can be measured in skin samples	May be associated with neurologic abnormalities

ARCI, Autosomal recessive congenital ichthyosis; CIE, congenital ichthyosiform erythroderma; FISH, fluorescent *in situ* hybridization analysis.

\*Previously known as epidermolytic hyperkeratosis, bullous congenital ichthyosiform erythroderma, and ichthyosis bullosa of Siemens (superficial form).

exposure to cats to prevent atopic dermatitis and should abstain from smoking to prevent asthma.<sup>9</sup>

Although rare in children, “acquired” ichthyotic scaling has been described in patients with nutritional disorders such as hypovitaminosis or hypervitaminosis A, hypothyroidism, sarcoidosis, dermatomyositis, leprosy, tuberculosis, human immunodeficiency virus (HIV) infection, and neoplastic disorders, particularly lymphomas. It should be noted that these forms were described before the availability of testing for profilaggrin mutations; given the many undiagnosed patients, it is possible that the underlying condition served as a trigger for increased cutaneous inflammation or dryness that led to increased expressivity of the gene mutation. Pityriasis rotunda, a rare variant of acquired ichthyosis, is characterized by asymptomatic, circular or oval, brown scaly patches on the trunk or extremities. Seen primarily in individuals of Japanese, African, and West Indian origin, its occurrence in Caucasians is extremely rare. The condition may at times be associated with an underlying disorder, may follow pregnancy, or may be familial. In contrast to ichthyosis vulgaris, pityriasis rotunda is chronic, is resistant to treatment, and tends to improve only when the underlying disorder is treated.

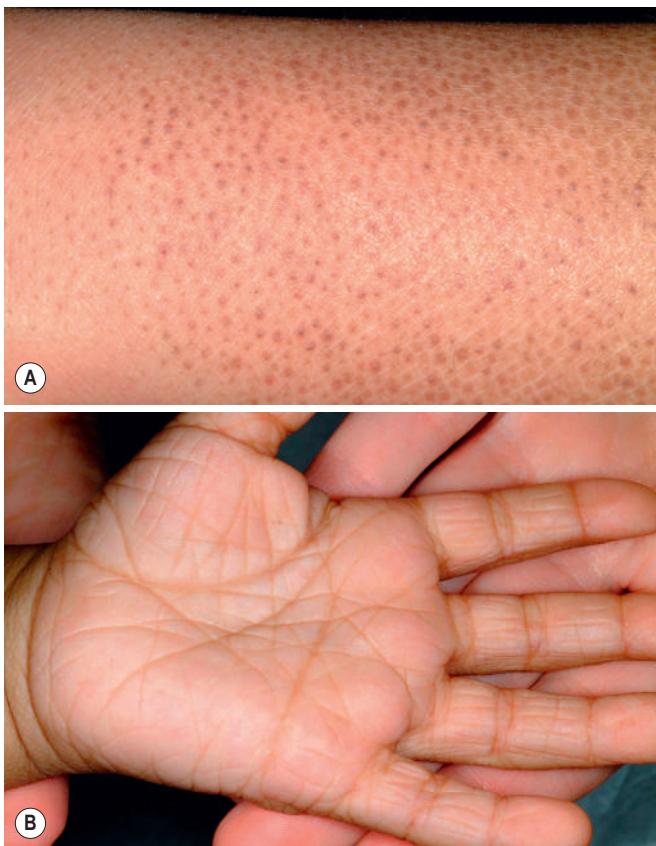

### RECESSIVE X-LINKED ICHTHYOSIS

Recessive X-linked ichthyosis (RXLI) occurs in 1:2500 to 5000 males and results from mutation (and usually a complete deletion) in the *ARSC1* gene that encodes steroid sulfatase (STS), also known as *arylsulfatase C* (see Table 5-1). The disorder has rarely been described in

females who have Turner syndrome or carry the mutation on both alleles. Female carriers do not tend to show ichthyosis, because the affected gene is located at the distal tip of the X chromosome, a location that escapes X-inactivation. Thus rather than having random inactivation of one of the X chromosomes as dictated by the Lyon hypothesis, both of the alleles are expressed in every cell, providing sufficient enzyme. STS normally is concentrated in lamellar bodies and secreted into the spaces between stratum corneum cells. It degrades cholesterol sulfate, generating cholesterol for the epidermal barrier. Cholesterol sulfate itself is an epidermal protease inhibitor, so STS deficiency prevents normal degradation of the stratum corneum desmosomes and leads to corneocyte retention.<sup>16,17</sup>

Low placental production of estrogens and elevated sulfated steroid levels have been described in the urine of mothers of boys with RXLI, associated with a difficult or prolonged labor and failure to have cervical dilation. Deletion of both *ARSC1* and a contiguous gene (up to 10% of patients) results features of ichthyosis and Kallmann syndrome (associated with mental retardation, hypogonadism, and anosmia) and/or X-linked recessive chondrodysplasia punctata (bone dysplasia with stippled epiphyses).<sup>18</sup>

RXLI usually manifests within the first 3 months of life. Approximately 17% of affected individuals show scaling at birth, often in the form of a mild collodion-like membrane. Most develop scaling during the first 6 months of life (Fig. 5-2). The severity of the scaling can range from mild to severe. This form of ichthyosis generally involves the entire body with accentuation on the scalp, neck, abdomen, back, front of the legs, and feet, but sparing the palms, soles, central face,

**Figure 5-1** Ichthyosis vulgaris. **(A)** Scales are most prominent on the extensor surfaces of the extremities, especially the lower extremities. **(B)** The palms and soles are thickened with increased palmar markings.

**Figure 5-2** Recessive X-linked ichthyosis. Scaling may be subtle, particularly in younger infants. This 6-month-old boy was diagnosed *in utero* by increased maternal estradiol levels and then FISH analysis of chorionic villus samples. Note the fine scaling on the trunk (**A**) and the large scales on the scalp (**B**).

and flexural areas (Fig. 5-3, A). Scales may be small to large and tend to be brown in coloration and darker in darker-skinned patients. The sides of the neck often appear dark and unwashed (Fig. 5-3, B). Patients may shed or molt their scales episodically, particularly in the spring and fall.

Boys with X-linked ichthyosis rarely have hypogonadism and/or cryptorchidism; testicular cancer has been described in one patient.<sup>19</sup> Deep corneal opacities may be found in approximately 50% of affected adult males and less often in female carriers of this disorder. The opacities, easily detectable by slit-lamp examination, are discrete and diffusely located near the Descemet membrane or deep in the corneal stroma. Although they are a marker for the disorder in older patients, these opacities do not affect vision.

X-linked ichthyosis is often suspected prenatally, because fetal STS deficiency leads to low maternal serum and urinary estriol levels.<sup>20</sup> Fluorescent *in situ* hybridization analysis (FISH) for the STS gene shows deletion of the gene found in 90% of patients. RXLI can also be confirmed by reduced arylsulfatase C activity in leukocytes. Elevated blood levels of cholesterol sulfate and increased mobility of  $\beta$ -lipoproteins have also been seen.<sup>21</sup>

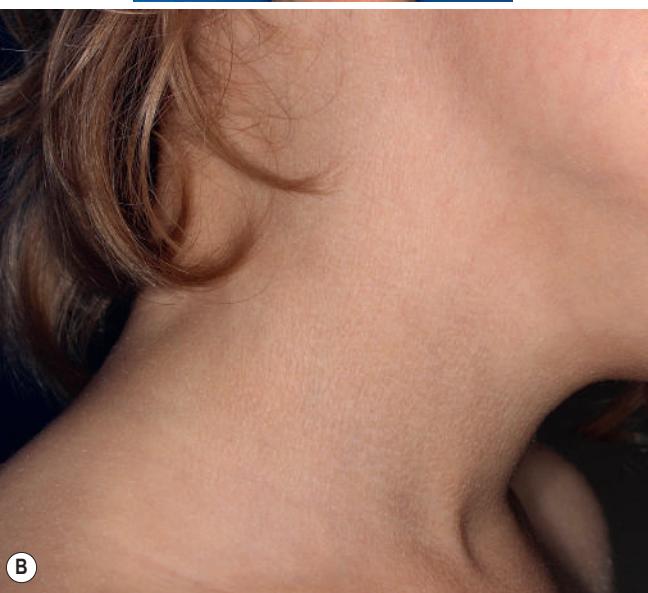

The features of RXLI may be seen in patients with autosomal recessive multiple sulfatase deficiency, a syndromic form of ichthyosis characterized by features of mucopolysaccharidoses, metachromatic leukodystrophy, X-linked recessive chondrodysplasia punctata, and RXLI. The disorder results from mutations in sulfatase-modifying factor 1 (*SUMF1*), which encodes  $\alpha$ -formylglycine generating enzyme required for posttranslational modification of sulfatases.<sup>22,23</sup> Progressive neurologic deterioration, a feature of the metachromatic leukodystrophy, usually leads to death during infancy.

## KERATINOPATHIC ICHTHYOSSES

The new classification of the ichthyoses has renamed the group of epidermolytic forms of ichthyosis associated with keratin gene mutations as *keratinopathic*. The major subgroups are epidermolytic ichthyosis (EI) (formerly called *bullous CIE, Brocq type*)<sup>24</sup> and superficial EI (formerly called *ichthyosis bullosa of Siemens*). The designation *epidermolytic hyperkeratosis* is a histologic description that is not specific to this group of disorders, although it traditionally referred to EI.

Mutations are usually point mutations that lead to an abnormal but full-length keratin that incorporates into the keratin filament. The resultant keratin network functions poorly, leading to skin cell collapse and clinical blistering, especially in response to trauma. The thickening of skin is thought to be compensatory to protect against blistering but has also been linked to abnormal lamellar-body secretion.<sup>25</sup> Virtually all forms are inherited in an autosomal dominant manner, although EI may rarely be autosomal recessive.<sup>26,27</sup> EI results from mutations in *KRT1* or its partner in intermediate filament formation, *KRT10*; both are expressed throughout the suprabasal layers of epidermis. Superficial EI is caused by mutations in *KRT2*, which is only expressed in more superficial epidermis and also partners with keratin 10.<sup>28-30</sup>

EI affects approximately 1 in 300,000 individuals, and 50% of patients have new mutations. The skin is red and may be tender at birth. Superficial bullae generally appear within the first week of life (often within a few hours after delivery; Fig. 5-4) and may be confused with those of epidermolysis bullosa (see Chapter 13) or with staphylococcal scalded skin syndrome (see Chapter 14). Skin thickening often appears from the third month on, but subtle thickening may be

**Figure 5-3** Recessive X-linked ichthyosis. **(A)** Scales may be large and hyperpigmented, especially in darker-skinned individuals. The popliteal and antecubital areas are typically spared. **(B)** The neck is typically affected with darker scaling that can appear as a dirty neck.

detectable during the first month of life, especially over the elbows and knees, and may be useful in suggesting the diagnosis. The blisters occur in crops and vary from 0.5 cm to several centimeters in diameter. They tend to heal quickly, consistent with their superficial location. When ruptured, they discharge clear fluid and leave raw denuded areas. Secondary bacterial infection, especially with *Staphylococcus aureus*, is commonly associated with this disorder.

Verruciform grayish-brown scales eventually cover most of the skin surface; the flexural creases and intertriginous areas show particularly marked involvement (Fig. 5-5).<sup>31</sup> Palms and soles have varying degrees of thickening and scaling (Fig. 5-6), but more

**Figure 5-4** Epidermolytic ichthyosis. In the neonate superficial blisters predominate and may be mistaken for epidermolysis bullosa.

marked involvement often occurs in individuals with mutations in *KRT1*, because keratin 9 expression in the palms and soles can compensate for abnormal keratin 10 expression, but expression of *KRT1* (which is the partner for both keratins 9 and 10) remains critical.<sup>31</sup> Facial involvement may occur, but ectropion does not; although scalp involvement may result in nit-like encasement of hair shafts, the hair, eyes, teeth, and nails are normal. A disagreeable body odor is commonly associated with severe forms of this disorder owing to the thick, macerated scale and overgrowth of bacteria and, less often, candida. Skin-biopsy specimens show marked hyperkeratosis with lysis of the epidermal cells above the basal cell layer (epidermolytic hyperkeratosis) leading to the bullae.<sup>32</sup> Keratolytic agents are often poorly tolerated in keratinopathic forms of ichthyosis and can increase skin fragility.

Mutations in *KRT1* and *KRT10* can lead to other ichthyotic phenotypes as well. Mutations in either can lead to an annular variant (annular EI).<sup>33</sup> Annular erythematous polycyclic scaling plaques on the trunk and extremities slowly enlarge, resolve, and later recur.

Ichthyosis Curth–Macklin (formerly called *ichthyosis hystrix*) has its onset of manifestations during early childhood as progressively worsening diffuse or striate palmoplantar keratoderma (PPK) that can be associated with deep fissuring, flexural contracture, and digital constriction. Affected individuals develop characteristic “porcupine quill-like” verrucous yellow-brown scaling especially on the hands and feet and overlying the large joints. Binuclear cells and pathognomonic concentric perinuclear “shells” of aberrant keratin are characteristic ultrastructural findings.<sup>34</sup> Keratin 1 mutations have been described in some<sup>35,36</sup> but not all affected patients.

The epidermolytic hyperkeratotic form of epidermal nevus shows a histologic appearance identical to that of epidermolytic hyperkeratosis (see Chapter 9). This form of nevus represents a mosaic condition in which the affected skin but not the normal intervening skin carries a mutation in *KRT1* or *KRT10*.<sup>37</sup> Individuals with more extensive forms of the epidermolytic hyperkeratotic form of epidermal nevus can have offspring with generalized epidermolytic hyperkeratosis, reflecting germline mutations. Prenatal diagnosis can be performed in at-risk families.<sup>38</sup>

Superficial EI shows milder thickening and more superficial blistering. Palms and soles are minimally thickened if at all. Although large, tense bullae can occur intermittently (Fig. 5-7, A), in general the appearance of blisters has been likened to molting (Mauserung phenomenon) (Fig. 5-7, B) because of the superficial location of the cleavage plane. Accordingly, less hyperkeratosis is seen in sections of skin biopsies, and the lysed areas of epidermis only begin halfway up the stratum spinosum. Affected individuals may be misdiagnosed as mild EI clinically, but the limited localization of the epidermolysis histologically and the finding of mutations in *KRT2* by molecular genetic testing can distinguish the disorders.<sup>39,40</sup>

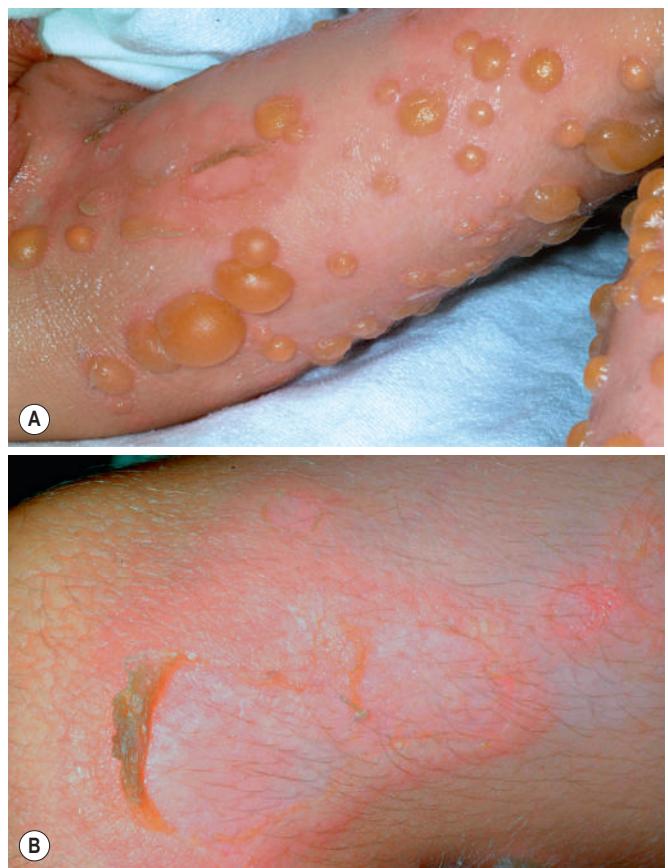

**Figure 5-5** Epidermolytic ichthyosis. (A) Thick verrucous scale on the legs of a 6-year-old boy. Note the intensification of scaling over the knees and ankles and the areas of blistering on the legs. (B) The scaling can take on a corrugated appearance.

Ichthyosis *en confetti*, also called *congenital reticular ichthyosiform erythroderma* or *ichthyosis variegata*, is a rare autosomal recessive keratinopathy that resembles nonbullous CIE but progressively shows reversion to normal-appearing skin in a “confetti” pattern of macules.<sup>41,42</sup> Mutations occur in the sixth or seventh exon of *KRT1* or *KRT10*, which seem to be predisposed to postzygotic translocations that allow protein expression of the mutated allele and correct the phenotype. The keratin is produced but stays intracellular and is not able to function normally. In some patients this reversion starts during the first years of life and is progressive, especially with keratin 1 mutations,<sup>41</sup> whereas in others the onset is later during childhood or even young adulthood, especially with keratin 10 mutation.<sup>43</sup> Other major

**Figure 5-6** Epidermolytic ichthyosis. The marked hyperkeratotic sole in this child virtually assures that the underlying gene defect involves *KRT1*.

**Figure 5-7** Superficial epidermolytic ichthyosis. (A) Occasionally, affected individuals may show tense bullae that resemble bullous pemphigoid (see Chapter 13). The bullae on this patient arose when he developed a viral exanthema. (B) Note the milder hyperkeratosis and the “molting” appearance of desquamation of superficial scale.

features include malformation of ears, hypoplasia of mammae, and dorsal acral hypertrichosis.<sup>44</sup>

### COLLODION BABY

*Collodion baby* is a descriptive term for an infant who is born with membrane-like covering resembling collodion (Fig. 5-8).<sup>45,46</sup> The

**Figure 5-8** Collodion baby. Note the shiny thickened skin, mild ectropion, mild eclabium, and ear deformity. In this 5-day-old baby, the “membrane” is starting to crack and desquamate.

collodion baby is not a disease entity but is a phenotype common to several forms of ichthyosis. At least 65% of collodion babies have ARCI (see [Autosomal Recessive Congenital Ichthyosis](#) section), a group of genetically distinct forms of ichthyosis with overlapping clinical features<sup>47</sup>; some infants in this group (5% to 6%) shed their collodion membranes and show apparently normal skin (self-healing collodion baby [SHCB]).<sup>48,49</sup> Less often, collodion babies shed their membranes and show features of syndromic forms of ichthyosis (Conradi-Hünermann–Happle syndrome, trichothiodystrophy [see Chapter 7], or RXLI). Using a new severity score for newborns with a collodion membrane, classic nonsyndromic ichthyoses were found to have higher severity scores.<sup>47</sup> Recently, a collodion baby was born to a mother who received infliximab before and throughout the course of the pregnancy; although the collodion membrane shed and the skin appeared normal 1 year after birth, genotype analysis was not reported to distinguish a drug effect versus a gene mutation to cause the ichthyosis.<sup>50</sup>

Collodion babies are often born prematurely. At birth they are completely covered by a cellophane or oiled parchment-like “membrane” that, owing to its tautness, may distort the facial features and extremities. Thus peripheral edema with digital constriction, flattened ears, and bilateral eversion of the eyelids, lips, and at times the vulva often cause affected infants to resemble one another during the first few days of life. Among the problems facing these infants are an inability to suck properly, respiratory difficulty because of restriction of chest expansion by the thick membrane, cutaneous and systemic infection, and aspiration pneumonia. Despite the thickening of the stratum corneum, this membrane is a poor barrier, leading to excessive transcutaneous fluid and electrolyte loss,<sup>51</sup> hypernatremic dehydration, increased metabolic requirements, and temperature instability.

Supportive care is of primary importance in the management of collodion babies.<sup>45,52,53</sup> They are best managed in a humidified incubator with special attention given to the prevention of temperature instability, sepsis, and fluid and electrolyte imbalance. Systemic antibiotic therapy should be initiated if infection is detected but not prophylactically. Desquamation is encouraged by the application of emollients rather than manual debridement; given the poor cutaneous barrier and potential toxicity, use of keratolytic agents should be avoided during the first several months of life.

## AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSIS

Autosomal recessive congenital ichthyosis (ARCI) encompasses a wide range of clinical phenotypes that range from classic harlequin ichthyosis (HI) and nonbulloous CIE to classic LI.<sup>54</sup> The same individual may show a range of overlapping clinical features; for example, retinoid treatment may decrease the lamellar scaling but increase erythroderma.<sup>55</sup> Failure to thrive is a feature of ARCI, especially if severe, and short stature may ensue.<sup>56</sup> Overall, ARCI occurs in approximately 1 in 100,000 to 300,000 live births. The diagnosis is based on clinical findings; biopsy is not helpful unless needed to exclude alternative

**Figure 5-9** Lamellar ichthyosis phenotype of autosomal recessive congenital ichthyosis (ARCI). Large plate-like scaling on the forehead and cheeks. This patient shows moderate ectropion.

diagnoses. The features of the ARCI group of disorders usually persist throughout the affected individual’s lifetime. Many affected individuals complain of associated pruritus. Owing to the obstruction of eccrine glands by the overlying hyperkeratosis, severely affected patients tend to experience hyperpyrexia, heat intolerance, difficulty with perspiration, and heat exhaustion during periods of warm or hot, humid weather and vigorous physical exercise. Squamous cell carcinomas have been reported at a younger age.<sup>57</sup>

Mutations in nine known genes have been shown to result in the ARCI phenotype, and most of these mutated genes have been related to both LI and CIE phenotypes (see [Table 5-1](#)). A few cases of autosomal dominant LI have been described.<sup>58</sup> The discovery of the underlying genetic basis in families with ARCI has facilitated the prenatal diagnosis based on genotyping rather than the riskier diagnosis by fetal skin biopsy.<sup>59</sup> Up to 55% of individuals with ARCI have mutations in the gene encoding transglutaminase 1 (*TGM1*), particularly patients with the LI phenotype.<sup>60</sup> *TGM1* crosslinks several proteins to form the cornified envelope surrounding corneocytes. In patients missing transglutaminase, transglutaminase activity is undetectable in frozen skin specimens.<sup>61</sup> HI has been shown to result from nonsense mutations in the gene encoding the ABCA12 transporter.<sup>62,63</sup> Deficiency of ABCA12 leads to perturbation of lipid transport, which then leads to a paucity of lamellar bodies, the upper epidermal lamellar structures that provide intracellular lipids to the stratum corneum,<sup>63</sup> and to premature terminal differentiation of keratinocytes. ABCA12 has also been shown to be important for protease function.<sup>64,65</sup> Mutations in *ABCA12* that lead to the LI or more commonly CIE phenotype tend to be missense mutations,<sup>66</sup> so that some gene product is present for function, leading to the milder phenotype. Other genes found to be mutated in ARCI encoding include lipoxygenase-3 (*ALOX3*), 12(R)-lipoxygenase (*ALOX12B*),<sup>67,68</sup> ichthyin (*NIPAL4*)<sup>69–71</sup> *CYP4F22*, lipase N (*LIPN*),<sup>72</sup> *PNPLA1*,<sup>73</sup> and ceramide synthase 3 (*CERS3*).<sup>74,75</sup> Some of these encode proteins of the hepxolin pathway (*ALOX12B*, *ALOX3*, and *NIPAL4*). In addition to their disruption of stratum corneum lipid synthesis, these enzymes (or the ichthyin receptor) within the lipoxygenase pathway may also disrupt the processing of profilaggrin.<sup>76</sup>

The clinical features of the classic LI phenotype may range from very mild to severe. Individuals who show the greatest severity of LI have large lamellar plate-like scales with relatively mild underlying erythroderma, ectropion (eversion of an edge or margin of the eyelid resulting in exposure of the palpebral conjunctiva) (Fig. 5-9), and mild eclabium (eversion of the lips) (see [Table 5-1](#)). Lamellar scales are large, quadrangular, yellow to brown-black, often thick, and centrally adherent with raised edges resembling armor plates (hence the term LI) (Fig. 5-10). Scales are most prominent over the face, trunk, and extremities, with a predilection for the flexor areas. Cheeks are often red, taut, and shiny; more scales appear on the forehead than on the lower portion of the face. The palms and soles are almost always affected in LI; severity varies from increased palmar markings to a thick keratoderma with fissuring. The scalp is often scaly with scarring

**Figure 5-10** Lamellar ichthyosis phenotype of autosomal recessive congenital ichthyosis (ARCI). Large plate-like scaling on the legs.

**Figure 5-12** Congenital ichthyosiform erythroderma phenotype of autosomal recessive congenital ichthyosis (ARCI). Marked erythroderma underlying fine white scaling.

**Figure 5-11** Bathing suit distribution, lamellar ichthyosis phenotype of autosomal recessive congenital ichthyosis (ARCI). This distribution of the ichthyosis, largely involving the trunk and intertriginous areas with sparing of the face and limbs, signals a temperature-sensitive mutation in *TGM1*, encoding transglutaminase 1. This baby was born with a full collodion membrane.

**Figure 5-13** Harlequin ichthyosis. Profoundly thickened, armor-like skin with fissuring, leading to the polygonal, triangular, or diamond-shaped plaques that simulate the costume of a harlequin. Note the severe ectropion, ecbium, and digital infarction. (Courtesy of Sylvia Suarez, MD.)

partial hair loss (especially with *TGM1* mutations). Involvement of the nails is variable. They may be stippled, pitted, ridged, or thickened, often with marked subungual hyperkeratosis.

Variant forms of LI from mutations in *TGM1* manifest in a more limited distribution of lesional skin. Patients with bathing suit ichthyosis (BSI) are born with a full collodion membrane and transition to LI, but within the first months of life the scaling on the extremities clears (Fig. 5-11). The residual LI on warmer skin areas (axillae, trunk, scalp, neck) has been linked to temperature-sensitive mutations in *TGM1*.<sup>77</sup> Mutations in *TGM1* that encode proteins sensitive to hydrostatic pressure can result in the SHCB. Affected neonates show either a generalized or acral<sup>78</sup> collodion membrane at birth that clears entirely as the baby transitions to the dry environment postnatally.<sup>48</sup> The *TGM1* mutations in both BSI and SHCB phenotypes are missense mutations that are predominantly in the catalytic core domains.<sup>79</sup> *ALOX12B* and *ALOX3B* mutations have also been described with SHCB.<sup>49,80</sup>

Classic nonbulloous CIE is characterized by a much more prominent erythrodermic component that may first become apparent as the colloidion membrane is shed; some patients show CIE at birth without a classic collodion membrane. Affected individuals show fine white scales on the face, scalp, and trunk, although scaling may be more plate-like scales on the extensor surfaces of the legs (Fig. 5-12). The degree of ectropion is variable but often milder than with LI, and there is less PPK. Cicatricial alopecia is possible, and nails may show

thickening and ridging. Some patients with CIE show intrauterine growth retardation and/or failure to thrive, although nutritional deficiency and gastrointestinal abnormalities are uncommon.<sup>81</sup> Patients with CIE may have associated neurologic abnormalities.

HI is the most severe form of ARCI. At birth, the disorder manifests as profoundly thickened, armor-like skin that is fissured into polygonal, triangular, or diamond-shaped plaques that simulate the traditional costume of a harlequin (Fig. 5-13).<sup>82</sup> Rigidity of the skin results in marked ectropion; everted O-shaped lips with a gaping fishmouth deformity; and a distorted, flattened, and undeveloped appearance to the nose and ears. The skin rigidity can restrict respiratory movements, sucking, and swallowing. The hands and feet are ischemic, hard, and waxy, often with poorly developed digits and an associated rigid and claw-like appearance. Flexion deformity of the limb joints is common, and the nails may be hypoplastic or absent. Restrictive dermopathy (see Chapter 6) shows congenital contractures, tight skin, ectropion, and intrauterine growth retardation and can thus sometimes be confused with HI, but it shows no hyperkeratosis or scaling.

Death is usually associated with prematurity, pulmonary infection (in part associated with hypoventilation caused by thoracic rigidity), poor feeding, excessive fluid loss, poor temperature regulation, or sepsis as a result of cutaneous infection. The severity may be variable, however, and prolonged survival has been achieved by intensive supportive measures, emollients and, in some cases, oral administration of systemic retinoids.<sup>83-86</sup> Initiation of aggressive intervention for

**Figure 5-14** Harlequin ichthyosis. This boy survived the neonatal period without retinoid intervention and is thriving with severe erythroderma and residual deformation (now 5 years of age). Note the severe erythroderma with scaling, persistent eclabium, and residual deformities of the fingers after the harlequin scaling is shed.

**Figure 5-15** Erythrokeratoderma variabilis. This girl shows well-demarcated plaques that sometimes are migratory.

babies with HI is controversial. Even with administration of systemic retinoids or spontaneous clearance of the armor-like scaling, the optimal outcome resembles that of severe CIE (Fig. 5-14). Physicians often reserve initiation for babies who survive the first few weeks, because most infants are stillborn or die during the neonatal period (usually during the first few hours or days of life); however, it is unclear whether use of systemic retinoids leads to a better outcome than excellent supportive care, especially during the neonatal period therapy.<sup>87</sup> Pulmonary issues can be ongoing in infants and young children. Prenatal diagnosis of HI has been suspected based on ultrasound-based discovery of distal arthrogryposis<sup>88</sup> and can be performed definitively by molecular analysis.<sup>89</sup>

## OTHER FORMS OF NONSYNDROMIC ICHTHYOSIS

### Loricrin Keratoderma

Loricrin keratoderma (also called *Camisa disease*, a variant of Vohwinkel keratoderma) is an autosomal dominant disorder with ichthyosis and PPK. <sup>90,91</sup> Mutations occur in the gene encoding loricrin, a protein that is linked by transglutaminase-1 to involucrin and other proteins of the corneocyte envelope, thereby participating in barrier function and normal epidermal maturation.<sup>92,93</sup> Affected individuals may be born with a collodion membrane and later show a mild, nonerythrodermic generalized ichthyosis with flexural accentuation. The PPK is initially noted during the first weeks of age, is often transgrediens, and may show a honeycomb pattern that resembles that of Vohwinkel syndrome (connexin defect). Pseudoainhum (constricting bands of the digits) may occur but usually not until adolescence or even adulthood; the starfish-shaped keratoses of Vohwinkel syndrome are not seen with loricrin keratoderma. Alopecia is occasionally seen but not other ectodermal abnormalities or hearing impairment. Parakeratosis on routine skin biopsy is a characteristic histologic feature, but termination mutations in the C-terminus have been linked to milder PPK without pseudoainhum and without parakeratosis on affected skin biopsy.<sup>94</sup>

### Erythrokeratoderma Variabilis and Progressive Symmetric Erythrokeratoderma

Erythrokeratoderma variabilis (EKV) is a dominantly inherited ichthyosis characterized by two distinct types of lesions: (1) sharply marginated, pruritic, or burning areas of erythema with finer scaling that are often figurate in configuration and undergo changes in size, shape, and distribution during a period of days to weeks; and (2) hyperkeratotic plaques with thick, yellow-brown scales that usually overlie erythema (Fig. 5-15). Lesions are most often symmetrically distributed on the limbs, trunk, and buttock with relative sparing of the face, scalp, and flexures. In contrast to the chronic but remitting appearance of these plaques and figurate lesions, plaques on the knees, elbows,

Achilles tendons, and soles of the feet are often persistent. PPK has been described in 50% of affected families.

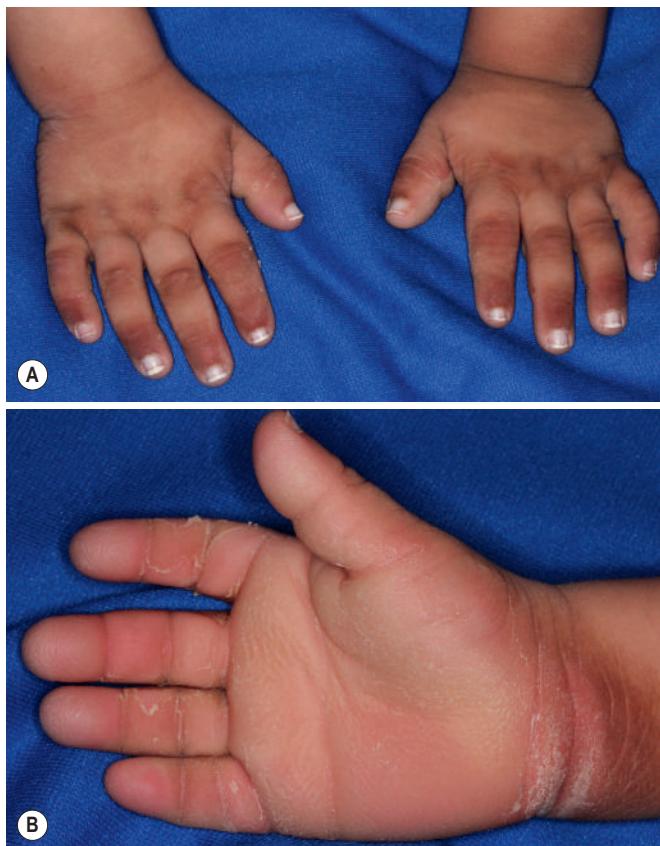

Although lesions are usually noted at birth or shortly thereafter during the first year of life, in a few individuals the onset has been noted during late childhood or early adulthood. The disorder may partially regress at puberty and tends to improve in summer. Patients usually tend to respond well to systemically administered retinoids.<sup>95</sup>

EKV has been known to result from mutations in genes that both map to chromosome 1p35.1 and encode interacting connexins: *GJB3* encoding connexin 31<sup>96</sup> and *GJB4* gene encoding connexin 30.3.<sup>97,98</sup> Most recently, EKV with hyperpigmented, well-delineated keratotic plaques was shown to result from mutations in *GJA1* encoding connexin 43 (Fig. 5-16).<sup>99</sup> Individuals with symmetrical EKV lesions during early infancy that clear by 25 years of age may develop progressive spinocerebellar ataxia in adulthood in association with heterozygous mutations in *ELOVL4*.<sup>100</sup> *ELOVL4* encodes an elongase needed for synthesis of very long-chain fatty acids in skin, eyes, and the neurologic system. When *ELOVL4* mutations affect both alleles, ichthyosis can occur in association with spastic diplegia and severe neurodevelopmental delay.<sup>101</sup> Homozygous *ELOVL4* mutations must be distinguished from Sjögren–Larsson syndrome (see *Sjögren–Larsson Syndrome* section).

Progressive symmetric erythrokeratoderma (PSEK; Darier–Gottron syndrome) is a dominant disorder that tends to have its onset during infancy, tends to stabilize after 1 or 2 years, and may partially regress at puberty. PSEK has been distinguished from EKV by the absence of the migrating red patches, the typical sparing of the chest and abdomen with scaling plaques limited to the extremities, buttocks, and face, and a higher incidence of PPK (~50% of cases); however, the conditions overlap phenotypically, and patients have been described with features of both,<sup>102</sup> suggesting that PSEK and EKV are a single disorder with variable manifestations. In fact, a *G12D* missense mutation in connexin 30.3 has been shown to cause both PSEK and EKV.<sup>103</sup>

### Peeling Skin Syndrome

Peeling skin syndrome (PSS), or keratolysis exfoliativa congenita, is an unusual autosomal recessive disease characterized by life-long, spontaneous superficial peeling of the skin that may be persistent or periodic.<sup>104–106</sup> The Nikolsky sign tends to be positive. The desquamation has been associated with increased stratum corneum and serum kallikrein levels. Two generalized types have been described. Desquamation is generalized, other than the palms and soles, which may be mildly thickened. Seasonal variation with worsening during summer months has been described.

**Figure 5-16** Erythrokeratoderma variabilis (EKV). A newly discovered underlying cause of EKV is mutations in *GJA1*, encoding connexin 43. One distinguishing feature of these patients is the marked hyperpigmentation of skin that progressively appears starting in infancy or childhood. (A) Note the hyperpigmentation and skin thickening on the dorsal aspects of the hands, the white nails, and (B) the keratoderma of the palm with typical “honeycombing” as is often seen with connexin gene defects.

In type A, the onset may be at birth but commonly begins in early childhood (by 6 years of age). These patients are asymptomatic. Skin biopsy shows a thickened stratum corneum with an intracorneal or subcorneal separation. Type A is caused by mutations in *CHST8*, which encodes a Golgi transmembrane N-acetylgalactosamine-4-O-sulfotransferase (GalNAc4-ST1).<sup>107</sup> In type B, the condition always begins at birth. Patients show erythematous migratory peeling patches and complain of associated pruritis or burning. Patients with the type B form may show short stature and easily removable anagen hairs.<sup>104</sup> Biopsy specimens reveal psoriasiform thickening of the epidermis and a subcorneal or intracorneal split. Type B results from loss of corneodesmin,<sup>108</sup> found in the stratum corneum and hair follicle.

An acral form of hereditary PSS is characterized by life-long painless peeling of predominantly the dorsal aspect of the hands and feet in superficial sheets<sup>109</sup> and exacerbation during summer months with increased sweating.<sup>107,110</sup> A facial variant has been described.<sup>111</sup> This acral form is caused by mutations in *TGM5* encoding transglutaminase-5,<sup>112,113</sup> which crosslinks epidermal proteins. Acral PSS in association with plantar keratoderma and peeling can be associated with mutations in encoding cystatin A (*CSTA*), a protease of the cornified cell envelope.<sup>114</sup> Cystatin A mutations can also be associated with generalized mild scaling and exfoliation.<sup>115</sup> Acral PSS may be misdiagnosed as localized epidermolysis bullosa simplex.

#### Keratosis Linearis-Ichthyosis Congenital-Keratoderma

Keratosis linearis-ichthyosis congenital-keratoderma (KLICK) is a rare, autosomal recessive disorder characterized by distinctive striate hyperkeratosis in the flexures (perpendicular to the fold) and PPK.<sup>116,117</sup>

It results from a single-nucleotide deletion in the 5' untranslated regions (UTRs) of the proteasome maturation protein (*POMP*) gene, which reduces levels of *POMP* and leads to proteasome insufficiency, increased endoplasmic reticulum (ER) stress, and perturbed processing of profilaggrin in differentiating keratinocytes.<sup>118,119</sup>

#### Syndromic Forms of Ichthyosis

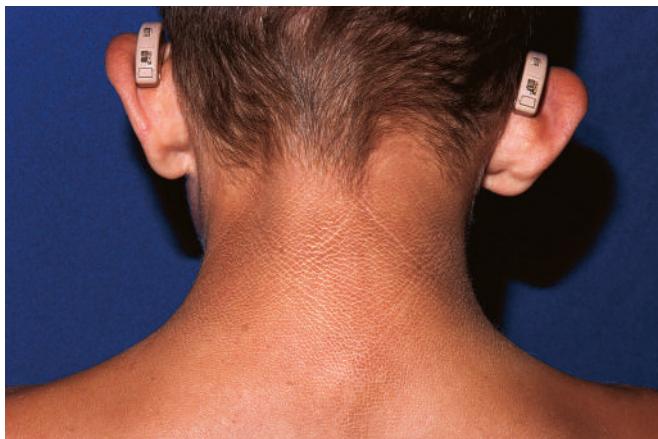

Syndromic forms of ichthyosis may be associated with a variety of extracutaneous abnormalities, most commonly involving the hair (e.g., Netherton; ichthyosis follicularis, alopecia, and photophobia [IFAP] and ichthyosis, hypotrichosis, and sclerosing cholangitis [IHSC] syndromes and ichthyosis with hypotrichosis; trichothiodystrophy) and neurologic system (e.g., Sjögren-Larsson; Refsum; dysgenesis, neuropathy, ichthyosis, and palmoplantar keratoderma [CEDNIK]; and mental retardation, enteropathy, deafness, neuropathy, ichthyosis, and keratoderma [MEDNIK] syndromes). Some syndromic disorders are lethal in the neonate (e.g., Neu-Laxova syndrome), infant (e.g., Gaucher disease type 2; arthrogryposis, renal dysfunction, and cholestasis [ARC] syndrome; multiple sulfatase deficiency) or child (e.g., CEDNIK syndrome).

#### NEUTRAL LIPID STORAGE DISEASE WITH ICHTHYOSIS

Neutral lipid storage disease with ichthyosis, or Chanarin-Dorfman syndrome, is a rare autosomal recessive disorder seen primarily in individuals of Middle Eastern or Mediterranean descent.<sup>120</sup> The clinical phenotype can variably include liver steatosis with hepatomegaly, muscle weakness/myopathy, ataxia, neurosensory hearing loss, subcapsular cataracts, nystagmus, strabismus, and mental retardation, but ichthyosis of the CIE phenotype is an almost constant finding. Patients are often born as collodion babies, occasionally with ectropion and eclabium. Skin biopsies show skin thickening with foamy keratinocyte cytoplasm owing to prominent neutral lipid droplets in the basal cells and eccrine glands seen best on oil-red O-stained frozen sections. Serum lipids are normal, although the triglyceride content of lymphocytes, macrophages, and fibroblasts in culture is two to 20 times that of normal cells. Muscle and liver enzymes may be elevated twofold to threefold. The diagnosis is confirmed by a peripheral blood smear, which shows lipid droplets in granulocytes (Jordan anomaly) that are also seen in the leukocytes of heterozygous carriers of Chanarin-Dorfman syndrome. Mutations have been identified in *ABHD5* or *CGI-58*,<sup>121</sup> a gene that encodes an enzyme expressed during differentiation in lipid transporting lamellar granules of epidermis<sup>122</sup> that is required for triglyceride degradation and normal barrier function.<sup>123,124</sup> A diet of moderate amounts of carbohydrates and medium-chain triglycerides, together with oral acitretin 0.5 mg/kg per day, has been shown to improve both the CIE and liver function tests.<sup>125</sup>

#### CHIME SYNDROME

Individuals with CHIME syndrome (also called *Zunich neuroectodermal syndrome*) show a combination of coloboma, heart defects, ichthyosis-form dermatosis, mental retardation, and ear anomalies, including conductive hearing loss.<sup>126,127</sup> The disorder is caused by mutations in *PIGL*,<sup>128</sup> a de-N-acetylase required to make glycosylphosphatidylinositol (GPI) anchors, which are membrane glycolipids that anchor the C-terminus of proteins during posttranslational modification.<sup>129</sup> The skin is notably thickened and dry at birth, with pruritis often developing during the first months of life (Fig. 5-17). The colobomas are usually retinal, although choroidal colobomas have been described. Several heart defects, including pulmonic stenosis, ventricular septal defect, transposition of the great vessels, and tetralogy of Fallot, have been associated. Patients show a typical facies with hypertelorism; a broad, flat nasal root; upslanting palpebral fissures; epicanthic folds; a long columella but short philtrum; macrostomia; full lips; and cupped ears with rolled helices. All patients show brachydactyly. The hair may be fine and sparse, and trichorrhexis nodosa has occasionally been described. Some patients have renal or urologic anomalies, and cleft palate has been described in association.

**Figure 5-17** CHIME syndrome. Thickened skin on the back of the neck. Note the hearing aids because of conductive hearing loss.

**Figure 5-18** KID syndrome. Note the fine, stippled papules studding the dorsal aspect of the fingers and the subungual hyperkeratosis.

## KID SYNDROME

KID syndrome is a rare autosomal dominant disorder characterized by keratitis, congenital ichthyosis, and neurosensory deafness.<sup>130,131</sup> Patients are usually born with erythematous skin that progressively becomes more thickened and leathery during the first months of life. Generalized tiny stippled papules are characteristic (Fig. 5-18), and 90% of patients develop well-defined verrucous plaques, especially on the face and limbs. Alopecia may be congenital (25%) and ranges from sparse hair to total alopecia (Fig. 5-19); a thick yellow scale may cover the scalp at birth. Most patients show PPK with a stippled or leathery pattern. Nails tend to be dystrophic, and sweating may be diminished.

The hearing loss is congenital, neurosensory, and nonprogressive; it can be detected by brainstem auditory-evoked potential testing. In contrast, ocular features are rarely seen at birth but progress and become evident by childhood or early adolescence. Photophobia may be the earliest sign, and the characteristic corneal vascularization and keratoconjunctivitis sicca lead to pannus formation and marked reduction in visual acuity.<sup>132</sup> KID syndrome must be distinguished from IFAP syndrome (see Chapter 7), an ichthyotic condition in which patients have total alopecia, thickened skin with spiny projections, PPK, and photophobia with decreased visual acuity.

Almost half of patients with KID syndrome have recurrent bacterial and candidal infections of the skin, eyes, and ear canals.<sup>130,133</sup> Some patients have demonstrated abnormal chemotaxis and impaired lymphocyte proliferative responses to *Candida albicans*. The follicular occlusion syndrome (including hidradenitis suppurativa) has been described in some patients, may lead to scarring alopecia, and may require surgical intervention.<sup>134</sup> More than 10% of patients develop squamous cell carcinoma of the skin, especially acral, or

**Figure 5-19** (A) KID syndrome. Markedly thickened skin with fine stippling on the cheeks and perioral skin. Note the total alopecia in this patient who was found to have a mutation in *GJB2*, which encodes connexin 26. (B) Note the fine projections, including between the thick scales, in this newborn. (A Courtesy of Amy Theos, MD. B Courtesy of Sapna Vaghani, MD and Daniela Russi, MD.)

tongue<sup>130,135</sup> occasionally during childhood, and trichilemmal tumors have also been described.<sup>136–139</sup> Dandy–Walker malformation has been described in several affected individuals.<sup>140</sup>

The disorder results from mutations in one of *GJB2* or *GJB6*, encoding connexins (proteins that create channels critical in intercellular communication) 26<sup>141</sup> and 30,<sup>142</sup> respectively. The latter connexin is also mutated in patients with Clouston syndrome, which shares the alopecia, nail dystrophy, PPK, and sometimes photophobia of KID syndrome (see Chapter 7). A baby with KID syndrome from a connexin 26 mutation has recently been described whose unaffected mother had the same point mutation but had an additional, more distal null mutation in the same allele that protected her from having phenotypic manifestations; the second mutation was lost in the baby, presumably by prezygotic reversion during meiosis of the maternal gamete.<sup>143</sup>

Therapy of KID syndrome is largely supportive. Chronic administration of fluconazole has improved the verrucous plaques of cutaneous candidiasis.<sup>144</sup> Cochlear implants<sup>145</sup> and corneal transplants have been used to correct the sensorineural hearing loss and corneal vascularization, respectively.<sup>132,146–148</sup> Recent research has suggested that mefloquine, a US Food and Drug Administration (FDA)-approved antimalarial drug, inhibits the aberrant connexin 26 hemichannels in keratinocytes from a mouse model of KID syndrome and may be a future intervention.<sup>149</sup>

## NETHERTON SYNDROME

Netherton syndrome (NS) is an autosomal recessive condition that combines ichthyosis, atopy, and hair shaft deformities. NS presents during the neonatal or early infantile period with generalized scaling

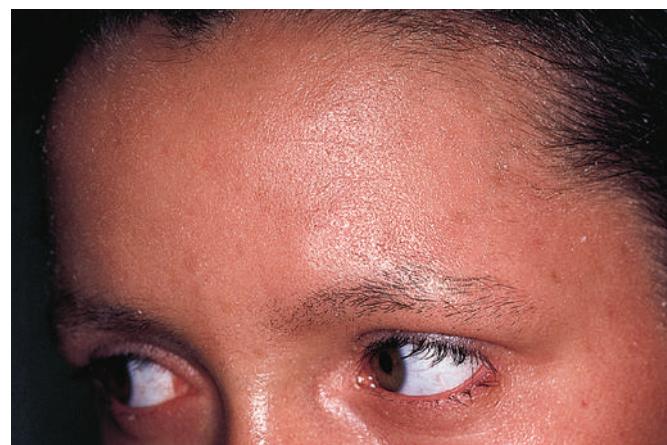

**Figure 5-20** Netherton syndrome. Polycyclic scaling lesions, many showing the scale edge. (A) Note the underlying erythroderma, scalp involvement, and short hair. (B) Sometimes there is more global erythroderma and larger desquamative scaling.

erythroderma but not a true collodion-baby phenotype. Neonates with NS are usually born prematurely and develop the eruption *in utero* or during the first weeks of life. Failure to thrive is often profound, requiring hospitalization for nutritional support and correction of the hypernatremic dehydration that may be associated.<sup>150</sup>

Patients may have diarrhea associated with intestinal villus atrophy, and the majority experience sepsis, upper and lower respiratory infections, and cutaneous *S. aureus* infection.<sup>151</sup> Adults with NS are also at risk for extensive papillomavirus infection,<sup>152</sup> usually involving the genital region, and may develop squamous cell carcinoma.<sup>57</sup> A variety of immunologic abnormalities have been described, suggesting that NS should be considered a primary immunodeficiency disorder. These include reduced memory B cells, defective response to vaccination, impaired antibody amplification and class switching, decreased natural killer (NK)-cell cytotoxicity, a skewed T-helper (Th) 1 phenotype, and increased proinflammatory cytokine levels.<sup>151</sup> Treatment with intravenous immunoglobulin may cause an increase in NK cell cytotoxicity and clinical improvement.<sup>151</sup>

Ichthyosis linearis circumflexa, the characteristic skin change associated with NS, is characterized by migratory, polycyclic scaly lesions with a peripheral double-edged scale (Fig. 5-20). Although most commonly seen in association with NS, patients may show only the ichthyosis linearis circumflexa without the hair shaft abnormalities or other features of NS. Ichthyosis linearis circumflexa is not generally seen before 2 years of age and occurs eventually in only 70% of patients. The ichthyosiform erythroderma that is the typical

**Figure 5-21** Netherton syndrome. Dry, lusterless hair that breaks and thus remains short and unmanageable. Note the eyebrow alopecia and facial erythroderma.

manifestation in the neonatal and infantile periods tends to improve with increasing age. Partial remissions have been noted and spontaneous fluctuation is common, but there is little tendency to spontaneous resolution. Routine histologic examination of skin-biopsy sections is not helpful, but immunohistochemical studies show absent or reduced expression of *LETKI*,<sup>153–155</sup> and electron microscopic studies have revealed features that are specific to NS.<sup>156,157</sup>

The classic hair shaft abnormality, trichorrhexis invaginata ("bamboo hairs," "ball-and-socket deformity"), is thought to result from a defect in keratinization of the internal root sheath. The hair defect results in easy hair breakage and hair that is poorly manageable, dry, and lusterless (Fig. 5-21) (see Chapter 7, Fig. 7-5). Multiple hairs from different areas should be examined, because only 20% to 50% of hairs may be affected. Examination of hairs from the eyebrow region often is most fruitful, and dermoscopy facilitates visualization of the "matchstick" hair defect.<sup>158,159</sup> Finding the hair shaft disorder is particularly difficult in the affected neonate.

NS results from loss-of-function mutations in *SPINK5*, which encodes lymphoepithelial Kazal-type-related inhibitor (*LETKI*), a serine protease inhibitor.<sup>160</sup> The increase in serine protease activity (kallikrein 5) leads to decreases in desmosomal proteins (desmoglein 1 and desmocollin 1) with premature degradation of corneocyte desmosomes and excessive desquamation.<sup>161–163</sup> Approximately two-thirds of patients show pruritic atopic-like dermatitis, food allergies, urticaria, angioedema, asthma, and/or anaphylaxis. In addition, most patients have increased levels of circulating eosinophils and immunoglobulin (Ig) E. These atopic manifestations likely result from the unregulated kallikrein 5 activity, which activates *PAR2* and *TSLP* (as in atopic dermatitis, see Chapter 3) as well as other cytokines<sup>164</sup> and contributes to both the very poor skin barrier and the cutaneous inflammation. The marked impairment in barrier function can lead to significant absorption of topically applied medication, necessitating careful monitoring of serum levels or adrenal suppression. Application of hydrocortisone 1% ointment caused Cushing syndrome in an 11-year-old boy, and immunosuppressive serum levels may be detectable after application of tacrolimus ointment.<sup>165</sup> Nevertheless, several patients have responded well to application of topical calcineurin inhibitors without detectable absorption.<sup>166,167</sup>

NS should be distinguished from other forms of ichthyosis, especially with abnormal hair, barrier defects, and early failure to thrive (Table 5-2). These include severe dermatitis, multiple allergies, and metabolic wasting (SAM) syndrome<sup>168</sup>; epidermal growth factor receptor (EGFR) deficiency<sup>169</sup>; and ADAM17 deficiency.<sup>170–177</sup> Alopecia with ichthyosis is also a feature of trichothiodystrophy<sup>170</sup> (see Chapter 7), ichthyosis hypotrichosis syndrome,<sup>173–176</sup> and IHSC syndrome<sup>171,172</sup> (see Table 5-2).

Treatment of NS is largely supportive, although administration of infliximab led to sustained improvement and decreased thymic stromal lymphopoitietin levels,<sup>178</sup> and narrow-band ultraviolet B (UVB) light

**Table 5-2** Differential Diagnosis of Netherton Syndrome: Disorders with Ichthyosis and Alopecia (Hereditary Disorders Only)\*

Disorder	Inheritance	Gene	Features Resembling Netherton Syndrome	Differentiation from Netherton Syndrome
SAM syndrome	AR Loss-of-function mutations	<i>DSG1</i>	CIE with PPK, no collodion membrane; failure to thrive; hypernatremia; barrier defect; dermatitis; high IgE; malabsorption; eosinophilic esophagitis; multiple food allergies; recurrent infections; hypotrichosis; hypoalbuminemia	May have microcephaly, growth hormone deficiency, developmental delay, cardiac defects; psoriasisiform dermatitis with acantholysis in skin sections; absence of desmoglein
ADAM17 deficiency	AR Loss-of-function mutations	<i>ADAM17</i>	Psoriasisiform erythroderma/widespread pustules; failure to thrive; malabsorption; short, broken hair; recurrent infections	Bloody diarrhea; cardiomyopathy/cardiomyositis
EGFR deficiency	AR Loss-of-function mutations	<i>EGFR</i>	Erythema, scaling, and widespread pustules; alopecia; failure to thrive, watery diarrhea, high IgE and eosinophils, hypernatremia, hypoalbuminemia; recurrent bronchiolitis	Cardiovascular issues
Trichothiodystrophy	AR Loss-of-function mutations	<i>ERCC2, ERCC3, GTF2H5, C7orf11</i> (see Chapter 7)	CIE-like ichthyosis; short, brittle hair; "tiger tail" hair shaft defect under polarized microscopy	May have impaired intelligence, decreased fertility, short stature, and photosensitivity
IHS (also called autosomal recessive ichthyosis with hypotrichosis [ARIH] syndrome)	AR Loss-of-function mutations	<i>ST14</i> (encodes matriptase); abnormal filaggrin processing	Generalized, congenital ichthyosis with sparing of face, palms, and soles; diffuse nonscarring alopecia of scalp, eyelashes, and eyebrows from birth, but improves to sparse, unruly hair during adolescence and merely recession of the frontal hair line by adulthood	May have patchy follicular atrophoderma and hypohidrosis; photophobia from corneal abnormalities; blepharitis; dental abnormalities; hair microscopy may show pili torti or pili bifurcati
IHSC (or NISCH) syndrome	AR Loss-of-function mutations	<i>CLDN1</i> (encodes claudin 1, structural protein of tight junctions)	Congenital generalized scaling, predominantly on the limbs and abdomen and sparing skinfolds, palms and soles; coarse, curly hair with frontotemporal cicatricial alopecia	Congenital paucity of bile ducts or sclerosing cholangitis leads to neonatal jaundice with hepatomegaly; oligodontia, and enamel dysplasia; blood smears show small eosinophils and keratinocyte vacuoles without lipid contents

AR, Autosomal recessive; CIE, congenital ichthyosiform erythroderma; Ig, immunoglobulin; IHS, ichthyosis hypotrichosis syndrome; IHSC, ichthyosis-hypotrichosis-sclerosing cholangitis; NISCH, neonatal ichthyosis sclerosing cholangitis; SAM, severe dermatitis, multiple allergies, and metabolic wasting; PPK, palmoplantar keratoderma.

\*Netherton syndrome must also be distinguished from severe atopic dermatitis and immunodeficiency disorders.

has led to marked cutaneous improvement within a few months.<sup>179,180</sup> A Phase 1 *ex vivo* gene therapy trial is underway in the United Kingdom, with the normal *SPINK5* gene introduced by lentivirus into the grafted patient keratinocytes.<sup>155</sup>

### REFSUM DISEASE

Refsum disease is an autosomal recessive neurocutaneous disorder caused by deficiency in oxidation of phytanic acid, a branched, long-chain fatty acid derived from dietary chlorophyll.<sup>181–183</sup> The clinical features usually develop in late childhood or early adult life and progress slowly during months to several years. Neurologic manifestations are most prominent and include sensorineural deafness, anosmia, failing vision, night blindness owing to retinitis pigmentosa and a progressive weakness, foot drop, and loss of balance caused by a mixed sensorimotor neuropathy and cerebellar involvement. Delayed diagnosis may result in severe neurologic impairment, wasting, and depression. The associated ichthyosis, which can either coincide with or postdate the neurologic features, resembles ichthyosis vulgaris or in severe untreated cases, LI. Accentuated palmoplantar markings are associated.

Refsum disease results from mutations in one of two genes, either *PHYH* (also named *PAHX*), which encodes the peroxisomal enzyme phytanoyl-CoA hydroxylase, or *PEX7*, which encodes the PTS2

(peroxisomal targeting signal 2) receptor.<sup>184</sup> Phytanic acid cannot be synthesized by humans and is mainly derived from plant chlorophyll. Normally serum levels are undetectably low but in Refsum disease may account for up to 30% of serum lipids. The accumulation of phytanic acid disturbs the cholesterol balance and may alter lipid degradation.<sup>185</sup> Histology shows variably sized vacuoles in the epidermal basal and suprabasal cells, corresponding to the lipid accumulation seen with lipid stains of frozen sections. The diagnosis is based on the demonstration of increased levels of phytanic acid in the patient's serum, tissue, or urine. Therapy consists of a chlorophyll-free diet and avoidance of phytanic acid-containing foods.

### SJÖGREN–LARSSON SYNDROME

The ichthyosis of the autosomal recessive disorder, Sjögren–Larsson syndrome (SLS), usually manifests in the neonatal period as fine, white scaling, accentuated in flexural areas.<sup>186</sup> Erythema is occasionally present at birth but clears within months. Presentation as a collodion baby is rare. By 1 year of age, the ichthyosis of SLS is not erythrodermic but shows generalized velvety lamellar thickening (often with a yellowish hue) particularly on the trunk and neck with minimal desquamation (Fig. 5-22), PPK, and relative sparing of the face.<sup>187,188</sup> The skin is characteristically pruritic, and most patients are hypohidrotic. The degree of scaling varies from mild to severe (Fig. 5-23) and does

**Figure 5-22** Sjögren–Larsson syndrome. The skin shows velvety lamellar thickening with a yellowish hue and minimal desquamation.

**Figure 5-23** Sjögren–Larsson syndrome. Thick, lamellar scaling in an adolescent with severe retardation.

not change with increasing age.<sup>189,190</sup> Hair and nails are normal. The neurologic disease usually presents within the first year with failure to reach normal developmental milestones and the onset of spasticity. Phenotypic variability is seen, and some patients have been described with mild neurologic features of SLS without associated skin disease.<sup>191</sup> Spasticity and muscle paresis is most pronounced in the legs,<sup>189</sup> and most affected persons become dependent on a wheelchair for mobility. Most patients have a learning disability to a variable degree and a speech disorder, and some show seizures, short stature, kyphosis, and enamel hypoplasia. The pathognomonic retinal “glistening dots” are not present in all patients, but photophobia is common.

SLS results from mutations in the fatty aldehyde dehydrogenase gene (*FALDH* or *ALDH3A2*), a component of fatty alcohol, fatty alcohol oxidoreductase (FAO), which converts fatty alcohol to fatty acid.<sup>192</sup> Epidermal cells in affected individuals show abnormal lamellar bodies and lipid droplets, consistent with defective lipid metabolism.<sup>193</sup> Prenatal diagnosis of SLS is possible by measurement of FAO activity

in cultured amniocytes or chorionic cells, histologic analysis, and/or analysis of fetal deoxyribonucleic acid (DNA) if the gene defect is known. The ichthyosis is treated with topical keratolytic agents and retinoids<sup>189</sup>; dietary supplementation with medium-chain fatty acids is generally not helpful.<sup>187</sup> The leukotriene inhibitor zileuton may decrease the associated pruritus,<sup>194</sup> but no therapy to date has been found to slow the progressive neurologic deterioration. Ichthyosis with more severe neurologic changes than SLS (spastic diplegia, seizures, and intellectual disability) can also result from biallelic mutations in *ELOVL4*, a fatty acid elongase that catalyzes the first and rate-limiting step in very long chain fatty acid synthesis (see *Erythrokeratoderma Variabilis* and *Progressive Symmetric Erythrokeratoderma* section).<sup>101</sup>

### ICHTHYOSIS PREMATURITY SYNDROME

Ichthyosis prematurity syndrome (IPS) is an autosomal recessive disorder in which affected babies are born more than 6 weeks prematurely in association with polyhydramnios and opaque amniotic fluid because of the extensive shedding of epidermal cells.<sup>195,196</sup> Neonates often have perinatal respiratory distress and sometimes life-threatening neonatal asphyxia of amniotic keratin debris. Typically babies are born with generalized thick spongy desquamating skin that resembles vernix caseosa, accentuated on the scalp and eyebrows.<sup>197</sup> During the neonatal period the scaling may resemble cobblestones overlying moderate erythroderma. Although the marked thickening clears in survivors, xerosis with follicular keratosis and pruritus persists, and patients often show atopic dermatitis, dermatographism, asthma, and eosinophilia. More than 70% develop respiratory and/or food allergy.<sup>198</sup> Mutations have been identified in *SLC27A4*, the fatty-acid transport protein 4 (*FATP4*) gene, which encodes a fatty-acid transporter and leads to defective stratum corneum lipid homeostasis. *FATP4* may associate with ichthyin and transglutaminase 1 in lipid processing essential for maintaining the epidermal barrier function.<sup>199</sup>

### NEU–LAXOVA SYNDROME

Another autosomal recessive form of congenital ichthyosis associated with a high risk of early death is Neu–Laxova syndrome, characterized by severe intrauterine growth retardation, an edematous appearance, lung hypoplasia, microcephaly, and abnormal brain development with lissencephaly and agenesis of the corpus callosum.<sup>200–203</sup> The ichthyosis tends to be present at birth but ranges in severity from mild ichthyosis to an HI appearance. Patients tend to show typical facies, including protuberant eyes with a flattened nose, slanted forehead, micrognathia, deformed ears, and a short neck. Some affected neonates show microphthalmia or cleft palate. Syndactyly, limb or digital hypoplasia, and limb contractures are common, and X-rays often show poor bone mineralization. Mutations occur in one of three genes of the L-serine biosynthesis pathway, phosphoglycerate dehydrogenase (*PHGDH*),<sup>204</sup> phosphoserine aminotransferase (*PSAT1*) and phosphoserine phosphatase (*PSPH*).<sup>205</sup> Neu–Laxova represents the severe end of the spectrum of disorders caused by mutations in these genes (others have variable neurologic manifestations). Craniofacial and limb defects have been seen in a variety of syndromes with reduced intrauterine movement (fetal akinesia/hypokinesis sequence).

### GAUCHER SYNDROME TYPE 2

Gaucher syndrome type 2 results from an absence of lysosomal β-glucocerebrosidase, which hydrolyzes glucosylceramide to ceramide. The neonate with Gaucher syndrome type 2 (acute infantile cerebral form) may be a collodion baby<sup>206,207</sup> with the onset during infancy of neurologic signs and hepatosplenomegaly.<sup>208</sup> Glucosylceramide and ceramide are critical components of the intercellular bilayers of the stratum corneum and play a role in epidermal barrier function.<sup>4</sup> The absence of glucocerebrosidase leads to abnormal skin thickening and increased transepidermal water loss. Even when the skin appears normal clinically in affected patients, ultrastructural abnormalities in lamellar membranes may be seen.<sup>209</sup> Despite enzyme replacement therapy, nonneurologic manifestations of Gaucher disease may progress.<sup>210</sup>

### CEDNIK SYNDROME

CEDNIK syndrome first manifests between 5 and 11 months of age with progressive neurologic deterioration.<sup>211</sup> Affected infants show a generalized mild LI phenotype with sparing of skin folds but palmo-plantar thickening. The hair tends to be fine and sparse. Microcephaly, neuropathy, cerebral dysgenesis, sensorineural deafness, optic nerve atrophy, neurogenic muscle atrophy, and cachexia are associated, and affected individuals usually die within the first decade of life. Patients with CEDNIK syndrome have mutations in *SNAP29*, a component of the secretory (SNARE [soluble NSF attachment protein receptor]) pathway that is important for vesicle fusion and lamellar granule maturation and secretion. In CEDNIK syndrome, glucosylceramide and kallikrein-containing granules are abnormally retained in the stratum corneum, leading to retention hyperkeratosis and an abnormal epidermal barrier.

### MEDNIK SYNDROME

MEDNIK syndrome is an autosomal recessive disorder that shows manifestations at birth or within the first weeks of life.<sup>212,213</sup> Among the ichthyoses, it most closely resembles EKV and in fact has also been called *EKV3*. Nail thickening and mucosal involvement may be associated. Patients show congenital sensorineural deafness, psychomotor and growth retardation, mental retardation, and peripheral neuropathy. The severe, congenital, chronic diarrhea is life-threatening. MEDNIK syndrome results from mutations in *AP1S1*, encoding a subunit (1A) of an adapter protein complex (AP-1) that is involved in

the organization and transport of proteins during skin and spinal-cord development.<sup>214</sup>

### ARC SYNDROME

ARC syndrome presents with generalized desquamative lamellar scaling within the first days to weeks of life but not at birth.<sup>215–217</sup> Ectropion and mild scarring alopecia may be present. The distinguishing features are the associated arthrogryposis (contractures of the limbs, particularly of the knee, hip and wrist; rocker bottom feet; talipes equinovarus), renal tubular degeneration with metabolic acidosis, and intrahepatic bile-duct hypoplasia with cholestasis. Patients may also show cerebral malformations, hypothyroidism, deafness, dysmorphic features, and large, dysfunctional platelets. Death ensues during the first year of life. ARC syndrome results from mutations in *VPS33B*, which regulates SNARE protein-mediated fusion of membrane vesicles required for lamellar body secretion.<sup>218</sup> Incomplete ARC syndrome has been described without the arthrogryposis.<sup>219</sup>

### CONRADI–HÜNERMANN–HAPPLE SYNDROME

The key clinical features of Conradi–Hünermann–Happle (CHH) syndrome (also called *X-linked dominant chondrodysplasia punctata type II*) are linear ichthyosis, chondrodysplasia punctata, cataracts, and short stature.<sup>220</sup> Neonates tend to show severe ichthyosiform erythroderma with patterned yellowish markedly hyperkeratotic plaques (Fig. 5-24, A). After the first 3 to 6 months of life the erythroderma and scaling resolve, leaving erythema and later follicular atrophoderma in

**Figure 5-24** Conradi–Hünermann–Happle syndrome. Congenital scaling (A) and residual hyperpigmentation during infancy after scale clearance (B) and later during childhood (C) in a distribution that follows Blaschko lines.

**Figure 5-25** Conradi–Hünermann–Happle syndrome. Cicatricial alopecia of the eyebrows. Approximately half of this patient's scalp hair was replaced by cicatricial alopecia as well. Note the deformity of the nose.

**Figure 5-27** CHILD syndrome. Unilateral congenital ichthyosiform erythroderma with marked deformity of the arm. This girl's ipsilateral leg was also markedly shortened and required amputation.

**Figure 5-26** Conradi–Hünermann–Happle syndrome. Bilateral ptychotropism with psoriasiform plaques.

a distribution that follows Blaschko lines, hypopigmentation and hyperpigmented streaks particularly on the trunk (Fig. 5-24, B and C), and circumscribed cicatricial alopecia of the scalp and eyebrows (Fig. 5-25). Patients may show persistent psoriasiform lesions in intertriginous areas (ptychotropism) (Fig. 5-26). In addition to the cutaneous findings, patients with CHH show asymmetric skeletal involvement with punctate calcification of the epiphyseal regions that usually results in an asymmetric shortening of the long bones (especially the humeri and femora) and sometimes in severe kyphoscoliosis, facial dysplasia, and hip dislocation. Unilateral or bilateral sectorial cataracts; patchy, coarse, lusterless hair; nasal bone dysplasia with saddle-nose deformity (see Fig. 5-25), and a high-arched palate further characterize the disease. The bony abnormalities but not the skin lesions of CHH syndrome have been described in association with teratogenic exposures to medications and infections and maternal autoimmune diseases.<sup>221</sup>

X-chromosomal inactivation explains the distribution of skin lesions along Blaschko lines, the sectorial cataracts, and the asymmetric skeletal abnormalities. Abnormal cholesterol synthesis/metabolism has been detected in patients with CHH, and mutations

have been identified in emopamil binding protein (EBP), which encodes 3 $\beta$ -hydroxysteroid- $\Delta$ 8,  $\Delta$ 7-isomerase, a key component in cholesterol biosynthesis. Abnormal lamellar granules and malformed intercellular lipid layers have been detected ultrastructurally,<sup>222</sup> and plasma sterol analysis shows markedly elevated levels of 8(9)-cholesterol and 8-dehydrocholesterol.<sup>223</sup>

## CHILD SYNDROME

The CHILD syndrome is a congenital disorder characterized by congenital hemidysplasia, ichthyosiform erythroderma, and limb defects.<sup>224</sup> Also known as *unilateral CIE*, the hallmark of the disorder is the sharp midline demarcation and its largely unilateral cutaneous and skeletal features (Fig. 5-27). This X-linked dominant condition occurs almost exclusively in girls and is presumed to be lethal in affected males. The only case in a boy is thought to represent early postzygotic mosaicism.<sup>225</sup> The inflammatory ichthyosiform skin lesions of CHILD syndrome may be present at birth or develop during the first few months of life. They are characterized by yellow and waxy scaling and/or streaks of inflammation and scaling that is often patchy but may follow Blaschko lines. Similarly, streaks of normal skin may be interspersed within the area of the CHILD nevus. Unilateral alopecia and severe nail dystrophy with claw-like nails have been described. The face is typically spared. With increasing age, lesions may improve or even clear spontaneously, but lesions in intertriginous areas (ptychotropism) tend to persist and be the most severely affected sites.<sup>226</sup> Rarely a localized hyperkeratotic plaque with a sharp demarcation at the midline is the sole manifestation of the CHILD syndrome (CHILD nevus) (Fig. 5-28). A mild form of CHILD syndrome has been described in three generations,<sup>227</sup> suggesting genetic control of the skewing of X inactivation.<sup>228</sup>

Ipsilateral skeletal hypoplasia, ranging in severity from hypoplasia of the fingers to complete agenesis of an extremity, is an important feature of CHILD syndrome. As with the skin changes, unilaterality is not absolute, and slight changes may be present on the contralateral side. The molecular basis for the unilaterality is not understood, but the epidermal changes correlate with mutant gene expression in the epidermis; leukocytes show skewing of X-chromosome inactivation, and virtually all circulating cells express the normal gene.<sup>229</sup> Punctate epiphyseal calcifications may be demonstrable by radiography but tend to disappear after the first few years of life. Cardiovascular and renal abnormalities are the major visceral manifestations of CHILD syndrome, although anomalies of other viscera have been described. Biopsy of skin lesions shows epidermal thickening with characteristic infiltration of the papillary dermis of histiocytes showing foamy cytoplasm (verruciform xanthoma). Inactivating mutations have been identified in the NSDHL gene encoding a 3 $\beta$ -hydroxysteroid dehydrogenase,<sup>230</sup> which functions upstream of EBP in the cholesterol synthesis pathway. Treatment with keratolytic agents and retinoids is poorly

**Figure 5-28** CHILD nevus. The ptychotropism of a sharply demarcated thickened plaque of the inguinal area that ends abruptly at the midline. This girl showed mild thickening and hyperpigmentation involving only the right side of her body but no limb deformities or hemidysplasia.

tolerated, but topical application of compounded 2% lovastatin/2% cholesterol leads to dramatic improvement.<sup>229</sup>

#### TREATMENT OF LESIONAL SKIN OF NONSYNDROMIC AND SYNDROMIC ICHTHYOSSES

Treatment of patients with most forms of ichthyosis involves topical application of keratolytic agents and topical or systemic administration of retinoids.<sup>1,231</sup> The Foundation for Ichthyosis and Related Skin Types (FIRST; [www.firstskinfoundation.org](http://www.firstskinfoundation.org)) is a support group for patients and families with disorders of cornification. In addition to educational materials, FIRST provides information about commercially available treatment options. Several other foundations worldwide support families with ichthyosis and have educational websites as well (e.g., [www.ichthyosis.org.uk](http://www.ichthyosis.org.uk) and [www.ictiosis.org](http://www.ictiosis.org)).

The management of all types of ichthyosis consists of retardation of water loss, rehydration and softening of the stratum corneum, and alleviation of scaliness and associated pruritus. Daily to twice-daily baths using a superfatted soap or a soapless cleanser followed immediately by application of the emollient to moist skin can be helpful for all forms. Shorter baths are preferred for patients with ichthyosis vulgaris, especially with associated atopic dermatitis. However, many patients with LI or EI have found long baths to be particularly helpful. Ichthyosis vulgaris and RXLI can be managed quite well by topical application of emollients and the use of keratolytic agents to facilitate removal of scales from the skin surface.  $\alpha$ -Hydroxy acid preparations such as lactic and glycolic acids are the most commonly used as agents to desquamate excessive scale and increase hydration.<sup>231,232</sup> Urea in concentrations of 10% to 20% has a softening and moisturizing effect on the stratum corneum and is helpful in the control of dry skin and pruritus. Salicylic acid is another effective keratolytic agent and can be compounded into petrolatum at concentrations between 3% and 6% to promote shedding of scales and softening of the stratum corneum. When it is used to cover large surface areas for prolonged periods, however, patients should be monitored for salicylate toxicity, most commonly complaints of tinnitus. The combination of 6% salicylic acid in propylene glycol may be particularly helpful for

**Figure 5-29 (A)** and **(B)** Clearance of the lamellar phenotype of ichthyosis with topically applied tazarotene. After 2 months of nightly application of tazarotene 0.1% cream, this girl experienced remarkable improvement in her ichthyosis.

keratoderma of the palms and soles, especially when used under occlusive wraps. The LI phenotype of ARCI generally requires more potent keratolytic agents; individuals with milder forms of LI often respond well to the topical application of tazarotene (Fig. 5-29).<sup>233,234</sup> As the skin normalizes, the risk of irritation from tazarotene increases, sometimes leading to dermatitis and then requiring therapy to be intermittent. Topical N-acetylcysteine with or without urea (e.g., 10% N-acetylcysteine in 5% urea) has also been used for LI.<sup>235,236</sup> Recombinant transglutaminase-1 enzyme encapsulated in liposomes reversed the ichthyosis phenotype and barrier function in a skin-humanized mouse model of LI.<sup>237</sup>

The skin of EI is quite fragile, and patients generally will tolerate only intermittent, short-term use of keratolytic agents, if at all. Similarly, individuals with NS and CHILD syndrome tolerate topically applied keratolytic agents poorly. It should be remembered that individuals with ichthyosis usually have a barrier abnormality that can lead to increased percutaneous absorption. Although topical anti-inflammatory medications may be used for associated dermatitis or to decrease intense pruritus, the risk of detectable levels of corticosteroids or calcineurin inhibitors must be kept in mind. For example, topical tacrolimus ointment has been found to be helpful for individuals with NS, but toxic levels have sometimes been detected,<sup>165</sup> emphasizing the need for careful monitoring.<sup>167</sup>

Oral retinoids (isotretinoin, acitretin) have led to dramatic improvement in some pediatric patients with the ichthyoses but should be used with caution because of their many potential side effects that limit long-term therapy, particularly bone toxicity.<sup>238,239</sup> Liarazole, a retinoic acid-metabolism blocking agent (RAMBA),<sup>240</sup> has shown the efficacy of acitretin with fewer retinoic acid-related adverse events.<sup>241–243</sup> These systemic agents are generally reserved for use in adolescents and adults with more severe ichthyotic disorders that do not show a satisfactory response to topical agents.

Patients with the ichthyoses tend to be more susceptible to cutaneous infection, particularly dermatophyte and staphylococcal infections. Secondary infection should be considered when patients with ichthyosis (particularly ARCI and EI) develop a new eruption. The accumulation of scale predisposes to overgrowth of bacteria and an odor, which in addition to the significant cosmetic ramifications of these disorders, may lead to additional problems in social acceptance by peers. Patients with thick scale may benefit from use of mild antibacterial soaps (e.g., Lever 2000 or Cetaphil antibacterial soap) or use of antibacterial washes if not too irritating. Many patients benefit from the addition of bleach (4 cc per gallon or 1 cc per L;  $\frac{1}{2}$  cup per full standard tub) or baking soda (1 cup) into the bath water. Dermatophyte infections often require administration of systemic antifungal medications.<sup>244</sup>

Sweating is often inadequate in patients with ichthyosis owing to the occlusion of eccrine ducts. Affected individuals should be guarded against overheating during winter months and kept in air-conditioning during warmer months, with frequent wetting of the skin or even cooling suits (see Chapter 7) during sports activities. The ectropion of patients with ARCI exposes the conjunctivae and cornea, resulting in irritation.<sup>245</sup> Bland moisturizing drops can be administered several times daily to provide protective moisture, and patients may benefit from wearing eye patches at night if the eyes cannot close entirely. Some physicians recommend plastic surgery to correct the ectropion, because damage to the cornea may impair vision; however, this surgery is complex and often unsuccessful. Periorbital application of tazarotene (0.05% cream)<sup>246</sup> and N-acetylcysteine have decreased ectropion when used sparingly. Ichthyosis of the ear canal can lead to accumulation of skin debris and conductive hearing loss. In a recent survey, 80% with ichthyosis reported ear pruritus, 66% had trouble hearing, and 29% reported ear pain.<sup>247</sup> Regular professional ear cleaning and use of ear softeners can decrease the risk of hearing loss and recurrent ear infections.

In countries without significant dietary supplementation with vitamin D<sub>3</sub>, ichthyosis, particularly the epidermolytic and lamellar forms (Fig. 5-30), has been associated with an increased risk of the development of rickets in association with increased levels of parathyroid hormone and alkaline phosphatase.<sup>248–251</sup> Serum levels of parathyroid hormone at 75 pg/mL or less and 25(OH)D<sub>3</sub> at 8 ng/mL or less significantly increase the risk of developing rickets.<sup>252</sup> The increased risk may relate to decreased ultraviolet light exposure, failure of UVB light to penetrate the thickened scale, and/or an abnormality in processing of vitamin D<sub>3</sub> in response to UVB light. Nevertheless, vitamin D<sub>3</sub> supplementation should be considered.

## Other Disorders of Differentiation

### DARIER DISEASE

Darier disease (keratosis follicularis, Darier–White disease; acral form, acrokeratosis verruciformis of Hopf) is an autosomal dominant disorder that most commonly first manifests between 8 and 15 years of age as flesh-colored papules that become covered with a yellow, waxy scaling crust (Figs. 5-31 and 5-32).<sup>253</sup> Lesions often coalesce to form thickened, warty plaques that are malodorous. Sites most often affected include the forehead, temples, ears, nasolabial folds, scalp, upper chest and back, in the so-called “seborrheic” distribution. Isolated scalp involvement has been reported and may be the presenting sign.<sup>254</sup> Linear streaks of Darier disease along Blaschko lines have been attributed to gene mosaicism.<sup>255</sup> Localized congenital Darier disease has been described and may represent type 2 mosaicism,<sup>256</sup> but Darier disease can be bilateral and present during infancy (Fig. 5-33). Lesions of Darier disease are often worsened by exposure to ultraviolet

**Figure 5-30** Patients with ichthyosis are at increased risk for the development of rickets, as shown in this boy from Nigeria.

**Figure 5-31** Darier disease. Thickened, warty plaques on the forehead and temples are characteristic and tend to be symmetrically distributed.

radiation, heat,<sup>257</sup> friction, and other forms of trauma. Secondary bacterial or herpes simplex virus infection is common.<sup>258</sup> *S. aureus* has been isolated from almost 70% of lesional skin areas, and colonization is correlated with more severe disease.<sup>259</sup>

Punctate keratoses on the palms and soles, either raised or with a central pit, occur in most patients. Keratoses resembling flat warts may be found on the dorsal aspects of the hands (acrokeratosis verruciformis). In some patients, these acral keratotic lesions are the only manifestation. The nails are easily broken and often show a

**Figure 5-32** Darier disease. The discrete keratotic papules of Darier disease have led to the alternative name of *keratosis follicularis*.

**Figure 5-33** Darier disease. This infant showed erosive plaques of the genital region and histology that was suggestive of Darier disease in the first months of life. Genotyping confirmed the *ATP2A2* mutation.

characteristic V-shaped scalloping of the free edge (see Chapter 7, Fig. 7-65). Subungual thickening with streaks of discoloration and subungual hemorrhage may be seen. White, centrally depressed papules or verrucous white plaques simulating leukoplakia are often seen on the mucosae of the cheeks, palate, and gums,<sup>260</sup> and may involve the rectum and vulva. Neuropsychiatric problems including learning disability (in more than 40% of patients),<sup>261</sup> schizophrenia, bipolar disorder, and/or seizures are seen in approximately 5% of patients,<sup>262</sup> and bone cysts may be associated with Darier disease as well.<sup>263</sup>

The characteristic histopathologic changes of Darier disease include intraepidermal suprabasal clefts or lacunae and the formation of acantholytic “corps ronds” (cells with a basophilic nucleus surrounded by a clear halo) and “grains” (small, dark cells with a pyknotic nucleus) in the stratum corneum. Mutations responsible for Darier disease involve *ATP2A2*, which encodes the sarcoplasmic/endoplasmic reticulum calcium ATPase type 2 (SERCA2).<sup>264</sup> Epidermal differentiation requires elevations in calcium levels for intercellular junction assembly, and the affected enzyme participates in the calcium pump system.<sup>265-271</sup> Systemic<sup>272,273</sup> administration of retinoids has resulted in significant improvement in most affected individuals.<sup>274</sup> Infection control is of paramount importance for some

**Figure 5-34** Hailey–Hailey disease. Crusted, erosive plaques that are symmetrically distributed, especially at fold areas.

individuals. Topical application of 5-fluorouracil,<sup>275,276</sup> tacrolimus ointment,<sup>277</sup> and diclofenac gel<sup>278</sup> have been reported to be helpful. Recalcitrant areas have been treated successfully with carbon dioxide, erbium:yttrium-aluminum-garnet (YAG) and pulsed-dye lasers.<sup>279-281</sup> Miglustat, a commercially available inhibitor of sphingolipid synthesis, corrects the defect in differentiation and adhesion of Darier keratinocytes *in vitro* and may be a future systemic treatment.<sup>270</sup> Cyclooxygenase-2 inhibition has been shown to restore the UVB-induced downregulation of SERCA2 expression in keratinocytes, suggesting the possibility that celecoxib could be another therapeutic modality for Darier disease.<sup>282</sup>

#### HAILEY–HAILEY DISEASE (FAMILIAL BENIGN PEMPHIGUS)

Hailey–Hailey disease is an autosomal dominant genodermatosis characterized by recurrent vesicles and erosions that most commonly appear on the sides and back of the neck, in the axillae, in the groin, and in the perianal regions (Fig. 5-34).<sup>283</sup> The disorder usually has its onset in the late teens or early 20s but has been reported in a 5-month-old infant.<sup>284</sup> Most cases have a fairly constant course. The primary lesions are small vesicles that occur in groups on normal or erythematous skin. The vesicles may enlarge to form bullae and rupture easily, leaving an eroded base; they exude serum and develop crusts resembling impetigo. The Nikolsky sign may be present. Lesions tend to spread peripherally with an active, often serpiginous, border, and central resolution with peripheral extension often results in circinate lesions. In the intertriginous area lesions tend to form erythematous plaques with dry crusting and soft, flat, and moist granular vegetations. Burning or pruritus is common, and particularly in the intertriginous areas lesions tend to become irritating, painful, and exceedingly uncomfortable. Mucosal involvement is uncommon, but papular lesions of the oral mucosa, esophagus, vagina, and conjunctivae have been described. As with Darier disease, mosaic forms of Hailey–Hailey disease have been described and course along lines of Blaschko<sup>285</sup>; streaks of Hailey–Hailey disease may present during childhood in individuals with genomic *ATP2C1* mutations who develop a second mutation in the normal allele (type 2 mosaicism).<sup>286</sup>

Skin sections from the advancing border of a lesion show a suprabasal vesicle with acantholysis of epidermal cells that resembles a dilapidated brick wall. Mutations have been identified in *ATP2C1*, encoding a secretory calcium ( $\text{Ca}^{++}$ )/manganese ( $\text{Mn}^{++}$ )-adenosine triphosphatase (ATPase) pump of the Golgi apparatus.<sup>287</sup>

The cutaneous lesions of Hailey–Hailey disease are induced by several external stimuli, particularly heat, humidity, friction from ill-fitting clothing, exposure to ultraviolet light, and bacterial or candidal infection. Intervention includes avoidance of these precipitating factors through wearing lightweight clothing, avoidance of friction and overheating, and treatment with topical or systemic antimicrobials as required for colonization or infection. Patients may experience spontaneous improvement with exacerbations and remissions. Topical

**Figure 5-35** Porokeratosis. Multiple erythematous annular lesions surrounded by a wall-like ridge of scaling.

**Figure 5-36** Porokeratosis. Annular lesions with a hyperkeratotic peripheral wall-like ridge.

application of corticosteroids or calcineurin inhibitors<sup>288</sup> has been the mainstay of treatment for most patients; topical calcitriol has led to improvement as well.<sup>289</sup> Topical application of gentamicin led to lesional clearance in a patient with an *ATP2C1* premature stop mutation, attributed both to the antibacterial effect and to the ability of aminoglycoside therapy to induce readthrough of a pathogenic non-sense mutation<sup>290</sup>; oral antibiotics are used for recurrent secondary infections. Because of the role of sweating as an exacerbation, botulinum toxin type A injections have been useful for selected patients.<sup>291</sup> In persistent and disabling cases, oral retinoids,<sup>292</sup> photodynamic therapy,<sup>293</sup> ablative laser therapy, dermabrasion, or excision of involved regions followed by split-thickness skin grafts have been used.

## Porokeratoses

The porokeratoses are a group of hyperkeratotic disorders characterized by a thread-like raised hyperkeratotic border that shows a typical thin column of parakeratosis, or cornoid lamella, on histologic examination of lesional tissue.<sup>294,295</sup> The cornoid lamella can be more easily seen clinically by dermoscopy.<sup>296</sup> Porokeratosis is thought to be a disorder of dysregulated keratinization with epidermal cell hyperproliferation and premature apoptosis of keratinocytes.<sup>297</sup>

The porokeratoses may appear in several forms:

1. Classic porokeratosis of Mibelli
2. Linear porokeratosis
3. Porokeratotic eccrine ostial and dermal duct nevus (PEODDN)
4. Punctate porokeratosis
5. Porokeratosis palmaris et plantaris disseminata (PPPD)
6. Disseminated superficial actinic porokeratosis (DSAP).

Porokeratosis of Mibelli may manifest as one, a few, or many annular lesions that usually appear during childhood, enlarge over years, and persist indefinitely (Figs. 5-35 and 5-36).<sup>298</sup> Boys are affected more commonly than girls. The disorder has a predilection for the face, neck, forearms, and hands but also may affect the feet, ankles, buccal mucosa, and glans penis. Porokeratosis on the scalp may be associated with alopecia. The initial lesion begins as a crateriform hyperkeratotic papule that gradually expands to a plaque of circinate or irregular

contour measuring from a few millimeters to several centimeters in diameter. If several lesions are present, they are usually unilateral. The diagnostic feature of this disorder is the raised hyperkeratotic peripheral ridge, which has been compared to the Great Wall of China. Lesions are commonly mistaken for tinea corporis, warts, or granuloma annulare.

Linear porokeratosis presents in infancy or childhood as one to several collections of porokeratotic lesions that resemble porokeratosis of Mibelli but follow the lines of Blaschko, similar to epidermal nevi.<sup>299,300</sup> Ulcerated forms of linear porokeratosis have been described.<sup>301</sup>

PEODDN could be considered a form of linear porokeratosis, except that the porokeratosis involves adnexal structures, specifically the eccrine ostia and ducts and hair follicles.<sup>302-304</sup> PEODDN includes the previously termed *porokeratotic eccrine and hair follicle nevus* and *porokeratotic adnexal ostial nevus*. The nevus may be present at birth and if not, usually appears during the first years of life and occasionally during adulthood. Lesions present as multiple asymptomatic hyperkeratotic sometimes spiny papules and plaques, and punctate pits, often filled with a comedo-like keratin plug.<sup>305,306</sup>

The collections of papules tend to be distributed along Blaschko lines, particularly on the distal extremities, although lesions have been described on the face, proximal extremities, and trunk, including associated with unilateral breast hypoplasia. Lesions may be erythematous and eroded, especially during the neonatal period. Biopsy sections show a dilated eccrine acrosyringium and, in some cases, hair follicle with an overlying cornoid lamella. In most patients, the lesions are static, but progressive extension has been described. Spontaneous improvement of lesions on the extremities has been noted, whereas lesions on the palms and soles tend to persist. The association of spiky hyperkeratotic papules with deafness<sup>307</sup> and KID syndrome<sup>308</sup> have suggested that PEODDN results from a *GJB2* mutation (encoding connexin 26), which has now been demonstrated.<sup>309</sup>

Punctate porokeratosis presents as 1- to 2-mm punctate papules of the palms and soles during adolescence or adulthood. The peripheral raised rim may be difficult to appreciate, and differentiation from keraoderma punctata, Darier disease, and Cowden disease may require biopsy.

PPPD is an autosomal dominant variant of punctuate porokeratosis that occurs more often in males. Small “seed-like” keratotic papules

with a slightly elevated peripheral rim first develop during childhood or adolescence on the palms and soles. Lesions subsequently disseminate to other areas of the body, including parts not exposed to sunlight and the mucous membranes. Lesions may be asymptomatic to pruritic.

DSAP is the most common form of porokeratosis but rarely presents in its disseminated form during childhood<sup>310–312</sup> and only occasionally during late adolescence. Women are more often affected than men. An autosomal dominant disorder, most cases are sporadic and first show manifestations during the third or fourth decade of life. Lesions appear on sun-exposed areas of the skin, particularly on the lower legs and forearms, and are usually multiple, with most patients having more than 50 lesions. Most lesions measure 0.5 to 1 cm, with a range from 0.1 to 4.5 cm in diameter, and are asymptomatic to mildly pruritic. In contrast to the borders of the lesions of porokeratosis of Mibelli, the ridges are only slightly elevated above the cutaneous surface. Several individuals have been described with both DSAP and linear porokeratosis. Linear porokeratosis may be present during childhood in patients with DSAP as type 2 mosaicism with mutation in the normal allele (loss of heterozygosity), leading to an earlier and more severe lesion distributed along a line of Blaschko with DSAP appearing later, especially after ultraviolet light exposure.<sup>310,312–314</sup> Disseminated superficial porokeratosis is also autosomal dominant and has its onset during the third or fourth decade of life. Lesions primarily occur on the extremities and are bilaterally symmetric but do not spare sun-protected areas, as occurs in DSAP.

DSAP is a genetically heterogeneous disorder that has been shown to result most often from mutations in *MVK*, the gene encoding mevalonate kinase, which plays a role in regulating calcium-induced keratinocyte differentiation and could protect keratinocytes from apoptosis induced by UV light, a known trigger.<sup>315</sup> Immunosuppression (e.g., HIV infection or organ transplantation<sup>311</sup>) can also trigger the appearance of disseminated porokeratotic lesions.<sup>316</sup> *SLC17A9* (Solute carrier family 17, member 9) mutations also result in DSAP,<sup>317</sup> and other gene loci have been linked.<sup>318–320</sup>

Porokeratosis is a feature of CDAGS syndrome, an autosomal recessive disorder characterized by craniostenosis and clavicular hypoplasia, delayed closure of the fontanel and deafness, imperforate or anteriorly displaced anus, genitourinary malformations (especially hypospadias and urethrorectal fistula), and the porokeratotic skin eruption.<sup>321,322</sup> Other features include hearing loss and nonscarring alopecia.<sup>322</sup> The lesions typically affect the face (especially cheeks and chin) and extremities (elbows, knees, dorsal aspect of hands). The disorder has been mapped to chromosome 22q12-13,<sup>323</sup> but the underlying molecular defect is unknown.

Lesions of porokeratosis are slowly progressive and relatively asymptomatic but may require intervention for cosmesis. The development of squamous cell carcinoma or Bowen disease within lesions has occasionally been reported with all forms except the punctuate form, but the risk is highest with long-standing lesions. A variety of therapies have been used, many unsuccessfully, to destroy the abnormal clone of keratinocytes. Among these are keratolytics, diclofenac gel,<sup>324</sup> topical and oral retinoids,<sup>325,326</sup> topical imiquimod,<sup>327</sup> topical 5-fluorouracil, cantharidin,<sup>328</sup> cryotherapy, electrode desiccation, laser ablation,<sup>329,330</sup> photodynamic therapy with methyl aminolevulinate cream,<sup>331–333</sup> dermabrasion, curettage, and excision.

## Palmoplantar Keratodermas

Palmoplantar keratodermas (PPK; palmar and plantar hyperkeratosis, keratoderma of the palms and soles) describes a diffuse or localized thickening of the palms and soles that may occur as part of a genetic disorder or as an inflammatory disorder such as pityriasis rubra pilaris, psoriasis, or reactive arthritis (see Chapter 4).<sup>334,335</sup> Genetic forms of PPK may appear alone or as part of a more generalized disorder such as epidermolysis bullosa simplex and Kindler syndrome (see Chapter 13), LI, EI, Sjögren-Larsson syndrome, Conradi syndrome (see **Conradi-Hünermann-Happle Syndrome** section), pachyonychia congenita (PC), or hidrotic ectodermal dysplasia (see Chapter 7). Several classification systems have been proposed for the inherited forms of PPK, the simplest of which is diffuse, focal, or punctate PPK. The identification of the underlying molecular defect allows further

classification. Finally, a classification by functional subgroup has also been proposed and includes abnormalities in structural proteins (keratins), cornified envelopes (loricrin), cell-cell communication (connexins), cohesion (desmoplakin 1, desmoglein 1, plakophilin), and transmembrane signaling (cathepsin C).<sup>336</sup> Hereditary forms of PPK often first manifest when the affected child starts to walk and are usually symmetrical. Diffuse forms may initially appear focal, but the more extensive involvement is notable within the first few years of life.

In general, the treatment of all forms of hyperkeratosis of the palms and soles is palliative and consists of application of keratolytic formulations, such as 10% to 20% salicylic acid in a thick emollient cream (under occlusion at night if tolerated), intermittent use of Keralyt gel or 40% salicylic acid (Mediplast) plasters, periodic soaking of the affected area in water, and gentle removal of excessive keratinous material by a pumice stone, scalpel, or single-edged razor blade. Painful fissures can be treated by a formulation of 30% tincture of benzoin in zinc oxide or cyanoacrylate (Superglue) before the application of a keratolytic formulation. Patients should wear comfortable shoes and avoid pressure or friction to affected areas. Although oral retinoids are helpful, they are recommended only for short-term use for the temporary relief of individuals with significant disability; topical retinoids may be helpful for more limited keratoderma. Surgical excision and grafting has been used with variable results.<sup>337</sup> Specific therapeutic recommendations are noted below for certain forms of PPK.

## DIFFUSE KERATODERMAS

Epidermolytic PPK (EPPK; Vörner type) is an autosomal dominant disorder characterized by sharply circumscribed congenital thickening of the palms and soles (Fig. 5-37). Most patients have hyperhidrosis, which may lead to maceration and fissuring. The waxy hyperkeratosis, limited to the palms and soles, is surrounded by an erythematous border. Transgrediens (to the dorsal surface) may be seen, and some patients show thickened skin over the joints (knuckle pads).<sup>338,339</sup> Mild thickening over the elbows and knees may occur. An associated odor suggests secondary bacterial or fungal infection. Biopsy sections often show epidermolytic hyperkeratosis similar to that seen in EI, although more than one sample may be required to demonstrate the epidermolysis. Blistering, however, is not usually seen except the increased fragility that can occur with retinoid therapy. The disorder results from mutations in keratin 9, a form of keratin protein expressed only in the palms and soles.<sup>340</sup> Personalized ribonucleic-acid interference (RNAi)-based therapy has been developed in a *KRT9*-mutated mouse model of EPPK.<sup>341</sup>

Diffuse nonepidermolytic PPK (NEPPK; Unna type) is an autosomal dominant genodermatosis that clinically is indistinguishable from EPPK other than tending to be milder, but it does not show epidermolysis in biopsy sections. This form of PPK has been attributed largely to mutations in noncritical regions of the gene that encodes

**Figure 5-37** Epidermolytic palmoplantar keratoderma. Waxy thickening is limited to the palms and soles and usually surrounded by an erythematous border. This is an autosomal dominant disorder, as shown in mother and daughter.

**Figure 5-38** Knuckle pads. These hyperkeratotic plaques can be seen as an isolated entity but may be associated with palmoplantar keratoderma.

keratin 1 and to mutations in *KRT6a* or *16* (without the nail changes of PC, also caused by mutations in these genes).<sup>342</sup> Greither syndrome, with transgrediens involvement in a glove-and-sock distribution, is considered a more severe form of diffuse NEPPK, and mutations have been found in *KRT1*.<sup>343</sup> Diffuse NEPPK is a component of Naegeli-Franceschetti-Jadassohn syndrome and dermatopathia pigmentosa reticularis, allelic disorders resulting from mutations in *KRT14* that are also characterized by abnormal sweating, reticulate hyperpigmentation, absence of dermatoglyphics, and other ectodermal anomalies (see Chapter 7).<sup>344,345</sup>

PPK associated with hearing loss occurs in individuals with Vohwinkel syndrome, an autosomal dominant mutilating keratoderma characterized by extensive PPK with a distinct “honeycomb” pattern and constrictions (pseudoainhum) that may lead to amputation of distal digits.<sup>346</sup> In some cases, distinctive hyperkeratotic starfish-like plaques are present over the elbows, knees, and sometimes the knuckles. Sensorineural deafness is a common accompanying feature. Mutations in the *GJB2* gene encoding connexin 26 underlie Vohwinkel syndrome with deafness and are also responsible for KID syndrome, nonmutilating PPK with deafness, knuckle pads, and leukonychia (Bart–Pumphrey syndrome).<sup>347,348</sup> Knuckle pads can also be a feature of other forms of PPK<sup>336,338,349</sup> and occur as an isolated entity (Fig. 5-38).<sup>350</sup> The ichthyotic variant of Vohwinkel syndrome also shows PPK with a honeycomb appearance and pseudoainhum but has associated ichthyosis and no deafness (see *Loricrin Keratoderma* section, above).

Clouston syndrome (hidrotic ectodermal dysplasia) is an autosomal dominant condition that results from mutations in the *GJB6* gene encoding connexin 30 (see Chapter 7).<sup>351</sup> Keratoderma (hyperkeratosis) of the palms and soles is common and may be diffuse or focal. It occasionally extends to involve the sides and dorsal aspects of affected hands and feet. Nails grow slowly and may appear thickened or thinned, striated, discolored, brittle, or hypoplastic. The tips of the digits show pseudoclubbing (see Chapter 7, Fig. 7-22), and hyperpigmentation may overlie digital joints. Paronychial infections are common and may result in partial to complete destruction of the nail matrix. Body hair may be sparse, eyebrows and eyelashes may be thinned or absent, and the skin has a smooth texture. Scalp hair, generally normal during infancy and childhood, may become thin, fragile, or sparse to absent after puberty.

Mal de Meleda (keratosis palmoplantaris transgrediens) is an autosomal recessive form of diffuse PPK associated with inflammatory keratotic plaques that extend to the dorsal aspects of the hands and feet and may overlie joints (Fig. 5-39).<sup>352</sup> Hyperhidrosis, superinfection, and occasionally perioral erythema, brachydactyly, and nail abnormalities may be associated. Female carriers may show mild PPK with interdigital fissures and keratotic papules.<sup>353</sup> Flexion contractures and spontaneous amputation of the digits occurs in severe cases. Mal de Meleda is the result of mutations in *ARS* component B, which encodes *SLURP-1*.<sup>354,355</sup> The role of *SLURP-1* in epidermal homeostasis and tumor necrosis factor (TNF)  $\alpha$  inhibition explains the hyperproliferative and inflammatory phenotype.

**Figure 5-39** Mal de Meleda palmoplantar keratoderma. Diffuse plantar keratoderma overlying erythema that extends to the dorsal aspects of the feet and hands. The Mal de Meleda type is one of the few autosomal recessive forms of hereditary palmoplantar keratoderma.

**Figure 5-40** Olmsted syndrome. Mutilating, painful plaques of keratoderma on the palms and soles begin during infancy to early childhood.

Olmsted syndrome (mutilating PPK with periorificial plaques) is a rare autosomal dominant disorder characterized by the progressive development of mutilating, painful plaques of keratoderma on the palms and soles that begins during infancy to early childhood (Fig. 5-40).<sup>356,357</sup> The borders of the keratoderma tend to be erythematous, and hyperkeratotic plaques may affect intertriginous folds. Contractures and autoamputation from progressive constriction of the digits are common. Periorificial areas become thickened and fissured to varying degrees. Patients often show alopecia, corneal defects, and nail dystrophy. The risk of cutaneous squamous cell carcinoma is increased. Olmsted syndrome results from mutations in *TRPV3* (transient receptor potential cation channel, subfamily V, member 3),<sup>358,359</sup> which encodes a cation channel in the skin and brain that senses temperature and regulates vasoconstriction; this channel also plays a role in regulation of calcium-ion transport and hair cycling, which may explain the PPK and alopecia of Olmsted syndrome. Oral retinoids can be helpful in decreasing the keratoderma and the intense

**Figure 5-41** Huriez syndrome. Palmoplantar keratoderma is associated with sclerodactyly. Affected individuals have a high risk of developing local squamous cell carcinoma.

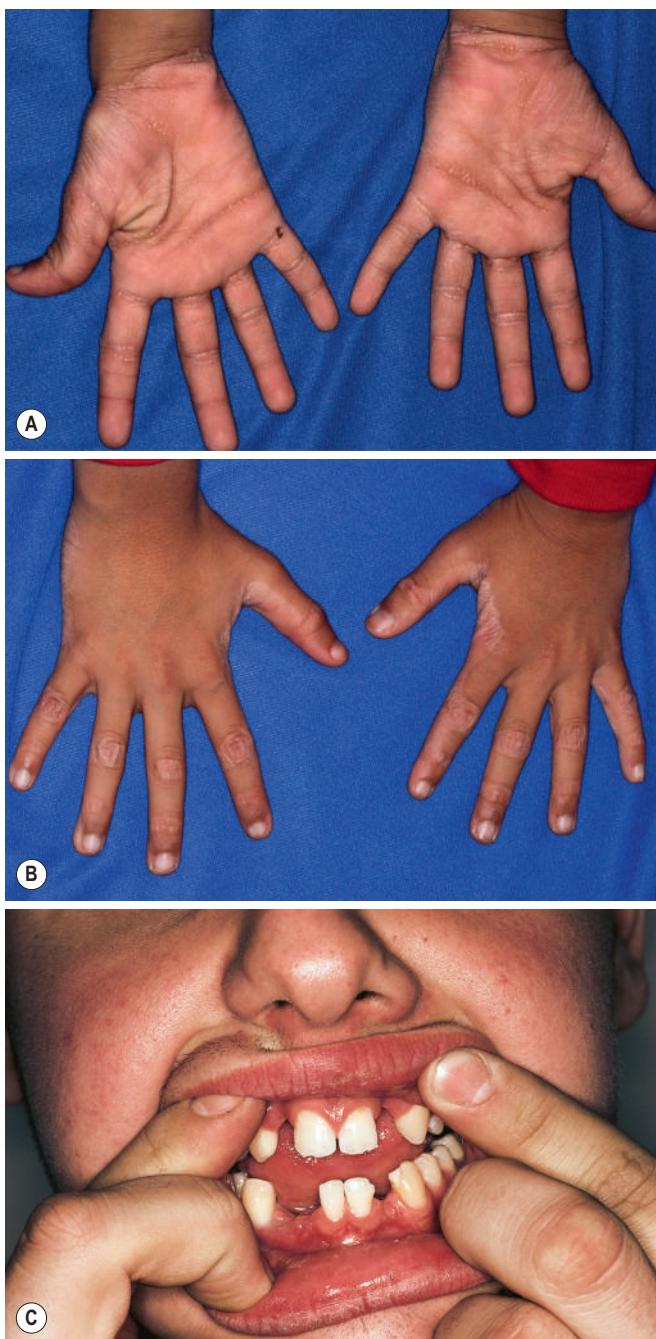

associated discomfort.<sup>360</sup> In addition to oral retinoids, EGFR inhibitors have been shown to improve the PPK.<sup>361</sup> Full-thickness excision of plaques with skin grafting has been successful in several patients.<sup>362</sup>

X-linked Olmsted syndrome has been linked to mutations in *MBTPS2*, and is allelic with IFAP and keratosis follicularis spinulosa decalvans (KFSD) syndrome (see Chapter 7).<sup>363</sup> The alopecia and mutilating keratoderma can also be seen in PPK-congenital alopecia syndrome, which can be autosomal dominant and milder or autosomal recessive and associated with pseudo-ainhum, sclerodactyly (which must be distinguished from Huriez syndrome, see next paragraph), contractures, and sometimes cataracts; the underlying cause is unclear.<sup>364</sup>

Sclerotylosis (Huriez syndrome, PPK with scleroatrophy) is an autosomal dominant PPK that presents at birth with a diffuse, symmetric keratoderma of the palms and soles. The fingers have a pseudosclerodermatous appearance with scleroatrophy (Fig. 5-41),<sup>365</sup> often with contractures and sometimes with reticulate erythema on the dorsal surface. Raynaud phenomenon is not associated. Nail abnormalities including longitudinal ridging, hypoplasia, and clubbing have been reported. Patients show an increased risk of developing squamous cell carcinoma of the palms or soles during the third and fourth decades,<sup>366</sup> and bowel cancer has been described. The gene has not yet been identified but is mapped to 4q23.<sup>367</sup> Sclerodactyly and PPK with an increased risk of squamous cell carcinoma are also features of Micali syndrome,<sup>368,369</sup> an autosomal recessive disorder that results from mutations in *RSPO1*, mapped to 1q34 and encoding R-spondin 1.<sup>370,371</sup> Variable features include chronic periodontal disease with early loss of teeth, bilateral cataracts and optic-nerve colobomata, and hypertriglyceridemia.

Deficiency of R-spondin 1 in males results in PPK and the risk of squamous cell carcinoma alone, but in female individuals with 46XX leads to sex reversal with the development of ambiguous genitalia, hypospadias, hypoplastic testes, and low testosterone levels.

Naxos disease and Carvajal syndrome (PPK with arrhythmogenic cardiomyopathy) are autosomal recessive forms of PPK associated with an early risk of sudden death from cardiac arrhythmia.<sup>372–375</sup> The keratoderma, which develops during infancy, tends to be more diffuse in Naxos disease and more striate in Carvajal syndrome. Patients with Carvajal syndrome also progressively develop striated lichenoid keratoses of the flexural areas and follicular keratoses of the knees and elbows. Both are associated with woolly hair from birth. The prominent cardiac abnormalities including electrocardiograph (ECG) changes, ventricular arrhythmias, and ventricular structural alterations may not become clinically apparent until the middle of the second decade of life. In general, right ventriculopathy has been associated with Naxos disease and left ventriculopathy with Carvajal

**Figure 5-42** Papillon-Lefèvre syndrome. Focal plaques of palmoplantar keratoderma (**A**) with transgrediens extension (**B**) are associated with the progressive periodontitis (**C**) and periosteal changes of the alveolar bone that begins during infancy or early childhood and result in loss of both deciduous and permanent teeth.

syndrome, but some patients have abnormalities of both ventricles.<sup>374</sup> The disorders result from mutations in *JUP*, which encodes the desmosomal component plakoglobin,<sup>376</sup> or in *DSP*, which encodes desmoplakin. Keratoderma and woolly hair but not cardiomyopathy can occur in individuals with mutations in *KANK2*, which encodes a non-desmosomal protein that controls activation of steroid receptors including the vitamin D receptor.<sup>377</sup>

The Papillon-Lefèvre syndrome and its variant, Haim-Munk syndrome, are autosomal recessive disorders that usually first show erythema and diffuse to localized psoriasiform hyperkeratosis of the palms (Fig. 5-42, A) and especially the soles during infancy or early childhood, coinciding with the timing of eruption of the primary

teeth.<sup>378–380</sup> The keratoderma often extends to the dorsal aspects of the hands and feet (Fig. 5-42, B). Psoriasisiform lesions occur on the knees and elbows. Rapidly progressive periodontitis and periosteal changes of the alveolar bone result in loss of both deciduous and permanent teeth (Fig. 5-42, C). Gingival involvement may manifest as early as 1 year of age and tends to be present by 5 years of age. Patients are usually edentulous by 15 years. Late-onset periodontitis after several years of PPK has also been described.<sup>381</sup>

Although an increased risk of acral lentiginous melanoma has been suggested, the reports are primarily in the Japanese population, which has a high incidence of this melanoma.<sup>382</sup> Haim–Munk syndrome (in individuals descended from Cochin, India) has the additional features of arachnodactyly, acroosteolysis, and onychogryphosis but not the calcification of the falk cerebri or susceptibility for bacterial infection described in some patients with Papillon–Lefèvre syndrome.<sup>383</sup>

Both disorders result from mutations in the *CTSC* gene, encoding cathepsin C, leading to impaired innate immune responses and desquamation from activation of serine proteases.<sup>384,385</sup> Diffuse NEPPK and chronic periodontal disease with loss of teeth are also a feature of Micali syndrome (see below). Papillon–Lefèvre syndrome responds well to topical tazarotene 0.1% cream or low-dose acitretin therapy.<sup>386</sup>

## FOCAL KERATODERMAS

PC describes a group of autosomal dominant conditions characterized most prominently by a characteristic nail dystrophy in association with painful plantar keratoderma that has a great impact on quality of life (see Chapter 7; Figs. 7-60 and 7-61). Mutations occur in one of five keratins: *KRT6a*, *KRT6b*, *KRT6c*, *KRT16*, and *KRT17*.<sup>387,388</sup> Presentation with focal PPK alone with minimal or no nail changes occasionally is caused by mutations in *KRT16* but is typical with mutations in *KRT6c*.<sup>389</sup> High-frequency ultrasound has shown bullae underlying the plantar keratoderma, which likely contribute to the pain.<sup>390</sup> Treatment is difficult, and only mechanical treatments, topical retinoids, and topical steroids have shown significant therapeutic efficacy.<sup>391</sup>

Striate PPK is an autosomal dominant condition characterized by focal keratoderma on the soles that often develops during infancy. Focal or characteristic streaks of keratoderma may develop on the palmar surface, especially if traumatized. Plantar involvement is nummular, not linear. The condition results from mutations in the gene encoding either desmoplakin or desmoglein-1<sup>392–396</sup> and affects the ability of keratin filaments to attach to the cell membrane. Striate PPK can be a feature of Carvajal syndrome and children with Costello syndrome.<sup>397</sup>

PPK and deafness due to mutations in the mitochondrial genome occur in the mitochondrial transfer RNA (tRNA) encoding the *MTTS1* gene. The focal PPK is typically first seen at 5 to 15 years of age.<sup>398</sup> Most prevalent over the plantar surface, keratotic plaques may also develop on the palm and at other pressure sites including the knees and elbows, Achilles tendons, and the dorsal surface of the toes. Palmar involvement is most pronounced in adults who are manual workers. Hearing loss occurs in approximately 60% of patients, and the PPK occurs in approximately 30%.

Richner–Hanhart syndrome (tyrosinemia type II) is an autosomal recessive disorder caused by a deficiency of hepatic tyrosine aminotransferase (mutations in the *TAT* gene)<sup>399</sup> and resulting in accumulation of tyrosine.<sup>400</sup> The early cutaneous lesions may be seen during childhood as sharply demarcated, yellowish keratotic papules of the palmar and plantar surfaces and sometimes occur during the late teenage years. The lesions become more erythematous, erosive, and painful with time. Nail dystrophy may be associated. Photophobia and bilateral tearing commonly occur within the first 3 months of life and progress to corneal erosions; herpetic ulceration is often erroneously diagnosed. Mildly affected individuals have been described, and may have just focal PPK with mild or no ocular manifestations.<sup>401,402</sup> The treatment of choice is dietary restriction of tyrosine with a low phenylalanine, low tyrosine diet.

Howel–Evans syndrome (tylosis with esophageal cancer) is a late-onset form of autosomal dominant focal PPK associated with the development of mucosal squamous cell carcinoma in 95% of affected patients by the age of 65 years, particularly of the esophageal mucosa

(38-fold increased risk).<sup>403</sup> The PPK is most prominent on pressure areas on the soles and is usually fully penetrant with the onset between 6 and 12 years of age. Palmar involvement is most prominent in manual laborers. Frictional hyperkeratosis may occur at other areas of trauma such as the elbows and knees, and oral leukokeratosis is often seen. Follicular hyperkeratoses are common and may be the initial manifestation in younger patients. The condition results from mutations in *RHBDF2*, which encodes the inactive rhomboid protease iRhom2 and results in dysregulation of EGFR signaling.<sup>404</sup>

Keratosis punctata palmaris et plantaris is an autosomal dominant disorder characterized by discrete keratoses of the palms and soles.<sup>405–407</sup>

Confined to the palmoplantar creases and volar aspects of the fingers, the central keratinous plug may be lost or can be picked out, leaving a shallow depressed pit with a keratotic base. Lesions can be particularly painful when walking or from pressure on the hands in persons who perform manual labor. The disorder results from mutations in one of two genes: heterozygous mutations in *AAGAB*,<sup>408,409</sup> which encodes a protein that participates in membrane trafficking of EGFR and other proteins, and *COL14A1*, which encodes collagen 14.<sup>410</sup> Oral retinoids have been used as treatment.<sup>411</sup> Punctate papules of the palms and soles are also a feature of porokeratosis punctata palmaris et plantaris, Cole disease (in association with guttate hypopigmentation),<sup>412,413</sup> keratosis punctata of the palmar creases, Darier disease, and Cowden syndrome (see Chapter 9).<sup>414</sup>

Aquagenic wrinkling of the palms (also called *acquired aquagenic PPK*, *aquagenic syringeal acrokeratoderma*, and *transient aquagenic palmar hyperwrinkling*) is a transient and recurrent keratoderma of the palms and lateral fingers induced by exposure to water.<sup>415–417</sup> Exposure to water elicits a whitening of the wet palm within a few minutes and visible thickening ("hand in the bucket sign"), often associated with a tight, tingling, pruritic, or even painful sensation (Fig. 5-43). The cause is thought to be influx of water across an osmotic gradient into eccrine ducts. Aquagenic wrinkling of the palms was originally described in patients with cystic fibrosis,<sup>418,419</sup> is most obvious in patients with the *DeltaF508* mutation,<sup>420</sup> and may be a cutaneous sign of carriers of cystic fibrosis.<sup>421,422</sup> Aquagenic wrinkling can also be seen in individuals with increased sweat chloride levels but without cystic fibrosis.<sup>423</sup> Unilateral involvement has been described in a child.<sup>424</sup> Tobramycin can induce aquagenic wrinkling without exposure to water.<sup>425</sup> Palmar injection of botulinum toxin has been used for symptomatic patients.<sup>426</sup> The lesions must be distinguished from hereditary papulotranslucent acrokeratoderma, an autosomal dominant disorder with onset during childhood with persistent palmar papules,<sup>427</sup> although exposure to water may lead to worsening. This condition also often begins at puberty and is often accompanied by palmar hyperhidrosis.

Exposure to water can also lead to a white, spongy appearance in autosomal dominant diffuse nonepidermolytic PPK in individuals with mutations in *AQP5*, encoding water-channel protein aquaporin-5.<sup>428</sup> This white, spongy reactivity to water exposure is also

**Figure 5-43** Aquagenic wrinkling of the palms. The palm becomes whitened and thickened within a few minutes after exposure to water.

seen in "Nagashima-type" palmoplantar keratosis, an autosomal recessive diffuse PPK in individuals of Japanese and Chinese descent. The PPK is well demarcated and erythematous with transgrediens extension to the dorsal surfaces of the hands and feet and the Achilles tendon but is mild and nonprogressive, in contrast with Mal de Meleda PPK. Nagashima-type PPK results from loss-of-function mutations in *SERPINB7*, which encodes a serine protease inhibitor, suggesting that the enhanced water permeation is caused by activation of proteases.<sup>429–431</sup>

Hereditary acrokeratoelastoidosis (of Costa) is a rare autosomal dominant disorder characterized by persistent, asymptomatic, whitish papules and plaques that are most prevalent at the margins of the hands (especially thenar and hypothenar areas) and pressure areas on the palms and soles (border of ventral and dorsal areas).<sup>432</sup> Lesions are sometimes found on the knuckles and nailfolds. The condition can begin during infancy but usually begins during adolescence. Biopsy of acrokeratoelastoidosis shows hyperkeratosis, acanthosis, and decreased numbers of coarsely fragmented elastic fibers in the dermis. Aquagenic PPK can be associated.<sup>433</sup> Although generally bilateral, unilateral involvement has been described.<sup>434</sup> The underlying genetic basis is unknown.

# 6

# Heredity Disorders of the Dermis

Several hereditary disorders of the skin primarily manifest as disorders of the dermis. Clinical manifestations range from laxity of skin to infiltrated papules and from rigidity to thinning of dermis. Disorders of mucopolysaccharides are reviewed in Chapter 24.

## Ehlers–Danlos Syndrome

Ehlers–Danlos syndrome (EDS) consists of a group of six inherited disorders of collagen characterized by increased cutaneous elasticity, hyperextensibility of the joints, and fragility of the skin, sometimes with the formation of pseudotumors and large gaping scars.<sup>1,2</sup> The 1997 Villefranche classification<sup>3</sup> is still used with some refinements and includes autosomal dominant (AD) and autosomal recessive (AR) forms; the genetic and clinical characteristics of the major subtypes of EDS are reviewed in Table 6-1. Most forms of EDS are linked to mutations in genes encoding fibrillar collagens, enzymes involved in posttranslational modification of these proteins, and extracellular matrix proteins. Mutations in type V and type III collagen cause classic or vascular EDS, respectively, whereas mutations involving the processing of type I collagen are involved in the kyphoscoliosis, arthrochalasis, and dermatosparaxis type of EDS.

The prevalence of EDS, including the mild forms, may be as high as 1:5000 individuals. The spectrum of severity of EDS ranges from almost imperceptible findings to severe, debilitating disease. Most common is the classical type (Box 6-1). The vascular type tends to be most devastating. The kyphoscoliosis, arthrochalasis, and dermatosparaxis types are considerably less common than other forms. The effect on quality of life can be considerable, and three-quarters of affected individuals report fatigue that may be impacted by pain, sleep disturbance, difficulty with concentration, and diminished social functioning.<sup>4</sup>

The skin of individuals with the classic type is velvety, soft, and has a doughy consistency. After being stretched, it returns to its normal position as soon as released, in contrast to the lax skin of cutis laxa. Skin hyperextensibility should be tested at a site not subjected to mechanical forces or scarring, such as the volar surface of the forearm (Fig. 6-1). In contrast to 10% of apparently normal individuals, approximately 50% of patients with EDS can touch the tip of their nose with their tongue (Gorlin sign) (Fig. 6-2). In addition, the skin of the hands, feet, and at times the elbows tends to be lax and redundant, thus resulting in a loose-fitting glove- or moccasin-like appearance. A number of patients have pressure-induced herniation of subcutaneous fat on the wrists or on the medial or lateral aspect of the heels, evident when the patient is standing (piezogenic pedal papules) (Fig. 6-3).<sup>5</sup> In addition to abnormal elasticity, the skin of patients with the classical (but not the hypermobile) form of EDS is extremely fragile, and minor trauma may produce gaping “fishmouth” wounds (Fig. 6-4). It has poor tensile strength and cannot hold sutures properly. This leads to dehiscence, poor healing, and the formation of wide, papyraceous, wrinkled hernia-like scars, particularly over areas of trauma (such as the forehead, elbows, knees, and shins). Blood vessels are fragile, resulting in hematomas and a chronic bruise-like appearance, particularly on the anterior aspect of the lower extremities (Fig. 6-5). The resolution of hematomas is accompanied by fibrosis, which produces soft subcutaneous nodules (pseudotumors) and calcified subcutaneous nodules, especially on the shins and forearms (spheroids). Hyperextensible joints may result in “double-jointed” fingers or subluxation of larger joints (Fig. 6-6). This may occur spontaneously or follow slight trauma. Generalized hypermobility is determined by a score of 5 or higher in the 9-point scale established by Beighton and colleagues<sup>3</sup> (Fig. 6-7; Table 6-2). Sprains, dislocations or subluxations, and pes planus occur as complications, and patients complain of

chronic joint and limb pain despite normal skeletal radiographs.<sup>6</sup> Muscle hypotonia and delayed gross motor development have been described. Hiatal hernia, postoperative hernias, and anal prolapse have been noted as manifestations of the tissue hyperextensibility and fragility.<sup>7</sup> Anomalies of the heart and dissecting aortic aneurysms have rarely been described in the classical form<sup>8</sup> in contrast to the arterial form. Mitral valve prolapse is a common manifestation, but aortic root dilation is uncommon; both can be assessed by echocardiography, computed tomography (CT), or magnetic resonance imaging (MRI) examinations.<sup>7</sup>

The diagnosis of classical EDS is primarily clinical. Routine histopathologic examination of skin from patients with EDS is usually normal but may show loose collagen and irregular fibroblasts<sup>9</sup>; electron microscopy demonstrates disorganized collagen fibers and fibrils with variable cross-sectional diameters. Studies of platelet function and coagulation are usually normal despite a tendency for bruising and increased bleeding, further implicating the defective structural integrity of skin and blood vessels.

The underlying molecular defect for 93% of patients with the classical form of EDS is mutations in the  $\alpha 1$  or  $\alpha 2$  chain of type V collagen, often leading to haploinsufficiency.<sup>10,11</sup> Type V collagen is a minor fibrillar collagen that regulates collagen fibril diameter. Patients with mutations in *COL1A1* at a nonglycine site (mutations at glycine sites lead to osteogenesis imperfecta [OI]) may exhibit features of classic EDS alone or with subtle features of OI (blue sclera, relatively short stature, osteopenia, or fractures).<sup>12</sup> Some children with nonglycine substitutions in type I collagen have classic EDS but develop spontaneous arterial rupture during adulthood.<sup>13</sup>

Several variants resemble classical EDS (see Table 6-1). A “classic-like” autosomal recessive form of EDS, caused by deficiency of the extracellular matrix protein tenascin-X, shows typical EDS but normal wound healing.<sup>14,15</sup> Heterozygous carriers may exhibit only joint hypermobility. A contiguous gene syndrome caused by a 6p deletion can present with tenascin-X deficiency as well as congenital adrenal hyperplasia (deletion in *CYP21A2*) with or without ovarian failure (deletion in *MSH5*).<sup>16,17</sup> The periodontal type (formerly type VIII EDS) is a variant of the classic type of EDS and shows variable inter- and intrafamilial clinical manifestations (including patients without skin or joint abnormalities).<sup>18</sup> The periodontal type is associated with periodontitis, a marfanoid body habitus, prominent eyes, and a short philtrum.<sup>19,20</sup> Patients with progeroid EDS (PEDS) exhibit loose, wrinkled facial skin; fine, curly hair; sparse eyebrows and eyelashes; downslanting palpebral fissures; developmental delay; skeletal abnormalities (spondyloepiphyseal dysplasia with bone fragility and severe kyphoscoliosis); and cutaneous and joint findings of classical EDS.<sup>21,22</sup> This variant is caused by biallelic mutations in either galactosyltransferase I ( $\beta 4GALT7$ ) or II ( $\beta 3GalT6$ ), key enzymes in initiating glycosaminoglycan (GAG) synthesis.<sup>22-24</sup>

Patients with the hypermobile type show extensive joint hypermobility and dislocations, particularly of the shoulder, patella, and temporomandibular joints. The skin is often soft and velvety but heals well and only occasionally shows hyperextensibility. Given that up to 40% of school-age children may show a score of 5 or higher using the 9-point Beighton criteria, the diagnosis of hypermobility-type EDS may be difficult.<sup>25</sup> It is also hard to distinguish from benign joint hypermobility syndrome,<sup>26</sup> and the term *joint hypermobility syndrome* has been suggested to encompass any child with symptomatic joint hypermobility,<sup>25,27</sup> including those with hypermobility-type EDS. The autonomic burden of hypermobility-type EDS is as high as in fibromyalgia and is primarily characterized by orthostatic issues (dizziness or even transient loss of consciousness with postural change or standing), palpitations, shortness of breath, and gastrointestinal (GI) complaints.<sup>28</sup>

**Table 6-1** Classification of Ehlers–Danlos Syndrome

Type	Mutations	Skin Findings	Joint Changes	Inheritance	Other Comments
Classic*	<i>COL5A1</i> , <i>COL5A2</i> (usually haploinsufficiency)	Hyperextensibility, bruising, velvety skin, widened atrophic scars, molluscoid pseudotumors, spheroids	Hypermobility and its complications, joint dislocations	AD	Mitral valve prolapse Hernias
<b>CLASSIC VARIANTS</b>					
EDS/OI overlap	<i>COL1A1</i>	Classic EDS features		AD	Blue sclerae, short stature, osteopenia/fractures May have late arterial rupture
Cardiac valvular	<i>COL1A2</i>	Classic EDS features		AR	Severe cardiac valve issues as adult
Periodontal	Unknown	Can have classic EDS features	Can have hypermobility	AD	Periodontitis Marfanoid habitus Prominent eyes Short philtrum
Progeroid	$\beta 4GALT7$ or $\beta 3GalT6$ , encoding galactosyltransferase I or II, key enzymes in GAG synthesis	Classic EDS features	Hypermobility	AR	Loose facial skin, curly hair, alopecia, developmental delay, spondyloepimetaphyseal dysplasia with bone fragility, and severe kyphoscoliosis
Classic-like	<i>TNXB</i>	Hyperextensibility, marked hypermobility, severe bruising, velvety skin, no scarring tendency	Hypermobility	AR	Parents (especially mothers) with one <i>TNXB</i> mutation can have joint hypermobility
Hypermobility*	Unknown; some may have <i>COL5A1</i> mutations	Mild hyperextensibility, scarring, textural change	Hypermobility, chronic joint pain, recurrent dislocations	AD	Sometimes confused with joint hypermobility syndrome
Vascular*	<i>COL3A1</i>	Thin, translucent skin; bruising; early varicosities; acrogeria	Small joint hypermobility	AD	Abnormal type III collagen secretion; rupture of bowel, uterus, arteries; typical facies; pneumothorax
Kyphoscoliosis*	<i>PLOD</i> (deficient lysyl hydroxylase)	Soft, hyperextensible, bruising, atrophic scars	Hypermobility	AR	Severe muscle hypotonia, congenital kyphoscoliosis, scleral fragility and rupture, marfanoid habitus, osteopenia
<b>VARIANTS WITH KYPHOSCOLIOSIS</b>					
Spondylocheirodysplastic form	<i>SLC39A13</i> , which encodes the ZIP13 zinc transporter	Similar to kyphoscoliotic form		AR	Bone abnormalities but without congenital hypotonia and progressive kyphoscoliosis Moderate short stature, wrinkled palms with thenar and hypothenar atrophy, blue sclerae
Brittle cornea syndrome	<i>ZNF469</i> or <i>PRDM5</i>	Skin hypermobility	Joint hypermobility	AR	Kyphoscoliosis Characteristic thin, brittle cornea, ocular fragility, blue sclera, and keratoconus
FKBP14 deficient	<i>FKBP14</i>	Features of kyphoscoliotic EDS		AR	Sensorineural hearing loss Severe congenital generalized hypotonia improved by childhood
Musculocontractural	<i>CHST14</i> (encoding dermatan 4-O-sulfotransferase) or <i>DSE</i> (encoding dermatan sulfate epimerase)	Fragile, hyperextensible skin with atrophic scars and delayed wound healing	Hypermobility	AR	Progressive kyphoscoliosis, adducted thumbs in infancy, clubfoot, arachnodactyly, contractures, characteristic facial features, hemorrhagic diathesis
Arthrochalasis*	Exon 6 deletion of <i>COL1A1</i> or <i>COL1A2</i>	Hyperextensible, soft skin with or without abnormal scarring	Marked hypermobility with recurrent subluxations	AD	Congenital hip dislocation Arthrochalasis multiplex congenita Short stature
Dermatosparaxis*	Type I collagen N-peptidase <i>ADAMTS-2</i>	Severe fragility Sagging, redundant skin		AR	Also occurs in cattle

AD, Autosomal dominant; AR, autosomal recessive; EDS, Ehlers–Danlos syndrome; GAG, glycosaminoglycan; OI, osteogenesis imperfecta.

\*In original Villefranche classification.

### Box 6-1 Most Common Features of Classic Ehlers–Danlos Syndrome

- Autosomal dominant
- Skin
  - Hyperextensible
  - Velvety, doughy skin
  - Fragile, thin, poor tensile strength, gaping scars after wounding
  - Easy bruising
  - Pseudotumors and spheroids
  - Piezogenic papules
- Joints/extremities
  - Hypermobility
  - Sprains, dislocations
  - Pes planus
  - Chronic joint and limb pain
  - Muscle hypotonia, delayed motor development
- Hiatal hernia, anal prolapse
- Mitral valve prolapse

**Figure 6-1** Ehlers–Danlos syndrome (EDS). Skin hyperextensibility on the arm.

**Figure 6-2** Ehlers–Danlos syndrome (EDS). Gorlin sign is five times more common in EDS than in normal individuals. Note the scars on the forehead.

**Figure 6-3** Ehlers–Danlos syndrome. Piezogenic pedal papules are caused by pressure-induced herniation of subcutaneous fat, seen here on the lateral aspect of the heel.

The vascular type of EDS is characterized by extensive bruising and often thin, translucent skin that is not hyperextensible.<sup>7,29,30</sup> Joint hypermobility is usually limited to the digits, and only 17% of patients meet Beighton criteria.<sup>31</sup> The facial appearance is often typical, with sunken eyes, a thin upper lip, and decreased facial fat. Spontaneous rupture of arteries, particularly midsized arteries, may occur during childhood, although its peak age of incidence is the third or fourth decade of life.<sup>32,33</sup> Arterial or intestinal rupture often presents as acute abdominal or flank pain (including from GI bleeding or bowel perforation), and intracranial aneurysms may be associated with cerebrovascular accidents.<sup>34</sup> Arterial rupture is the most common cause of death. Pregnancies may be complicated by prepartum and postpartum arterial bleeding and by intrapartum uterine rupture. Vaginal and perineal tears from the delivery heal poorly, and pneumothorax occurs in 11% of affected individuals. In one series, 94% of patients with vascular EDS showed blue sclerae.<sup>31</sup>

The vascular form of EDS has been associated with mutations in type III collagen (*COL3A1*), resulting in a reduced amount of type III collagen in dermis, vessels, and viscera. The prognosis for individuals with null mutations in *COL3A1* is better than with missense or exonskipping mutations.<sup>35</sup>

Vascular EDS may be confused with periodontal EDS and Loeys–Dietz syndrome. The latter is an autosomal dominant disorder characterized by joint hypermobility with dislocations; soft velvety skin; arterial tortuosity; widespread vascular aneurysm and dissection<sup>36</sup>; and an increased risk of atopy.<sup>37</sup> The disorder has been divided into Loeys–Dietz syndrome type 1 and type 2. Patients with type 1 disease have a marfanoid habitus (but do not fulfill Ghent criteria for Marfan syndrome [MFS]), craniofacial abnormalities, and mutations in *TGFB1* (transforming growth factor [TGF]- $\beta$ 1 receptor), whereas patients with type 2 have mutations in *TGFB2R* and no craniofacial or skeletal anomalies.<sup>36</sup>

The kyphoscoliotic type of EDS is characterized by generalized joint laxity with severe muscle hypotonia at birth, which leads to gross motor delay and congenital progressive scoliosis.<sup>38</sup> Severe hypotonia is predominant during infancy, and patients are thought to have congenital muscular dystrophy or myopathies. By the second or third decade of life, patients tend to lose the ability to ambulate. The skin may be fragile and heals with atrophic scars. Easy bruising and arterial rupture have been described.<sup>39</sup> Patients often show a marfanoid habitus, osteopenia, and scleral fragility with rupture of the ocular globe. Because of *PLOD1* mutations, this form shows a deficiency of collagen lysyl hydroxylase. The diagnosis can be confirmed by finding a high ratio of lysyl pyridinoline (LP) to hydroxylysyl pyridinoline (HP) crosslinks (LP/HP) in the urine by high-performance liquid chromatography (HPLC).<sup>38,40</sup>

**A****B**

**Figure 6-4** Ehlers–Danlos syndrome. (A) Minor trauma results in a large wound on the shin. The wound dehisced despite placement of several sutures. (B) Healed wound seen in (A). Note the old discoloration and scarring on the affected leg.

The spondylocheiropathic form of EDS resembles the kyphoscoliotic form but lacks the severe muscular hypotonia from birth and progressive kyphoscoliosis. In contrast to the kyphoscoliotic form, the spondylocheiropathic form shows moderate short stature, wrinkled palms with thenar and hypothenar atrophy, blue sclerae but no other eye abnormalities, and a variety of bone abnormalities.<sup>41</sup> Biallelic mutations in *SLC39A13*, which encodes the zinc transporter protein ZIP13, important for intracellular zinc homeostasis, are causative.<sup>42,43</sup>

**Figure 6-5** Ehlers–Danlos syndrome. Blood vessels are fragile, resulting in hematomas and chronic discoloration of the anterior aspect of the lower extremities of this adolescent girl.

**Figure 6-6** Ehlers–Danlos syndrome. Hyperextensible joints may result in double-jointed fingers, as seen in this girl.

Musculocontractural EDS is a variant with characteristic facial features, multiple contractures, a hemorrhagic diathesis with large subcutaneous hematomas, and several other systemic complications; this variant has been linked to dysfunction of dermatan sulfate from mutations in both alleles of genes encoding dermatan 4-O-sulfotransferase (*CHST14*)<sup>44,45</sup> or dermatan sulfate epimerase (DSE).<sup>46</sup> Another variant with progressive kyphoscoliosis, congenital hypotonia, joint hypermobility, and hyperelastic skin results from mutations in *FK506*-binding peptidylprolyl cis-transisomerasases (*FKBP14*)<sup>47</sup>; the presence of sensorineural hearing loss aids in diagnosis. The brittle cornea syndrome (BCS), an autosomal recessive condition caused by mutations in either *ZNF469* or *PRDM5*, is characterized by thin, brittle cornea; ocular fragility; blue sclera; and keratoconus; as well as associated skin and joint hypermobility and kyphoscoliosis.<sup>48–50</sup> Lysyl hydroxylase production and urinary pyridinoline excretion are normal in these variants.

Patients with the arthrochalasis type show generalized joint hypermobility with severe recurrent subluxations and congenital bilateral hip dislocation. The skin may be hyperextensible, fragile, and easy to bruise. Early and significant muscle hypotonia, kyphoscoliosis, and mild osteopenia have been described. Mutations in *COL1A1* or *COL1A2* that result in skipping of exon 6 lead to defective collagen synthesis.<sup>51</sup>

**Figure 6-7** Marfan syndrome (MFS). The long arm span and decreased upper-to-lower body ratio are characteristic of the “marfanoid habitus.”

**Table 6-2** Brighton Scale for Generalized Joint Hypermobility ( $\geq 5/9$  Meets Criteria\*)

Finding	Negative	One Side	Both Sides
Passive flexion of thumb to forearm	0	1	2
Passive dorsiflexion of fifth finger >90 degrees	0	1	2
Hyperextension of elbows >10 degrees	0	1	2
Hyperextension of knees <sup>†</sup> >10 degrees	0	1	2

\*Present = 1.

<sup>†</sup>Touching the floor with palms open and knees fully extended.

The dermatosparaxis form of EDS is characterized by severe skin fragility with sagging, redundant skin<sup>52</sup>; wound healing leads to wide atrophic scars, especially past infancy.<sup>53</sup> The skin may be soft and doughy in texture with easy bruising. Characteristic facies, gingival hyperplasia, large umbilical and inguinal hernias, delayed closure of the fontanelles, postnatal growth failure, and premature rupture of the fetal membranes may be seen. Electrophoretic demonstration of pro-collagen  $\alpha 1(I)$  or  $\alpha 2(I)$  chains from collagen or cultured fibroblasts is seen with the arthrochalasis and dermatosparaxis forms.

## MANAGEMENT OF EHLERS–DANLOS SYNDROME

Management is mainly supportive, but cardiovascular work-up, physiotherapy, pain management, and psychological and genetic counseling may be important. Wearing a medical bracelet warning of EDS and carrying information for teachers and healthcare workers can be helpful. The Ehlers–Danlos National Foundation ([www.ednf.org](http://www.ednf.org)) is a national support group. Children with skin fragility should use protective pads on the shins, knees, and forehead to decrease the risk of laceration and bruising. Low-impact sports (such as swimming) are preferable to contact sports and weight training in patients with

hypermobility. Physical and occupational therapists or rheumatologists can suggest devices (such as splints and braces) to make movement more comfortable. Children with significant hypotonia or motor developmental delay should be referred for appropriate physical therapy to improve muscular strength and coordination. Pain medication should be tailored to individual needs. Psychological counseling to help develop coping strategies and treat depression can be important, especially in patients with hypermobility and chronic pain.

A baseline echocardiogram should be performed in all patients with EDS in order to evaluate aortic root diameter and cardiac valves. Echocardiograms should be repeated in children and adolescents approximately every 3 years if the results are normal and annually if results are abnormal. Patients who have mitral valve prolapse and regurgitation should be given prophylactic antibiotics to prevent bacterial endocarditis.

Surgical procedures present problems, because tissues are friable and difficult to suture. Therefore edges of wounds should be approximated without tension by closely spaced sutures in two layers (absorbable and retained), adhesive reinforcement (e.g., Steri-Strips) to minimize scar spread, and pressure bandages to aid healing, diminish scarring, and lower the risk of hematoma and pseudotumor formation. Sutures should be kept in place for at least twice as long as for normal skin, and use of absorbable suture material without removal has been proposed. Prophylactic antibiotics after injury and close monitoring for postoperative infection are important to minimize post-operative complications. Ascorbate is a cofactor that stimulates prolyl hydroxylase and lysyl hydroxylase, enzymes that catalyze the formation of hydroxyproline and hydroxylysine to promote collagen deposition. Doses of 2 to 4 g/day have been administered to patients with the kyphoscoliosis type to improve wound healing and decrease the bleeding tendency.<sup>54</sup> Ascorbic acid sometimes decreases the bleeding tendency in other types. Anti-inflammatory drugs may improve the musculoskeletal pain associated with EDS, but those interfering with platelet function and prolonging bleeding (acetylsalicylic acids, non-steroidal anti-inflammatory drugs [NSAIDs] other than celecoxib family) should be avoided in patients with significant bruising. Dental procedures require extra precautions as well, because of increased bleeding.<sup>55</sup> More than half of patients who undergo posterior spinal fusion for scoliosis develop various complications.<sup>56</sup>

In patients with the vascular type of EDS, invasive vascular procedures (such as arteriography and catheterization) increase the risk of vascular rupture and should be replaced by ultrasound and/or subtraction angiography. Surgery should be avoided if possible but may be required for arterial or bowel complications.<sup>57</sup> Manipulation of vascular and other tissues should be minimized if surgery is required. Celiprolol, a long-acting  $\beta_1$  antagonist and partial  $\beta_2$  agonist, decreased by threefold the incidence of arterial rupture or dissection in patients with vascular EDS.<sup>58</sup> Pregnancy for women with the vascular type of EDS is high risk (up to 12% die from uterine rupture or peripartum arterial rupture). Planned caesarean section may be preferable to vaginal delivery.<sup>59</sup> Infants with EDS are prone to premature birth because of early rupture of membranes.<sup>60</sup> Preterm delivery occurs in 40% of pregnancies with affected neonates and 21% of pregnancies of affected mothers.<sup>61–64</sup>

## Marfan Syndrome

MFS is an AD disorder that occurs in approximately 1 : 5000 persons<sup>65</sup> and affects primarily the skeletal, ocular, and cardiovascular systems.<sup>66–72</sup> Mutations primarily occur in the *FBN1* gene that encodes fibrillin-1 (66% to 91%) and rarely in *TGFBR1* or *TGFBR2*, the genes also associated with Loey–Dietz syndrome (see *Ehlers–Danlos Syndrome* section). Fibrillin-1 is secreted into the extracellular matrix and polymerizes to form microfibrils of the zonular fibers of the lens and are associated with elastic fibers in the aorta and skin.<sup>73,74</sup> The microfibrils stabilize latent TGF- $\beta$ -binding proteins (LTBPs), which bind to and maintain TGF- $\beta$  in an inactive state.<sup>68</sup> Deficiency of fibrillin-1 thus leads to TGF- $\beta$  activation. About 27% of cases occur by spontaneous mutation; recurrence as a result of parental germline mosaicism has been described.<sup>75,76</sup>

Diagnosis is best made by clinical examination (including careful cardiac evaluation and measurement of body proportions) (Box 6-2),

## Box 6-2 Most Common Features of Marfan Syndrome

- Autosomal dominant disorder
- Present in ≥75% of individuals with Marfan syndrome (MFS):
  - Positive wrist and thumb sign
- Present in ≥50% and <75% of individuals with MFS:
  - Dolichostenomelia\*
  - Pes planus
  - Joint hypermobility
  - Aortic root dilation
  - Mitral valve prolapse
  - High arched palate with crowded dentition
  - Typical facial features
  - Lens displacement (ectopia lentis)
- Present in ≥25% and <50% of individuals with MFS:
  - Pectus excavatum or carinatum requiring surgery
  - Myopia
  - Scoliosis
  - Striae

\*Dolichostenomelia refers to a habitus in which the limbs are unusually long, as is typical of MFS (*dolichos*, long; *steno*, narrow or close; *melia*, of the limbs).

echocardiography, slit-lamp ophthalmologic examination, and radiographs or imaging as needed to find criteria. Cardiac examinations should be repeated every year until adulthood.<sup>67,72</sup> Early diagnosis is critical because of the potentially fatal complications, but the clinical features evolve with advancing age and diagnosis is difficult. Family history is also important, but manifestations may not be evident until adolescence and expressivity is variable, so that generations appear to be skipped. The Ghent diagnostic criteria (Box 6-3) were simplified in 2010, eliminating major and minor criteria and giving more weight to ectopia lentis and aortic root aneurysm/dissection.<sup>77</sup> Other organ involvement contributes to a systemic score to guide diagnosis if aortic disease, but not ectopia lentis, is present. A more important role is assigned to genotyping *FBN1* and other relevant genes. Criteria now enable diagnosis of ectopia lentis; mitral valve prolapse and myopia, mild and nonprogressive aortic root dilation, marfanoid skeletal changes, and skin features (MASS); and mitral valve prolapse syndrome. Criteria are still less reliable in children, especially since several of the more specific features are age-dependent (e.g., aortic dilation, ectopia lentis, dural ectasia, protrusion acetabuli),<sup>66,67,78</sup> and care should still be made to avoid branding children unnecessarily with MFS, given the potential stigma and lifestyle restrictions.

Patients are often tall with long extremities ("marfanoid habitus"; see Fig. 6-7). The arm span characteristically is greater than the height, and after puberty the upper segment (vertex to pubis)-to-lower segment (pubis to sole) ratio is less than 0.86. Arachnodactyly, kyphoscoliosis, pectus carinatum or excavatum, and a hindfoot deformity or flat feet are commonly seen in patients with this disorder. Joint laxity from capsular, ligamentous, and tendinous involvement may cause hyperextensibility and/or dislocation. Patellar dislocation is not uncommon; dislocation of the hip, often detected during the newborn period, may be the first sign of MFS. The thumb sign (thumb extends well beyond the ulnar border of the hand when overlapped by fingers) and wrist sign (thumb overlaps the fifth finger as they grasp the opposite wrist) are screening tests for the joint hypermobility of MFS.<sup>79</sup> Dural ectasia is occasionally seen in children, and imaging is performed largely to consider an additional Ghent criterion for diagnosis, but its presence is nonspecific. Specific facial features and pneumothorax are additional criteria (see Box 6-3).

Lack of subcutaneous fat and the presence of striae, most prominent on the upper chest, arms, thighs, and abdomen, are the most common cutaneous manifestations of MFS. In addition, elastosis perforans serpiginosa (see *Elastosis Perforans Serpiginosa section*) occurs with increased incidence in patients with MFS.

The most common ocular abnormalities are lens displacement (ectopia lentis; the hallmark of ocular involvement, seen in at least 55% of affected children) and myopia (almost half of children). Retinal detachment, cataracts, or glaucoma may impair vision and cause blindness. Cardiovascular abnormalities occur in almost 70% of children with MFS. Dilatation of the aorta is the most common defect

## Box 6-3 Revised Ghent Criteria for Marfan Syndrome

Without a family history of Marfan syndrome (MFS), any of these combinations allow diagnosis:

1. Aortic diameter (Z score\* ≥2) AND ectopia lentis
2. Aortic diameter (Z ≥ 2) AND fibrillin-1 (*FBN1*) mutation
3. Aortic diameter (Z ≥ 2) AND systemic criteria (≥7 points; see criteria below)
4. Ectopia lentis AND fibrillin-1 (*FBN1*) mutation with known aortic diameter (Z ≥ 2)

With a positive family history, these features allow the diagnosis:

1. Ectopia lentis
2. Systemic criteria (≥7 points) (see criteria below)
3. Aortic diameter (Z ≥ 2 above 20 years old, ≥3 below 20 years old)

Alternative diagnoses (no family history of MFS):

Ectopia lentis syndrome: ectopia lentis with or without systemic criteria  
AND: (1) with an *FBN1* mutation but one not known to be associated with aortic diameter (Z ≥ 2) OR (2) no *FBN1* mutation  
MASS: aortic diameter (Z < 2) AND systemic criteria (≥5 with at least one skeletal feature) but without ectopia lentis  
MVP syndrome: MVP AND aortic diameter (Z < 2) AND systemic criteria (<5) without ectopia lentis

Systemic criteria (maximum total: 20 points; score >7 indicates systemic involvement):

Wrist AND thumb sign = 3 (wrist OR thumb sign = 1)  
Pectus carinatum deformity = 2 (pectus excavatum or chest asymmetry = 1)  
Hindfoot deformity = 2 (plain pes planus = 1)  
Pneumothorax = 2  
Dural ectasia = 2  
Protrusio acetabuli = 2  
Reduced US/LS AND increased arm/height AND no severe scoliosis = 1  
Scoliosis or thoracolumbar kyphosis = 1  
Reduced elbow extension = 1  
Facial features (3/5) = 1 (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia)  
Skin striae = 1  
Myopia >3 diopters = 1  
MVP (all types) = 1

MASS, Mitral valve prolapsed and myopia, mild and nonprogressive aortic root dilation, marfanoid skeletal changes, and skin features; MVP, mitral valve prolapse; US/LS, upper segment/lower segment ratio.

\*Z score is the standard deviation from normal means of the inner to inner-edge diameter of the aortic root at the sinus of Valsalva, normalized for the subject's body surface area and age.

and is generally greatest at the sinuses of Valsalva, and diffuse dilation of the proximal segment of the ascending aorta with aortic regurgitation often occurs. Mitral valve prolapse occurs in approximately 60% of affected children and adolescents.<sup>80</sup> Left ventricular dilation may predispose to patients to alterations of repolarization and fatal ventricular arrhythmias.<sup>81</sup> The most severely affected children, those with neonatal MFS, almost always have aortic dilation and severely impaired valves, leading to congestive heart failure, pulmonary hypertension, and a risk of early death.<sup>76</sup> In a child diagnosed with MFS, serial echocardiography at 6- to 12-month intervals is recommended, the frequency depending on the aortic diameter in relation to the body surface area and the rate of increase. Pregnancy has been associated with significant cardiac complications (aortic dissection, arrhythmia), postpartum hemorrhage, thromboembolism, and premature and babies who are small for gestational age.<sup>82-84</sup>

Conditions most often considered when patients have cutaneous and other system concerns are vascular-type EDS (aortic root dilation or dissection), Loeys–Dietz syndrome (aortic root dilation or dissection), homocystinuria, and MASS. Patients with MFS do not have the translucent and velvety skin or easy bruising of EDS or Loeys–Dietz syndrome. Neither type I nor type II Loeys–Dietz syndrome includes myopia or ectopia lentis, and craniosynostosis, hypertelorism, and bifid uvula, features of Loeys–Dietz syndrome, are not features of MFS.<sup>68</sup> Homocystinuria is an autosomal recessive disorder caused by mutations cystathionine β-synthase in which patients also show ectopia lentis and a marfanoid habitus; the presence of mental

retardation in patients with homocystinuria is a distinguishing feature. A defect in cobalamin C, an essential cofactor for cystathione  $\beta$ -synthase, similarly presents with marfanoid features, arachnodactyly, joint laxity, and scoliosis, in addition to macrocytic anemia and developmental delay.<sup>85</sup>

Perhaps hardest to distinguish is MASS, a marfan-like disorder caused by *FBN1* mutations but with a better prognosis. Striae are a prominent feature, and atrophic skin patches with abnormal elastic fibers may be present.<sup>86</sup> Pectus excavatum and marfanoid skeletal features are most common.<sup>87</sup> Among the distinguishing features are a stable and mild aortic root dilation and lack of ectopia lentis.

The prognosis of MFS depends on the extent and severity of cardiovascular defects. Death usually occurs in adulthood, but occasionally during childhood, as a result of cardiovascular sequelae, especially owing to complications related to dilation of the aortic root.<sup>88,89</sup> A rare neonatal form of MFS features the marfanoid body disproportion, lax skin, emphysema, ocular abnormalities, joint contractures, kyphoscoliosis, adducted thumbs, crumpled ears, micrognathia, muscle hypoplasia, and deficient subcutaneous fat over joints.<sup>90</sup> Severe cardiac valve insufficiency and aortic dilation result in death during the first 2 years of life. A neonatal progeroid variant of MFS with prematurity, congenital lipodystrophy, and frameshift mutations at the 3' end of *FBN1* has been described. In the differential diagnosis of progeria, the marfanoid habitus with accelerated linear growth, severe myopia, and dilation of the aortic bulb allow correct diagnosis.<sup>91,92</sup>

Children with MFS but without serious cardiac issues can participation in some sports but should avoid potentially harmful exertion, particularly contact sports (to protect the aorta and lens), sports with bursts of activity (such as sprinting), and isometric exercises (such as weightlifting), which might lead to further aortic root dilation, aortic rupture, or congestive heart failure.<sup>72</sup> Scuba diving should be avoided because of the risk of pneumothorax. Long-term propranolol therapy may decrease myocardial contractility,<sup>93</sup> thus decreasing the risk of aortic dilation, but the relative value of  $\beta$ -blockers versus the angiotensin receptor blocker losartan (or the combination of the two) is undergoing testing.<sup>94–96</sup> In one study, long-term treatment with doxycycline was shown to be more effective than a  $\beta$ -blocker in preventing thoracic aortic aneurysm through its inhibition of matrix metalloproteinases-2 and -9.<sup>97</sup> Aneurysmal and valvular heart defects may require prosthetic replacement, but this should be postponed as long as possible to avoid recurrent prosthesis replacement, particularly in growing children. Prophylactic replacement of the aortic root to prevent aortic dissection has led to increased life expectancy; in one recent study striae together with elevated TGF- $\beta$  and matrix metalloproteinase (MMP)-3 serum levels correlated with a higher risk of aortic dissection.<sup>98</sup> Early and regular ophthalmologic examinations are required to detect correctable amblyopia and retinal detachment. Ectopia lentis and even complete luxation may be tolerated for decades, but lens extraction may be required to treat diplopia, glaucoma, cataracts, or retinal detachment. Repair of the pectus excavatum is indicated if cardiopulmonary compromise occurs but should be delayed until skeletal maturation is nearly complete to prevent recurrence and should employ internal stabilization. Scoliosis may be lessened in adolescent girls by estrogen therapy, but this therapy may also produce an overall decrease in height. Bracing, physical therapy, and vertebral fusion may all be necessary to prevent severe scoliosis. The website for the National Marfan Foundation is [www.marfan.org](http://www.marfan.org).

## Osteogenesis Imperfecta

OI refers to a group of inherited disorders of bone fragility in which the skin may be thin, atrophic, and somewhat translucent.<sup>99–101</sup> The easy bruising and bone fractures may raise the possibility of child abuse. Wound healing may be normal, but scars are commonly atrophic or hypertrophic. Patients often show hyperlaxity of ligaments and hypermobility of joints, but joint dislocation does not occur. Blue sclerae are distinctive features in approximately 90% of patients but can also be seen in MFS and EDS; increased electron-dense granular material between scleral fibers permits scattering of light by normal pigment within the orbit. Otosclerosis with hearing loss may begin during adolescence (50% of the common type I by adulthood), and

fragile, discolored teeth are particularly common in the more unusual forms (dentinogenesis imperfecta [DI]). Patients may show mitral and aortic valve dilation and regurgitation and cystic medionecrosis of the aorta.

More than one classification scheme has recently been proposed; the newer Sillence classification<sup>101</sup> includes types 1 through 5 and the more-newly recognized, less common, and largely autosomal recessive forms based on clinical features. The classification described by Marini et al.<sup>102</sup> separates types of OI based on genetics and extends the five Sillence classification subtypes to 12 subtypes (I through XII) and an unclassified/other category (Table 6-3). OI has also been classified by severity of clinical features (mild to extremely severe), fracture frequency, bone densitometry, and level of mobility.<sup>101</sup> Changes in 16 genes may be classified under OI,<sup>101</sup> presenting variable clinical features, severity, and prognosis.<sup>102</sup> More than 85% of affected individuals have AD OI, of which most are type I OI, which is by far the mildest form.

Patients with AD OI almost all have mutations in type I collagen, which is composed of two  $\alpha 1$  (*COLA1*) and one  $\alpha 2$  (*COLA2*) polypeptide chains, forming a triple helical structure. Dominant OI can also result from mutations in *IFITM5*, leading to abnormalities in matrix mineralization. Overall, 10% to 15% of cases are autosomal recessive and result from mutation in one of at least 11 genes involved in posttranslational processing of type I collagen and bone formation (see Table 6-3). Some of these encode proteins involved in a complex required for proline (P986) hydroxylation of type I collagen (*CRTAP*, *P3H1*, *CYPB*).<sup>103–105</sup> Others are involved in collagen mineralization (*BRIL* and *PEDF*), collagen crosslinking, folding and chaperoning (*FKBP65* and *HSP47*), and osteoblast development (*osterix*, *OASIS*, *TRICB* and *WNT1*) (see Table 6-3).

Supportive orthopedic therapy includes physical therapy to prevent contractures and immobility-induced bone loss, orthoses to protect the lower limbs,<sup>106</sup> and in more severe cases bisphosphonates.<sup>107</sup> Cyclical treatment with intravenous bisphosphonates is the mainstay of medical therapy for children with moderate to severe OI and has been shown to increase bone mass density, improve muscle strength and mobility, and decrease fractures and bone pain.<sup>99,108</sup>

## Cutis Laxa

Cutis laxa (generalized elastolysis) results from mutations in one of 11 genes that disrupt the elastic tissue network in skin<sup>74,109–114</sup> (Box 6-4; Table 6-4). In general, the products of these genes are either: (1) proteins involved in the assembly of elastic fibers and upregulation of TGF- $\beta$  signaling (e.g., *ELN*, *FBLN4*, *FBLN5*, and *LTBP4*); (2) Golgi proteins that facilitate secretion of elastic network components (e.g., *ATP6V0A2*, *RIN2*, and *GORAB*); or (3) mitochondrial proteins (e.g., *PYCR1*, *ALDH18A1*, and *SLC2A10*).<sup>110</sup>

Cutis laxa can be acquired or congenital, with the genetic forms inherited as AD or autosomal recessive forms, the latter usually being more severe. An X-linked form (X-linked cutis laxa, or occipital

### Box 6-4 Most Common Features of Cutis Laxa

- Autosomal dominant or autosomal recessive forms
- Autosomal recessive forms subdivided into those with cardiovascular features (ARCL-1), those with developmental delay (ARCL-2), and those with developmental delay, athetosis, and corneal clouding (ARCL-3). A variety of underlying molecular bases for each group have been discovered (see Table 6-4)
- Skin
  - Loose, inelastic skin
  - Most common other features:
    - Facial dysmorphisms
    - Aortic dilation
    - Pulmonary artery stenosis
    - Pulmonary emphysema
    - Diverticulae: gastrointestinal, genitourinary
    - Uterine or rectal prolapse
    - Ventral, hial, inguinal hernias

ARCL, Autosomal recessive cutis laxa.

**Table 6-3** Classification of Osteogenesis Imperfecta

Type	Frequency/ Inheritance	Gene; Protein	Clinical Features	Effect of Gene Alteration
I	AD (>50%)	<i>COL1A1</i> , <i>COL1A2</i> ; type I collagen	Also called <i>nondeforming OI with blue sclerae</i> Fractures (90% to 95%), blue sclerae (100%), hearing loss (begins in adolescence and is in >50% by 40 years), vertigo, normal stature, rarely DI	Collagen I quantity
II	AD*	<i>COL1A1</i> , <i>COL1A2</i> glycine substitutions; type I collagen	Also called <i>perinatal lethal OI</i> Multiple fractures, severe rib (beading) and long bone (crumpled, accordion-like) deformities, frog leg positioning, blue-gray sclerae, small for gestational age 20% stillborn and 40% die by 1 month	Collagen I structure
III	AD	<i>COL1A1</i> , <i>COL1A2</i> glycine substitutions; type I collagen	Also called <i>progressive deforming OI</i> Severe deformities; multiple fractures with progressive deformities, short stature (<3rd %) with severe progressive scoliosis, marked osteopenia, nonambulatory Triangular face, hearing loss in adults, may have DI Progressive whitening of sclerae Majority now survive into adulthood and have normal growth velocity/decreased fractures with cyclic IV bisphosphonates	Collagen I structure
IV	AD	<i>COL1A1</i> , <i>COL1A2</i> glycine substitutions; type I collagen	Also called <i>common variable OI</i> ; milder than OI III Moderately short, mild to moderate scoliosis, recurrent fractures with variable deformity, osteoporosis Typically ambulatory DI common, adult-onset hearing loss, usually normal sclerae	Collagen I structure
V	AD (4% to 5%)	<i>IFITM5</i> ; BRIL	Also called <i>OI with calcification in interosseous membranes</i> Mild to moderate fractures (especially forearms, legs affected) and short stature, dislocation of radial head White sclerae, no DI Rarely, painful hyperplastic callus	Matrix mineralization
VI	AR	<i>SERPINF1</i> ; PEDF	Similar to type III, moderately short, scoliosis, white sclerae, no DI Abnormal bone mineralization	Matrix mineralization
VII	AR	<i>CRTAP</i> ; cartilage-associated protein	Moderately deforming Clinically types II and III, but milder forms documented Rhizomelic shortening of humerus and femur, coxa vara, "popcorn epiphyses" White sclerae, no DI	3-hydroxylation of collagen
VIII	AR	<i>LEPRE1</i> ; prolyl-3-hydroxylase-1/P3H1	Moderately deforming Clinically types II and III, but milder forms documented Rhizomelic shortening of humerus and femur, coxa vara, "popcorn epiphyses" White sclerae, no DI	3-hydroxylation of collagen
IX	AR	<i>PPIB</i> ; peptidyl-prolyl isomerase B/CyPB	Clinically types II and IV Fractures with generalized osteopenia, wide anterior fontanel Moderate growth deficiency, gross motor delay No rhizomelia or DI, white sclerae	3-hydroxylation of collagen
X	AR	<i>SERPINH1</i> ; HSP47	Clinically type III	Collagen chaperone
XI	AR	<i>FKBP10</i> ; FKBP10 (also called FKBP65)	Clinically type III Can have joint contractures	Telopeptide hydroxylation for crosslinking
XII	AR	<i>BMP1</i> ; BMP1/mTLD	Clinically type III	Collagen processing (cleaves C-propeptidase)
<b>OTHERS</b>				
	AR	<i>CREB3L1</i> ; OASIS	Clinically type III	Osteoblast development
	AR	<i>SP7</i> / <i>OSX</i> ; <i>SP7</i> / <i>osterix</i>	Clinically type II	Osteoblast development
	AR	<i>TMEM38B</i> ; TRIC-B	Clinically type III	Osteoblast development
AD/AR		<i>WNT1</i> ; <i>WNT1</i>	Clinically type II (AD) or type III (AR)	Osteoblast development
	AR	<i>PLOD2</i> ; PLOD2	Clinically type III; can have congenital joint contractures	Telopeptide hydroxylation
XLR		<i>PLS3</i> ; plastin 3	Clinically closest to type IV; no features beyond childhood fractures; manifests in hemizygous males and variable in heterozygote females	Bone formation and remodeling

AD, Autosomal dominant; AR, autosomal recessive; DI, dentinogenesis imperfecta; OI, osteogenesis imperfecta; XLR, X-linked recessive.

\*Usually new mutation; parental germline mosaicism in 2% to 6% of cases.

horn syndrome; formerly Ehlers–Danlos syndrome type IX) is now classified as a copper transport disease caused by a mutation in the copper transporting adenosinetriphosphatase (ATPase),  $\alpha$ -polypeptide ATP7A.

Patients with cutis laxa present a striking picture of loose, inelastic, redundant skin that sags and hangs in pendulous folds, as if it were too large for the body. The drooping and ectropion of the eyelids, together with the sagging facial skin and accentuation of the nasal, labial, and other facial folds, help produce the “bloodhound” or aged appearance (Fig. 6-8).

Most dominant cases result from heterozygous frameshift mutations in the gene encoding elastin.<sup>115</sup> The AD form may appear at any age and presents as a cosmetic problem with few systemic changes.<sup>116</sup> The skin in cutis laxa is extensible, but, in contrast to that of EDS does not spring back to place on release of tension. Special stains for elastic tissue (Verhoeff–van Gieson stain) of skin biopsy specimens demonstrate significantly decreased or absent dermal elastic fibers.

Systemic manifestations caused by weakened supportive tissue include aortic root dilation (55%), hernias (51%; ventral, hiatal, or inguinal), pulmonary emphysema (37%), pulmonary artery stenosis, diverticulae of the GI tract or urinary bladder, and uterine or rectal

Figure 6-8 Cutis laxa. Sagging skin in an affected 8-year-old child.

**Figure 6-9** Cutis laxa. This 2-year-old girl with fibulin-4 deficiency shows the sagging infraorbital and cheek skin of cutis laxa.

prolapse.<sup>115</sup> In patients with the severe autosomal recessively inherited disease, the disorder is gradually progressive, and death from pulmonary complications related to emphysema may occur early in infancy or in many instances in the second to fourth decades of life.

The autosomal recessive forms have traditionally been divided into three subgroups based on clinical characteristics, autosomal recessive cutis laxa (ARCL)-1, -2, and -3 (see Table 6-4).<sup>117-129</sup> Most genes mutated in ARCL have been identified, and the group is quite heterogeneous. All patients tend to have cutis laxa with hernias (umbilical, inguinal, diaphragmatic) and facial dysmorphisms. ARCL-1 is characterized by severe cardiopulmonary lesions, including infantile emphysema and cardiac defects, and bladder diverticulae.<sup>130</sup> Fibulin-5 deficiency has been associated with supravalvular aortic stenosis. Fibulin-4 deficiency (mutations in *FBLN4*, also called *EFEMP2*) may be associated with mild to moderate cutis laxa and has been linked to arachnodactyly, tortuous vessels with aneurysm, joint laxity, microcephaly, bone fractures, and pulmonary artery occlusion<sup>131</sup> (Fig. 6-9). Fibulins-4 and -5 are critical in elastic fiber assembly in the skin and other elastic tissues. More recently, *LTBP4* mutations (ARCL type 1C) have been found in patients with emphysema and severe GI and genitourinary (GU) tract involvement but no vascular abnormalities.

Patients with ARCL-2 (which includes “wrinkly skin syndrome”) have mild cutis laxa with growth, distinct facial features, and developmental delay without prominent vascular lesions or emphysema, in contrast to ARCL-1. Patients with ARCL-2A may show pretibial pseudoeccymotic skin lesions that resemble those found in EDS.<sup>132</sup> ARCL-3 or De Barsy syndrome<sup>126</sup> can be distinguished from ARCL-2 by athetoid movements and corneal opacities, but otherwise there is overlap between ARCL-2 and ARCL-3.<sup>126,127,133,134</sup> Geroderma osteodysplastica, resulting from mutations in *GORAB*, shows features of ARCL-2A and ARCL-3 (De Barsy syndrome) but has no associated corneal opacities or athetoid movement and characteristically has osteopenia with fractures.

Cutis laxa is also a component of several additional syndromes (Box 6-5). Cutis laxa is a component of macrocephaly, alopecia, cutis laxa, and scoliosis (MACS) syndrome, an autosomal recessive disorder that results from deficiency of *RIN2*, leading to decreased fibulin-5 and microfibrils.<sup>141</sup> Arterial tortuosity syndrome (ATS) features facial dysmorphism, vessel tortuosity, and joint laxity with scoliosis. Costello syndrome is an AD disorder characterized by soft, loose skin of the neck, hands, and feet with excessive wrinkling and deep creases resembling cutis laxa.<sup>135,142,143</sup> The digits tend to be hyperextensible with loose skin and characteristic ulnar deviation at the wrist (Fig. 6-10). Affected children develop papillomata around the nares, mouth (Fig. 6-11), and anal areas; acanthosis nigricans; and sometimes striate palmoplantar keratoderma. Although prenatal overgrowth and polyhydramnios occur, patients tend to have postnatal failure to thrive and a distinctive appearance with craniofacial findings that resemble those of lysosomal storage disorders. The facies are coarse with thick lips, macroglossia, and relative macrocephaly. Severe short stature, mental retardation, curly hair, palmoplantar keratoderma

**Figure 6-10** Costello syndrome. Note the loose, hyperextensible skin of the digits.

GAPO, Growth retardation, alopecia, pseudoanodontia and optic atrophy; SCARF, skeletal abnormalities, cutis laxa, craniostenosis, psychomotor retardation, and facial abnormalities.

#### Box 6-6 Associations with Acquired Cutis Laxa

- Infections: *Toxocara canis* (cat scratch); *Treponema pallidum* (syphilis); *Borrelia burgdorferi* (Lyme disease); *Onchocerca volvulus* (onchocerciasis)
- Medications: isoniazid; penicillins; D-penicillamine
- Inflammatory diseases: celiac disease; sarcoidosis; dermatitis herpetiformis
- Rheumatic disorders: systemic lupus erythematosus; rheumatoid arthritis
- Others:  $\alpha$ 1-antitrypsin deficiency; mastocytosis; nephrotic syndrome; amyloidosis; malignancy

(sometimes striate), and hypertrophic cardiomyopathy are other associated manifestations. Costello syndrome results from activating mutations in *HRAS*<sup>146-148</sup> and is associated with a 15% lifetime risk for malignancy, most commonly rhabdomyosarcoma.<sup>149</sup> Cutis laxa has also been described in children with Lenz-Majewski syndrome in association with generalized hyperostosis, proximal symphalangism, syndactyly, brachydactyly, mental retardation, hypertelorism, and enamel hypoplasia.<sup>136</sup> Lenz-Majewski syndrome has recently been linked to gain-of-function mutations in phosphatidylserine synthase 1 (*PTDSS1*).<sup>144</sup> Deficiency of transaldolase (TALDO) presents with hepatosplenomegaly, liver failure, and cirrhosis in association with dysmorphic features, hypertrichosis, cutis laxa, congenital heart disease, hemolytic anemia, thrombocytopenia and GU malformations<sup>145,150</sup>; patients may die *in utero* with hydrops fetalis. Cutis laxa has also been described in a child with typical Kabuki makeup syndrome.<sup>140</sup>

Cutis laxa can be an acquired condition (Box 6-6), although it occurs less commonly in children than in adults.<sup>151</sup> It can be localized, but in its generalized form ill-defined areas of loose skin appear insidiously but progressively, usually first on the face and then

**Figure 6-11** Costello syndrome. In addition to their hyperextensible joints and loose skin, affected children develop papillomata on the face, including around the nares and mouth. Note the coarse, curled eyelashes.

progressing in a cephalocaudad direction. The development of cutis laxa is often preceded by an urticarial eruption. Emphysema, aortic aneurysms with subsequent rupture, and GI and GU diverticulae have been associated. Although most affected children have not had systemic evidence of acquired cutis laxa, aortic dilation, emphysema, and severe tracheobronchomegaly have led to the demise of children with acquired cutis laxa. Children may develop cutis laxa after drug exposure to penicillin, D-penicillamine,<sup>152</sup> or isoniazid. Elastosis perforans serpiginosa may be related<sup>153</sup> (see *Elastosis Perforans Serpiginosa* section). Marshall syndrome (also called *type II acquired cutis laxa*) is a postinflammatory elastolysis characterized by well-demarcated, non-pruritic erythematous plaques that appear in crops during a period of days to weeks, often in association with fever, malaise, and peripheral eosinophilia.<sup>154</sup> Several children have developed the cutis laxa after Sweet syndrome,<sup>155</sup> with areas of cutis laxa occurring at sites of previous inflammation.<sup>156</sup> Acquired cutis laxa has recently been described in a child with extensive cutaneous mastocytosis.<sup>157</sup> Systemic involvement is rare, but fatal aortitis has been described. Interestingly, a child with acquired cutis laxa after *Toxocara* infestation was found to have compound heterozygous mutations in elastin and a fibulin-5 mutation on one allele, suggesting that environmental factors may trigger acquired cutis laxa in genetically predisposed individual.<sup>158</sup>

Therapy for cutis laxa is limited. Surgery can correct diverticulae, rectal prolapse, or hernias, and plastic surgery can make a dramatic improvement in patients, inevitably with important psychological benefit.<sup>159</sup> Unlike patients with EDS, patients with cutis laxa have no vascular fragility and heal well, enabling repeated facelift procedures. Pulmonary function studies may aid in the early detection of emphysema.

## Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum (PXE) is a genetic disorder of the elastic tissue that involves the skin, eyes, and cardiovascular system (Box 6-7).<sup>160</sup> Approximately 1 : 60,000 individuals are affected.<sup>161</sup> PXE has been linked to mutations in the adenosine triphosphate (ATP)-binding cassette (ABC) subfamily C member 6 (*ABCC6*) gene, which encodes a transmembrane ABC transporter.<sup>162,163</sup> PXE is now recognized to be a metabolic disease rather than a primary disease of elastic tissue.<sup>164,165</sup> *ABCC6* is expressed primarily in the liver and kidneys and at low levels if at all in tissues affected by PXE. Cells expressing *ABCC6* excrete nucleoside triphosphates, which are the precursors of inorganic

**Figure 6-12** Pseudoxanthoma elasticum. Xanthoma-like papules and plaques on the neck have been likened to plucked chicken skin.

### Box 6-7 Most Common Features of Pseudoxanthoma Elasticum

- Autosomal recessive
- Skin
  - Yellow papules and plaques (*peau d'orange*, "plucked chicken skin")
- Ocular
  - Angioid streaks
  - Retinal epithelial mottling (*peau d'orange*)
  - Loss of central vision
- Vascular calcifications, hemorrhage
  - Gastrointestinal bleeding
  - Hypertension
  - Cerebrovascular accidents
  - Claudication, myocardial infarction

pyrophosphate (PPi), the circulating factor that inhibits mineralization and thus prevents PXE.<sup>166</sup>

Most of the demonstrated gene mutations would be predicted to lead to autosomal recessive inheritance patterns, although pseudodominant inheritance owing to familial consanguinity has been described. PXE demonstrates marked phenotypic heterogeneity even among patients from the same family,<sup>167</sup> suggesting an important role for genetic and environmental factors.<sup>168</sup>

Lesions often develop prepubertally, especially on the lateral aspects of the neck, but may be overlooked because they are small and asymptomatic.<sup>169–171</sup> Most commonly, the diagnosis becomes apparent when the patient reaches the second or third decade of life. The severity may range from extensive flexural cutaneous elastic tissue involvement with severe retinal and cardiovascular complications, often resulting in early blindness and coronary artery disease, to primarily skin changes, milder eye findings, and rarely vascular disease. Earlier onset of cutaneous signs has not been associated with a worse prognosis. The cutaneous lesions are characterized by soft, yellowish (xanthoma-like) papules and polygonal plaques on the neck (Fig. 6-12), below the clavicles, in the axillae, and on antecubital fossae, perumbilical areas, and the perineum and thighs. They vary from several papules to linear plaques resembling plucked chicken skin, morocco leather, or orange skin (*peau d'orange*). The skin becomes more redundant with advancing age and tends to show progressive calcification at affected sites. Oral, anal, and vaginal mucosal lesions may occur, most commonly infiltration of the lip mucosa. Skin lesions that are similar clinically and ultrastructurally to PXE have been described in patients with β-thalassemia<sup>172</sup> or sickle cell anemia<sup>173</sup> or as a complication of D-penicillamine use,<sup>174</sup> but these are rare in children.

The characteristic angioid streaks are slate-gray to reddish-brown linear bands, resembling vasculature radiating from the optic papilla. Seen ultimately in 94% of patients,<sup>175</sup> angioid streaks represent

visualization of the choroid through tears in the calcified and brittle elastic lamina of the Bruch membrane.<sup>176</sup> Angiod streaks usually do not appear until the third decade of life but have been described in children as young as 10 years of age. Characteristic irregular retinal epithelial mottling (*peau d'orange*), resulting from degenerated elastic tissue, is commonly detected in children with PXE and usually precedes angiod streaks.<sup>170</sup> Loss of central vision (because of retinal hemorrhage and choroidal neovascularization with scarring, not to the angiod streaks *per se*) is the most common disability and may develop in more than 70% of patients with this complication.<sup>177</sup> These retinal changes are not pathognomonic, because they may also be found in patients with thalassemia,<sup>178</sup> sickle cell anemia, Paget disease of the bone, idiopathic thrombocytopenic purpura, acromegaly, EDS, and lead poisoning.<sup>179</sup> Carriers uncommonly may experience ophthalmologic complications.<sup>180</sup>

Calcification of degenerated elastic tissue of the internal lamina of blood vessels with subsequent hemorrhage is a common and potentially serious complication of PXE. The midsized arteries of the extremities, GI tract, and renal vasculature are sites of early manifestations of this degenerative damage. Both hypertension from resultant renal artery stenosis and GI bleeding may occur during adolescence. Late vascular sequelae in PXE include cerebrovascular accidents, intermittent claudication, and myocardial infarction. Severe coronary artery disease has been noted in adolescents with PXE and may respond to bypass surgery, and cardiovascular manifestations may be present during the first decade of life.<sup>181</sup> In addition, an infant with ABCC6 mutations and a brother with typical manifestations of PXE since adolescence died of generalized arterial calcification, leading to extensive arterial stenosis and myocardial ischemia.<sup>182</sup> Early evidence suggests that carriers of ABCC6 loss-of-function mutations have an increased risk of coronary artery disease, so parents should be counseled about preventive intervention.<sup>183</sup> Recent studies in mice suggest that statins can prevent but not reverse aberrant mineralization in mouse models of PXE.<sup>184</sup>

The diagnosis of PXE is based on the clinical findings and on histopathologic evidence of calcification in elastic tissue and basophilic degeneration of the elastic tissue in the middle and deeper zones of the dermis. Elastic tissue degeneration also affects connective tissue elements of the aorta and medium-sized muscular arteries in the heart, kidneys, GI tract, and other organs.

ABCC6 is thought to distribute to the dermis a reduced form of vitamin K. The form of vitamin K is a cofactor of matrix Gla-protein, an inhibitor of ectopic calcification, suggesting a reason for the dermal calcification.<sup>161</sup> Interestingly, a disorder that resembles severe PXE (with pendulous PXE-like skin changes that usually start during adolescence and only spares the face, hands, and feet) results from deficiency of an enzyme that activates matrix Gla-protein. This matrix Gla-protein activator ( $\gamma$ -glutamyl carboxylase or GGCX) is also important for vitamin K-dependent clotting, leading to cerebral aneurysms and a bleeding diathesis in addition to PXE-like changes.<sup>185–189</sup> Generalized arterial calcification of infancy (GACI) with extensive tissue mineralization and PXE skin involvement is allelic with PXE<sup>190</sup> but more commonly is caused by mutations in ENPP,<sup>191</sup> which only occasionally lead to PXE.

Because of the risk of progressive visual loss, patients under 40 years of age are advised to have fundus examination every other year and self-monitor visual acuity with the Amsler grid.<sup>175</sup> Patients with PXE should be advised to protect their eyes from even mild trauma and about the potential for future visual loss. Intravitreal injection of vascular endothelial growth-factor antagonists prevent neovascularization and thereby reduce the loss of visual acuity<sup>192</sup> with or without laser and photodynamic therapeutic options.<sup>176,189,193,194</sup> Because of the potential risk to eyes and calcified vessels when traumatized, contact sports and high-intensity cardiovascular exercise should be prohibited for persons with PXE. Avoidance of high-cholesterol foods and smoking, control of blood pressure, and safe aerobic exercises are always appropriate because of the vascular risks. Serial cardiac evaluation (careful auscultation and echocardiographic monitoring) to detect mitral valve prolapse and ophthalmologic examinations are important. Ultrasound studies have shown impaired left ventricular function, impaired aortic elastic properties, and a high prevalence of peripheral artery disease in patients with PXE; in these studies carriers

also showed a milder cardiovascular phenotype, suggesting the need to identify and monitor carrier of PXE.<sup>195</sup>

Early studies suggested that patients who extensively ingested dairy products rich in calcium and phosphate had more severe later disease. In addition, clinical and histologic improvement in skin lesions has been described in 50% of patients treated systemically with aluminum hydroxide.<sup>196</sup> The demonstration in a mouse model of PXE that increased dietary intake of magnesium prevents connective tissue mineralization suggests a new dietary manipulation for affected patients.<sup>197,198</sup> Warfarin has been shown to accelerate the ectopic mineralization<sup>199</sup> and should be avoided if possible. Plastic surgery may improve the appearance of sagging skin, although extrusion of calcium particles through the surgical wound may result in delayed healing and unsightly scars.<sup>200</sup> GI bleeding can usually be managed conservatively. Two support groups, the National Association for Pseudoxanthoma Elasticum and PXE International (at [www.pxe.org](http://www.pxe.org)), are available.

## Elastosis Perforans Serpiginosa

Elastosis perforans serpiginosa (EPS; also termed perforating elastoma) is a disorder of elastic tissue characterized by an annular, arciform, or linear arrangement of keratotic papules.<sup>201</sup> The individual papules measure 2 to 4 mm in diameter but collectively can lead to lesions as long as 15 to 20 cm in overall length. The papules are generally capped by a distinctive keratotic plug, which when forcibly dislodged reveals a bleeding crateriform lesion. Biopsy shows elongated tortuous channels within the epidermis that are perforated by abnormal and degenerated elastic tissue extruded from the dermis. Lesions show a predilection for distribution on the posterolateral aspects of the neck (Fig. 6-13) and occasionally the chin, cheeks, mandibular areas of the face, antecubital fossae, elbows, and knees.<sup>202</sup>

This cutaneous disorder primarily affects young persons, especially those in the second decade of life, and generally disappears spontaneously within 5 to 10 years. Up to 44% of reported cases have been seen in association with Down syndrome, OI, EDS, PXE, cutis laxa, Rothmund-Thomson syndrome, acrogeria, morphea, or MFS or as a complication of penicillamine therapy.<sup>203–206</sup> Thorough history and physical examination should suffice to consider underlying causes.<sup>206</sup> Treatment with stripping of the surface keratinous material by repeated application of Scotch tape, cryosurgery, laser, and use of keratolytic agents or imiquimod<sup>207</sup> may result in improvement of some lesions, but recurrences are common if therapy is effective.

EPS must be distinguished from three other perforating disorders of the skin that feature transepidermal elimination of altered dermal substances: reactive perforating collagenosis (Fig. 6-14), perforating folliculitis, and Kyrie disease. These perforating disorders occur more commonly in adults, especially in association with chronic

**Figure 6-13** Elastosis perforans serpiginosa. Annular, arcuate, and linear arrangement of erythematous keratotic papules on the posterolateral aspects of the neck. (Courtesy of Annette Wagner, MD.)

**Figure 6-14** Reactive perforating collagenosis. Pruritic papules with keratotic plugs stud the legs of this otherwise normal girl; biopsy is helpful in distinguishing among the perforating disorders.

**Figure 6-15** Goltz syndrome (focal dermal hypoplasia). Linear streaks of dermal hypoplasia with visible telangiectasia in an affected boy. The condition is presumed to be lethal in male individuals, suggesting that this boy's manifestation reflects postzygotic mosaicism.

#### Box 6-8 Most Prominent Features of Focal Dermal Hypoplasia (Goltz Syndrome)

- X-linked dominant, 10% of patients are male
- Linear or reticular patterns of:
  - Thinned dermis
  - Focal fat herniation
  - Hyperpigmentation or hypopigmentation
  - Papillomas
  - Ulcerations
- Ectodermal abnormalities
  - Sparse hair
  - Thin nails
  - Hypodontia, enamel hypoplasia
- Skeletal abnormalities, especially digital anomalies
- Ocular colobomas, strabismus, microphthalmia
- Diagnosis
  - Clinical features
  - Osteopathia striata (plain radiography)

renal disease and diabetes,<sup>208</sup> but can occur in children, including siblings. The underlying basis for the perforation and extrusion of dermal material is poorly understood, but skin biopsy can distinguish among them. As with EPS, treatment can be difficult. Topical retinoids and topical and intralesional corticosteroids often provide no relief; narrow-band ultraviolet B (UVB) light has been shown to decrease the pruritis and promote resolution of reactive perforating collagenosis.<sup>209</sup>

## Focal Dermal Hypoplasia

Focal dermal hypoplasia (Goltz syndrome) is characterized by linear streaks of dermal hypoplasia (Box 6-8). The condition is X-linked dominant and thought to be lethal in homozygous males; 90% of patients are female. The disorder results from mutations in *PORCN*, which encodes a protein that is critical for the secretion of Wnt, an important protein for skin and bone development.<sup>210–212</sup> Although the disorder in male individuals usually reflects postzygotic mosaicism

of the mutated *PORCN* gene<sup>213,214</sup> (Fig. 6-15), classic features of Goltz syndrome have also been described in a male with Klinefelter syndrome.<sup>215</sup>

Many of the cutaneous manifestations of focal dermal hypoplasia are present from birth.<sup>216,217</sup> These include the widely distributed linear areas of hypoplasia of the skin often with associated telangiectasia (Fig. 6-16); soft, yellow, reddish-yellow, or yellow-brown nodular outpouchings, often in a linear distribution (caused by herniation of the subcutaneous fat through the thinned dermis); and sometimes large cutaneous ulcers (caused by congenital absence of skin) that gradually heal with atrophy. Patients often show streaky hyperpigmentation or hypopigmentation, and erythematous papillomas of the affected skin or mucosae of the oral, anal, or genital region may develop. Paper-thin nails, sparseness of hair, and hypodontia with enamel hypoplasia have been described. Skeletal abnormalities are most commonly digital abnormalities (adactyly, syndactyly, and “lobster claw” deformities) (Fig. 6-17). Associated ocular abnormalities include colobomas, strabismus, and microphthalmia of the eyes. Eye, hair, teeth, and limb abnormalities without cutaneous features may also occur.<sup>218</sup> Other associated abnormalities may include umbilical or inguinal hernia, cleft lip and/or cleft palate, central nervous system abnormalities (microcephaly, mental retardation, myelomeningocele, and hydrocephalus,<sup>219</sup> giant cell tumor of bone,<sup>220</sup> and multiple basal cell carcinomas.<sup>221</sup>

Virtually all cases of focal dermal hypoplasia reveal fine parallel linear striations in the metaphyses of long bones at or near epiphyseal junctions on radiographs. Although striations can be seen with other bony abnormalities, this linear change in the metaphyseal regions of the long bones (termed *osteopathia striata*) is a very useful index for the diagnosis of this disorder. Although rarely necessary to confirm the diagnosis, biopsy of an affected area of skin can be performed and shows hypoplasia of dermal connective tissue with upward extension of the subcutaneous fat tissue almost to the normal epidermis. Even mildly affected females (from mosaicism or skewed X-inactivation) or

**Figure 6-16** Goltz syndrome. Streaks of dermal hypoplasia with visible telangiectasia that follow Blaschko lines. This girl underwent a series of pulsed-dye laser treatments, which reduced the visibility of telangiectasia and improved cosmesis on her face, arms and legs.

**Figure 6-17** Goltz syndrome. Skeletal deformities are common, especially involving the hand.

males (mosaicism) require genetic counseling because of the risk of having severely affected offspring.<sup>216,222</sup> Surgical intervention can ameliorate the developmental defects such as syndactyly or polydactyly and remove papillomas of the skin or mucous membranes. Pulsed-dye laser therapy can reduce telangiectasia, and dental care

can dramatically improve the hypodontia and enamel dysplasia.<sup>223</sup> Families can find support resources internationally through the National Foundation for Ectodermal Dysplasias (see: [www.nfed.org](http://www.nfed.org)).

Focal dermal hypoplasia should not be confused with focal facial dermal dysplasia (FFDD), which is characterized by bitemporal, round, scar-like lesions that resemble forceps marks. Thought to result from incomplete fusion of the ectodermal groove between the maxillary and mandibular prominences,<sup>224</sup> FFDD is currently classified into four subtypes. Patients with type I FFDD (autosomal dominant Brauer syndrome) have additional facial characteristics (flattened nasal tip, sparse lateral eyebrows, distichiasis [double row of eyelashes]), that are mild. FFDD type II (autosomal dominant Brauer–Setleis syndrome) is characterized by the addition of thin and puckered periorbital skin, absent eyelashes and/or distichiasis, upslanting palpebral fissures, a broad nasal tip and flat nasal bridge, and large lips.<sup>116,225</sup> Individuals with type III FFDD (autosomal recessive Setleis syndrome, see also Chapter 2) show the bitemporal lesions of focal facial dermal hypoplasia in association with a coarse facial appearance, anomalies of the eyelashes and lateral eyebrows,<sup>226,227</sup> dysplastic low-set ears, and a characteristic mouth with large lips and an inverted V contour with downturned corners. Setleis syndrome results from mutations in *TWIST2*, a transcription factor important for development.<sup>228</sup> Heterozygotes for *TWIST2* mutations may show partial features such as distichiasis and partial absence of the lower eyelashes.<sup>229</sup> Patients with type IV FFDD (autosomal recessive) usually have no other associated anomalies but may have buccal mucosal polyps<sup>230,231</sup>; type IV FFDD results from homozygous loss of function mutations in *CYP26C1*, a retinoic acid-degrading enzyme.<sup>230</sup>

Focal dermal hypoplasia must also be distinguished from microphthalmia with linear skin defects (MLS) syndrome (also called *MDAS* for *microphthalmia, dermal aplasia, and sclerocornea syndrome*).<sup>232</sup> This X-linked dominant developmental defect is characterized by microphthalmia and other eye abnormalities, in association with linear, jagged skin defects typically involving the face, scalp, neck and occasionally the upper trunk.<sup>233</sup> Other features can include short stature, developmental delay, structural brain abnormalities,<sup>234</sup> seizures, dia-phragmatic hernia, congenital heart defects, and even pseudotail,<sup>235</sup> although there is wide phenotypic variability. Mutations in mitochondrial holocytochrome C-type synthase (*HCCS*) at chromosome Xp22.2 are responsible.<sup>236</sup> *HCCS* encodes a holocytochrome C-type synthase involved in mitochondrial oxidative activity.

## Werner Syndrome

Werner syndrome (progeria of the adult) is a rare autosomal recessive disorder that results from mutations in the *WRN* gene, which encodes Werner protein, a deoxyribonucleic-acid (DNA) helicase enzyme that maintains genomic stability.<sup>237–240</sup> Patients usually develop and appear normal until adolescence when they lack the pubertal growth spurt. Premature graying of hair at the temples may be seen then, and patients develop progressive alopecia, short stature, bird-like facies, and an apparent aged appearance. Cutaneous features include sclerodermod changes of the skin of the extremities and to a lesser degree the face and neck, telangiectasias, mottled or diffuse pigmentation, keratoses, and indolent ulcers over pressure points, particularly on the soles and ankles.

Patients with Werner syndrome develop severe, often generalized vascular disease; diabetes mellitus (71%); hypogonadism (80%); osteoporosis (91%); cataracts (100%); loss of subcutaneous tissue and severe muscle wasting in the legs, arms, feet, and hands with large abdominal fat deposits (leading to a body habitus of a stocky trunk with spindly extremities)<sup>241</sup>; soft-tissue calcification; a high-pitched voice or hoarseness; and a predisposition to neoplastic disease (hepatoma, thyroid adenocarcinoma, ovarian carcinoma, melanoma, meningioma, leukemia, fibrosarcoma, osteogenic sarcoma, and carcinoma of the breast).<sup>242,243</sup> Patients may be thought to have insulin resistance with lipodystrophy<sup>241</sup> or scleroderma.<sup>244</sup> The mean age of death is 54 years. “Atypical” Werner syndrome affects about 15% of patients clinically diagnosed with Werner syndrome but results from mutations in *LMNA* (see *Progeria* section) rather than *WRN*.<sup>245</sup> Affected individuals start to show aging as young adults but at an

accelerated rate compared with patients who have Werner syndrome and usually have no diabetes or cataracts. Therapy for Werner syndrome is supportive, but a recent study in a mouse model of Werner syndrome suggests that vitamin C supplementation may reverse aging abnormalities and lengthen the life span.<sup>246</sup>

## Progeria

Progeria (Hutchinson–Gilford syndrome [HGPS]) is a rare disease that most often results from a specific mutation (1824C→T; G608G) on one allele of *LMNA*, which encodes lamin A, a component of the nuclear lamina.<sup>247–249</sup> Although this common mutation does not even change an amino acid, it does activate a cryptic splice site so that mutant lamin A precursor, or progerin, lacks a series of 50 missing amino acids and is thus permanently modified by lipid farnesylation. Farnesylation of progerin prevents its proper insertion into the nuclear lamina and leads to progressive deformities in the nuclei of patients with HGPS. It is unclear if nonfarnesylated progerin also has toxicity.<sup>250</sup> Interestingly progerin has also been shown to accumulate with aging in normal cells<sup>251</sup> and is induced in adult cells exposed to ultraviolet A (UVA) but not UVB light.<sup>252</sup>

Although the mutations in HGPS are dominant negative, an autosomal recessive form with homozygous *LMNA* mutations (R527C) has been described.<sup>253</sup> Affected children show features of HGPS but have additional GI and skeletal abnormalities, and carrier parents are asymptomatic. Atypical progeroid syndrome may result from missense *LMNA* mutations other than G608G that lead to nuclear abnormalities but are not rescued by farnesyltransferase inhibitors.<sup>254</sup>

HGPS first manifests by 24 months of age with cutaneous alterations (mean age is <12 months).<sup>255</sup> The most reported early skin feature is sclerodermod change, which most commonly involves the abdomen and bilateral lower extremities.<sup>255</sup> Other early changes are perioral and nasolabial cyanosis, prominent superficial veins of the scalp and body (Fig. 6-18), hypopigmentation and hyperpigmentation at sites of sclerodermatos change, and scalp alopecia, which progresses in a predictable pattern with midscalp and vertex area loss after other areas.<sup>255–257</sup> Patients progressively develop additional signs of premature aging including early skin wrinkling, osteopenia with fractures, and atherosclerosis.<sup>258</sup> Other characteristics are reduced birthweight with postnatal growth retardation<sup>259</sup>; profound midfacial hypoplasia and micrognathia but the appearance of hydrocephalus because upper head size is minimally reduced; and generalized atrophy of muscle and subcutaneous tissue with a beaked nose and a bird-like appearance. The teeth become crowded, irregular in form, or deficient in number, and deciduous dentition is often retained.<sup>260</sup> Speech

becomes high-pitched and squeaky, and intelligence is generally normal. The chest becomes narrow and the abdomen protuberant; owing to a mild flexion of the knees, a “horse-riding” stance becomes apparent.

Cardiac murmurs commonly occur after the age of 5 years and are soon followed by atherosclerosis-induced hypertension, cardiomegaly, angina, myocardial infarction, and congestive heart failure. Without intervention, death usually occurs at a mean age of 13.4 years, usually owing to the coronary artery disease.<sup>261</sup> Progeria should be distinguished from scleroderma and from atypical Werner, Hallermann–Streiff, Cockayne, Bloom, and Rothmund–Thomson syndromes.

Growth hormone treatment increases weight by approximately 50% and linear growth by only about 10%. In preclinical models, treatment with three medications have been found to reverse the nuclear distortion in progeric cells: farnesyltransferase inhibitors, the combination of a bisphosphonate and a statin, and rapamycin, although all three have different effects on the many abnormalities in progeric cells.<sup>262,263</sup> Farnesyltransferase inhibitor treatment for at least 2 years has led to some type of improvement in all treated patients involving weight, cardiovascular flexibility, bone structure, and/or sensorineural hearing.<sup>264</sup> Farnesyltransferase inhibitor therapy also increased mean survival by 1.6 years<sup>265</sup> and decreased the rate of clinical strokes, headaches, and seizures.<sup>266,267</sup> A trial of statin and bisphosphonate<sup>268</sup> is ongoing.

## Restrictive Dermopathy

Restrictive dermopathy is a rare, fatal autosomal recessive disorder characterized by taut, translucent, thin skin with erosions and fissures.<sup>269,270</sup> The intrauterine course is characterized by polyhydramnios with reduced fetal movements beginning at about 31 weeks' gestational age.<sup>271,272</sup> Clavicular hypoplasia is a consistent *in utero* characteristic.<sup>273</sup> Affected neonates show a dysmorphic facies (fixed round open mouth with micrognathia, a small pinched nose, hypertelorism, enlarged fontanelles, and widened sutures) and flexion contractures. Death usually occurs shortly after birth<sup>274,275</sup> owing to pulmonary atelectasis, but affected babies have survived as long as months with respiratory and nutritional support. Biopsy sections show a flat epidermal junction and a thin dermis with compact collagen fibers, sparse elastic fibers, and rudimentary skin appendages. Restrictive dermopathy most commonly results from loss of function mutations in both alleles of *ZMPSTE24* (*FACE1*), and occasionally from dominant negative mutations in *LMNA*.<sup>276–280</sup> *ZMPSTE24* is an important metalloproteinase that processes lamin A; in the face of *ZMPSTE24* deficiency, prelamin A accumulates and leads to nuclear membrane toxicity.

## Stiff Skin Syndrome

Stiff skin syndrome (SSS) is a highly heterogeneous condition with scleroderma-like changes and associated contractures. Characterized by cutaneous and subcutaneous induration that first develops between the neonatal period and early childhood, SSS is most severe on the legs, thighs, buttocks, and overlying joints.<sup>281–286</sup> Congenital fascial dystrophy is considered a subset in which the involvement exclusively involves the fascia. Contractures primarily involve the lower extremities with characteristic demarcation at the inguinal canal, although the shoulder girdle may also be affected.<sup>287</sup> Joint stiffness begins during early childhood, can significantly limit movement, and can be progressive, although the skin induration is relatively stable. Hypertrichosis may be associated (primarily of the lumbar area), but viscera are not affected. Biopsies show a characteristic lattice-like array of thick collagen, although the site is variable (e.g., may involve dermis and subcutaneous tissue or fascia or both); inflammation and mucin deposition are absent.<sup>288,289</sup> The condition needs to be distinguished from scleredema neonatorum, subcutaneous fat necrosis, scleroderma, and other scleroderma-like conditions, including progeria.<sup>290</sup> Systemic administration of corticosteroids and other immunosuppressive agents has resulted in no improvement. Management is through physical therapy, which should be initiated as early as possible.<sup>291</sup>

**Figure 6-18** Progeria. Alopecia, subcutaneous atrophy, prominent scalp veins, and bird-like facies. (Courtesy of Schachner LA, Hansen RC, editors. Pediatric dermatology, 3rd ed. New York: Elsevier; 2003.)

## Winchester Syndrome

This autosomal recessive disorder has been described in fewer than a dozen patients<sup>292</sup>; in the reported cases, parents have been consanguineous. It is characterized by short stature, coarse facies, corneal opacities, thickened leathery and hypertrichotic skin, hypertrophic lips and gingivae, generalized osteolysis and progressive painful arthropathy with joint stiffness and contractures of distal phalanges.<sup>293</sup> Osteolysis may first be detectable after 1 year of age and can be progressive. Symmetrical restrictive banding has been reported to develop in early adulthood.<sup>294</sup> The disorder has been attributed to mutations in both alleles of matrix metalloproteinase 2 (*MMP2*).<sup>295,296</sup> Nodulosis, arthropathy, and osteolysis (NAO) and Torg syndromes are allelic.<sup>296,297</sup>

## Buschke–Ollendorff Syndrome

Buschke–Ollendorff syndrome is an autosomal dominant disorder that when fully expressed manifests as connective tissue nevi (with increased elastic fibers, collagen, or both) and osteopoikilosis.<sup>298–302</sup> The estimated incidence is estimated at 1:20,000.<sup>303</sup> It results from loss-of-function mutations in the *LEMD3* gene, which lead to enhanced TGF-β signaling.<sup>304,305</sup> Defects in *LEMD3* have also been detected in cases of isolated osteopoikilosis. In some affected individuals, dermal lesions are absent<sup>306</sup>; in others the radiographic changes are not seen.<sup>307</sup>

The connective tissue nevi appear as collections of subtle, 3-mm, skin-colored to yellow papules or plaques (dermatofibrosis lenticularis disseminata) on the buttocks, proximal trunk, and limbs. Most patients first develop lesions in early childhood.<sup>308–310</sup> The bony lesions most commonly appear after 15 years of age. They are discrete spherical areas of increased radiodensity, most often noted in the epiphyses and metaphyses of long bone, pelvis, scapulae, and carpal and tarsal bones (Fig. 6-19). The osteopoikilosis causes no clinical problems, but in the absence of cutaneous changes may be misdiagnosed as bony metastases. Other skeletal abnormalities including short stature, otosclerosis, spinal stenosis,<sup>299</sup> supernumerary vertebrae and ribs, syndactyly,<sup>311</sup> and ossifying fibromas<sup>312</sup> have been described. Limited anterior-posterior X-rays of the hands, wrists, ankles, knees, and pelvis rather than a full skeletal survey have been recommended.<sup>313</sup> Connective

**Figure 6-19** Buschke–Ollendorff syndrome. An oncology consultation was recommended, because the small round radiodensities on X-rays of this boy with Buschke–Ollendorff syndrome were not recognized to be osteopoikilosis.

tissue nevi (isolated or in association with tuberous sclerosis or Proteus syndrome,<sup>313,314</sup> papular elastorrhexis,<sup>315</sup> morphea, and PXE are the most common disorders considered in the differential diagnosis. The lesions of papular elastorrhexis resemble dermatofibrosis lenticularis disseminata but show decreased, fragmented elastic fibers rather than elastomas. Although usually sporadic, papular elastorrhexis has been described as familial with an AD mode of inheritance.<sup>316</sup> No therapy is available or necessary.

## Lipoid Proteinosis

Lipoid proteinosis (hyalinosis cutis et mucosae) is an autosomal recessive disorder characterized by hoarseness beginning in infancy and the later appearance of yellowish, beaded papules and nodules in the skin.<sup>317–319</sup> Both the hoarseness and the cutaneous lesions result from the abnormal deposition of hyaline material at the dermal–epidermal and microvascular basement membranes and papillary dermis.<sup>320</sup> The underlying molecular basis of lipoid proteinosis is mutations in extracellular matrix protein 1 (*ECM1*), a secreted protein that may play roles in skin adhesion and protein interactions near the basement membrane.<sup>321,322</sup> Interestingly, *ECM1* is an autoantigen in lichen sclerosus (see Chapter 22).<sup>323</sup>

Hoarseness secondary to vocal cord involvement is a clinical feature in virtually every case, and adolescents and adults with this disorder can be recognized instantly because of their husky voice and thickened eyelids. The voice may be hoarse from birth or become so within the first few years of life and becomes progressively worse during early childhood. Young children most commonly show vesicles or bullae that rapidly erode and become crusted.<sup>324,325</sup> Ultrastructural analysis of these lesions and cultured keratinocytes shows “free-floating” intact desmosomes, consistent with the role of *ECM1* in cell–cell adhesion.<sup>326</sup> Peculiar linear or discrete varioliform scars subsequently develop, particularly on the face, trunk, and upper extremities (Fig. 6-20). Herpes simplex infection, impetigo, or epidermolysis bullosa may be considered as alternative diagnoses.

Patients first develop the typical discrete or confluent 2- to 3-mm yellowish-white to yellowish-brown papules in later childhood. These papules are found most commonly on the face, eyelids, neck, and hands. In about 50% of individuals, a string of bead-like papules, often followed by a loss of cilia, appears on the free eyelid margins. The flexural areas often show a yellow waxy appearance with diffuse thickening of the skin. Many adults with lipoid proteinosis have hyperkeratotic plaques on elbows, knees, and palms, with infiltrative plaques at sites of trauma.

Also characteristic in patients with extensive manifestations are eversion of the lips (with their surfaces studded with tiny yellow nodules), hypertrophic or vegetative lesions at the corners of the mouth, round papules just below the lip on the midline of the chin, and radiating fissures at the corners of the mouth. Partial alopecia of the scalp, eyebrows, eyelashes, or bearded area is common by later childhood. Other features that have been described are hypohidrosis, hypertrichosis, hypoplasia or aplasia of permanent teeth, parotid pain and recurrent parotid swelling as a result of obstruction of the Stensen duct, and impaired nail growth.

Because of hyaline deposition, the tongue becomes thick, firm, and woody; is bound to the floor of the mouth; and is difficult to extrude. The soft palate, tonsils, uvula, and undersurface of the tongue show extensive irregular yellow-white infiltrations. Dysphagia caused by pharyngeal infiltration and respiratory obstruction as a result of severe laryngeal involvement can complicate the disorder. Central nervous system involvement has been associated with attacks of rage and psychomotor or grand mal seizures. Usually, however, the central nervous system involvement is restricted to asymptomatic calcification (seen in 70% of patients older than 10 years of age), which can be seen on radiographic examination as bilateral bean-shaped opacities above the sella turcica.

Diagnosis is aided by a history of hoarseness from early childhood; thickening, stiffening, and difficulty in extrusion of the tongue; an impaired ability to swallow; characteristic involvement of the skin and mucous membranes; and histopathologic examination of involved tissue. Histologic features consist of thick homogeneous bands of

**Figure 6-20** Lipoid proteinosis. **(A)** Linear or varioliform scars develop after clearance of the vesicular, crusted lesions of childhood. **(B)** Confluent bead-like papules line the upper eyelid in about 50% of individuals with lipoid proteinosis but tend to first appear later in childhood.

eosinophilic, periodic acid-Schiff-positive, hyaline-like amorphous material in the upper dermis, with an associated patchy distribution surrounding blood vessels, sweat glands, and arrector pili muscles.

Lipoid proteinosis has a chronic but relatively benign course. Treatment is chiefly symptomatic and consists of surgical or laser removal of laryngeal nodules or tracheostomy for laryngeal obstruction and cosmetic measures such as laser resurfacing or dermabrasion for unappealing cutaneous lesions on the face or other exposed surfaces. Acitretin can improve the hoarseness<sup>327</sup> and skin lesions.<sup>325</sup>

## Infantile Systemic Hyalinosis and Juvenile Hyaline Fibromatosis

Infantile systemic hyalinosis (ISH) and juvenile hyaline fibromatosis (JHF) are similar autosomal recessive conditions that represent allelic variants resulting from mutations in the gene that encodes capillary morphogenesis gene 2 (CMG2; also called *anthrax toxin receptor 2* or *ANTXR2*).<sup>328–330</sup> CMG2 is thought to play a role in basement membrane matrix assembly and endothelial cell morphogenesis (in addition to being the receptor for anthrax).<sup>331</sup> The histologic and ultrastructural features of ISH and JHF are also similar, and a unified classification based on severity has been suggested.<sup>332</sup> The deposition of hyaline material, characterized as an acellular proteinaceous material that appears pink and glassy in routine sections, occurs in multiple organ systems.

ISH represents the most severe end of the spectrum<sup>333</sup> with manifestations present within the first few weeks of life, although intrauterine growth retardation and reduced fetal movements have been described. The predominant cutaneous findings of ISH are diffusely

**Figure 6-21** Juvenile hyaline fibromatosis. Note the nodules on the nose and the gingival hypertrophy. Fine papules can be seen on the nose and perinasal area; the patient had dozens of visible 1- to 2-mm papules on the chin as well.

thickened skin; small nodules of the perianal region, ears, and lips; and a reddish-blue to hyperpigmented discoloration overlying bony prominences.<sup>334–336</sup> The joint contractures and osteopenia lead to the frog-leg position and virtual immobility that are typical of affected infants.<sup>337</sup> Patients with ISH also develop malabsorption and a protein-losing enteropathy, leading to diarrhea and failure to thrive. Oral manifestations include thickening of the oral mucosa, extensive overgrowth of the gingival tissue, marked curvature of the dental roots, and replacement of periodontal ligament by hyaline fibrous material. These oral findings may cause difficulty in feeding and compound the nutritional deficiency resulting from malabsorption. Thyroid dysfunction has also been described.<sup>338</sup> The condition is usually fatal by 2 years of age because of recurrent pulmonary infections and diarrhea.

JHF, also known as *juvenile systemic hyalinosis*, encompasses mild to moderate disease within the spectrum of CMG2 mutations.<sup>339</sup> JHF has a later onset than ISH and patients survive into adulthood. JHF is characterized by joint contractures (especially of the small joints of the hands and feet), gingival hypertrophy, generalized osteopenia, and papular and nodular skin lesions, typically on the scalp, perianal and perinasal areas (Fig. 6-21), palms, and trunk.<sup>340,341</sup> Some children experience rectal bleeding because of the anal lesions.<sup>342</sup>

There is no satisfactory treatment at this time, although administration of interferon  $\alpha$ -2b led to remarkable improvement in skin nodules, gingival hypertrophy, and joint mobility in a girl with JHF.<sup>343</sup> Early dental intervention is important, and gingivectomy may be required<sup>344</sup> with careful anesthetic management.<sup>345,346</sup> Lesions can be partially excised if ulcerated or disfiguring.

## Hair

Hair is a protein by-product of follicles distributed everywhere on the body surface except the palms, soles, vermillion portion of the lips, glans penis, penile shaft, nailbeds, and sides of the fingers and toes. Although hair is of minimal functional benefit to humans, the psychologic effects of disturbances of hair growth are commonly a source of great concern to children, adolescents, and their parents.

In the human fetus, groups of cells appear in the epidermis at about the eighth week of gestation. These differentiate to form the hair follicles, and hair begins to develop between the eighth and twelfth weeks of fetal life. This growth continues throughout fetal development. Although there are indications that some hair is lost during gestation and at the time of birth, the majority of hairs on the newborn are 5 to 6 months old.

Lanugo hairs are fine, soft, unmedullated, and poorly pigmented hairs seen only in fetal and neonatal life, except in the rare hereditary syndrome hypertrichosis lanuginosa. They appear as a fine, dense growth over the entire cutaneous surface of the fetus. Lanugo hair is normally shed *in utero* in the seventh or eighth month of gestation but may cover the entire cutaneous surface of the premature newborn infant. Postnatal hair may be divided into vellus and terminal types. Vellus hairs are the fine, lightly pigmented hairs seen on the arms and faces of children. Terminal hairs are the mature, thick, darker hairs on the scalp, eyebrows, eyelashes, and areas of secondary-sexual hair distribution. The number and distribution of individual hair follicles are genetically determined and constant from birth. As the infant's skin grows, however, the density of hair follicles reduces from 1135 per cm<sup>2</sup> at birth to 615 per cm<sup>2</sup> by adulthood.

The average human scalp contains 100,000 hairs. The average growth rate of terminal hair is approximately 2.5 mm/week (1 cm/month). The hair shaft represents the equivalent of the stratum corneum of skin, with the follicular keratinocytes dictating the characteristics of the shaft. The hair root is characterized by three definable cyclic stages of growth: anagen (Fig. 7-1, A), catagen, and telogen (Fig. 7-1, B; Box 7-1). The human hair follicle has a fairly long phase of regular growth (the anagen phase) that lasts 2 to 6 years, with an average of 3 years. The hairs then undergo a period of partial degeneration (the catagen phase), lasting up to 3 weeks, followed by a resting (telogen or club) phase. The telogen phase of the follicle lasts for about 3 months. At the end of this time, new growth is initiated. As new hairs grow, they push out the old telogen hairs that have remained in the resting follicles. In healthy individuals, 85% to 90% of the scalp is in the actively growing anagen stage, and 1% is in the brief transitional (catagen) stage; 10% to 15% is in the resting or telogen stage, with an average of 50 to 100 hairs shed and simultaneously replaced each day. Although scalp hair has a long anagen phase, eyelash and extremity hair have a lower anagen/telogen ratio and thus tend to be shorter.

### Neonatal Hair

The first crop of terminal scalp hair is in the actively growing anagen phase at birth, but within the first few days of life there is a physiologic conversion to the telogen phase. Consequently a high proportion of neonatal scalp hairs are shed during the first 4 months of life (Fig. 7-2). This telogen shedding (telogen effluvium of the newborn) usually is gradual hair loss, particularly between 2 and 4 months and most noticeable at the occipital area. Rarely the hair loss occurs in the first 4 weeks of life in a frontal-temporal pattern.<sup>1</sup> This physiologic hair

shedding at the occipital area is not related to the baby's sleeping position (i.e., friction).<sup>2</sup> Replacement of the first terminal hairs is generally completed before the first 6 months of life. The neonatal hairline commonly extends along the forehead and temples to the lateral margin of the eyebrows. These terminal hairs gradually convert to vellus hairs during the first year of life. Premature infants are often covered by lanugo hairs, which are more densely distributed on the face, limbs, and trunk. This retention of lanugo hair is probably related to the cyclic activity *in utero* and the normal shedding of telogen vellus hairs in the fetus during the last few weeks of gestation.

### Alopecias

Clinical examination allows hair loss disorders to be divided into non-scarring (non cicatricial) or scarring (cicatricial) types (Box 7-2).<sup>3-5</sup> Causes of non-scarring alopecia include alteration of the hair growth cycle, inflammatory cutaneous disease, and structural abnormalities of the hair.<sup>6,7</sup> Some traumatic disorders such as traction alopecia, pressure alopecia, or trichotillomania can scar if severe but often resolve without clinical evidence of scarring. Evaluation typically involves gentle traction on the hair (hair-pull test) to determine if hair comes out easily (as in loose anagen syndrome, alopecia areata [AA], or telogen effluvium) and microscopic or trichoscopic evaluation of hair shafts to seek hair shaft abnormalities (Box 7-3).

#### NONSCARRING ALOPECIAS WITH HAIR SHAFT ABNORMALITIES

##### Hair Shaft Abnormalities with Increased Fragility

Variations in the structure of the hair shaft are a common occurrence and at times may provide clues to other pathologic abnormalities (Box 7-4). Because each hair shaft anomaly has a distinctive morphology, the diagnosis often can be established in the office by trichoscopy (using a dermatoscope)<sup>8</sup> (see Box 7-3)<sup>5</sup> or by microscopic examination of snipped hairs.<sup>9</sup> Other than reduction of trauma to reduce breakage, there is no effective treatment for this group of disorders.

**Trichorrhexis Nodosa.** Trichorrhexis nodosa, the most common hair shaft anomaly, is a distinctive disorder manifested by increased fragility.<sup>6,9</sup> Grayish-white nodules may be seen on the hair (Fig. 7-3), which under trichoscopy or light microscopy have the appearance of two interlocking brushes or brooms, the result of segmental longitudinal splitting of fibers without complete fracture. The disorder features dry, lusterless, short hair that is easily fractured.

Usually "acquired" in adolescents without other issues, trichorrhexis nodosa most commonly results from trauma to the hair. The injury may result from the use of hot combs, excessively hot hairdryers, hair straighteners, other chemical treatments, or from the cumulative cuticular damage from vigorous combing and brushing, repeated salt-water bathing, prolonged sun exposure, and frequent shampooing. Cream rinses and protein conditioners are helpful. If hair-straightening procedures, vigorous grooming habits, and thermal and chemical trauma to the hair are discontinued, the acquired form of trichorrhexis nodosa generally improves within 2 to 4 years.

Less commonly trichorrhexis nodosa is genetic and manifests during infancy. Infants with the autosomal dominant form show normal hair at birth, but the hair that regrows within a few months is abnormal; the hair defect tends to improve with advancing age. Trichorrhexis nodosa may also be a manifestation of children with the late-onset form of argininosuccinic aciduria, a condition that results

**Figure 7-1** Stages of growth of the hair root. **(A)** Anagen hairs are the growing hairs that comprise 90% of hair at any time and persist for several years. Anagen hairs are pigmented and have a translucent sheath. **(B)** Telogen hairs are in a resting phase that persists for 3 months. Note the small bulb and lack of sheath.

#### Box 7-1 Cyclic Stages of Human Hair Growth

1. Anagen phase (active growth phase) lasts 2 to 6 years (average 3 years)
2. Catagen phase (stage of partial degeneration) lasts 10 to 14 days
3. Telogen phase (resting stage) lasts 3 to 4 months

**Figure 7-2** Telogen shedding of the newborn. This 4-month-old girl shows generalized thinning of scalp hair, reflecting telogen effluvium.

#### Box 7-3 Special Tests of Hair and Scalp

**Hair pull:** Grasp about 50 hairs between first three fingers and pull gently but firmly away from scalp at four scalp regions (i.e., frontal, occipital, temporal bilaterally); positive pull test means more than 10% of hairs pull out easily (are in telogen) and is seen with active alopecia areata.

**Hair tug:** Hold a group of hairs with one hand and use other hand to pull away at distal end, looking for hair breakage (which can then be analyzed microscopically in a hair mount). This can be helpful with fragile hair syndromes such as monilethrix.

**Hair mount:** Hairs are separated, oriented side-by-side on a glass slide, covered with mounting medium (such as Permount), and covered with a coverslip without air bubbles. This technique allows one to distinguish anagen from telogen bulbs based on shape and pigmentation, distorted bulbs and cuticles (as in loose anagen syndrome), and hair shaft abnormalities.

**Trichoscopy:** Can replace hair mounts and microscopy when examining shaft. Disease-specific findings such as for alopecia areata (follicular openings showing yellow dots; "exclamation-point" hairs), tinea capitis (comma or corkscrew hairs), and trichotillomania (coiled or flame hairs); black dots at follicular opening suggest broken hairs and can be seen with alopecia areata, tinea, and trichotillomania.

from lack of argininosuccinase. In this condition, the hair is usually normal at birth and first becomes fragile at 1 to 2 years of age with a dull, matted appearance, especially at the occipital area. The hair defects are associated with psychomotor retardation, cerebellar ataxia, and a marked increase of argininosuccinic acid in the blood, urine, and cerebrospinal fluid.<sup>10,11</sup> Dietary treatment of the metabolic abnormality leads to normalization of the appearance and integrity of the hair. Similar clinical manifestations are found in infants with citrullinemia, caused by a deficiency of argininosuccinic acid synthetase. Trichorrhexis nodosa is the most common hair shaft abnormality, but pili torti has been described and hair bulbs may be atrophic. Some patients show an eruption that resembles acrodermatitis enteropathica. Trichorrhexis nodosa has also been described in oculodentodigital dysplasia (see [Group 2 Ectodermal Dysplasia](#) section),<sup>12,13</sup> trichothiodystrophy (TTD), and trichohepatointestinal syndrome, characterized by facial dysmorphism, liver disease, immune defects, and severe diarrhea requiring intravenous nutrition.<sup>14</sup>

**Monilethrix.** Monilethrix (beaded hair) is an autosomal dominant disorder characterized by partial alopecia from breakage and variation in hair shaft thickness with small node-like deformities that produce a beaded appearance and internodal fragility. The nodal pattern can be seen by trichoscopy but can be subtle.<sup>15</sup> In individuals with this disorder, normal neonatal lanugo hairs are shed during the first few weeks of life. The regrown hair, which generally appears at about the second month of life, is dry, lusterless, and brittle and fails to grow to

#### Box 7-2 Clinical Examination of Alopecia

1. Overall characteristics: pattern of loss, extent, color, texture, length, breakage
2. Scalp features: scarring vs. nonscarring, inflammation, trichoscopy (follicular openings), pigmentary change, scaling, crusts, pustules
3. Hair beyond scalp: eyebrows, lashes, extremity hair, secondary sexual hair if adolescent
4. Special tests: trichoscopy of shaft, hair pull, hair tug, hair mount (see Box 7-3)

#### Box 7-4 Structural Hair Shaft Defects with Fragility (and Associated Disorders)

##### Trichorrhexis Nodosa

- Trauma (most common)
- Argininosuccinic aciduria
- Citrullinemia
- Oculodentodigital dysplasia
- Trichoiodystrophy
- Trichohepatoenteric syndrome

##### Monilethrix

- Hair keratin mutations (*KRT81*, *KRT83*, *KRT86*)
- Desmoglein 4 mutations

##### Trichorrhexis Invaginata

- Netherton syndrome

##### Pili Torti

- Menkes syndrome
- Crandall syndrome
- Björnstad syndrome
- Bazek-Dupré-Christol syndrome
- Rombo syndrome
- Hypotrichosis with juvenile macular degeneration
- Mitochondrial enzyme defects

##### Trichoiodystrophy

- Group I: mutations in *XPD*, *XPB*, *p8*
- Group II: mutations in *TTDN1*
- Group III: Pollitt syndrome, Sabinas syndrome (genes unknown)

**Figure 7-3** Trichorrhexis nodosa. Grayish-white nodules, which resemble two interlocking brushes or brooms microscopically, may be seen on the hair.

any appreciable length because of breakage (Fig. 7-4, A). In severe cases, the infant may remain bald or the scalp hair may be sparse, easily fractured, and stubble-like with follicular prominence from keratosis. Although generally a disorder of scalp hair, body hairs may also be affected. The clinical findings are limited to the occiput and nape in more limited cases (Fig. 7-4, B). Occasionally this disorder is not apparent during infancy but becomes apparent later in childhood or during adult life. Follicular keratosis is associated in some pedigrees and may affect the face, scalp, and extremities. Some patients show koilonychia. Spontaneous improvement or remission may occur at puberty or during pregnancy, suggesting a hormonal influence,<sup>16</sup> but the condition may persist unchanged throughout adulthood. Administration of oral retinoids<sup>17</sup> or 2% minoxidil<sup>18</sup> have been reported to improve the alopecia.

Monilethrix most commonly is autosomal dominant and results from mutations in hair (or trichocyte) keratins. These hair keratins have a high cysteine content, making them "hard" keratins with a high degree of crosslinking. Of the 26 known hair follicle-specific

**Figure 7-4** Monilethrix. (A) The hair is dry, lusterless, brittle, and fails to grow to any appreciable length. The occipital area is most commonly and most severely affected in most cases. (B) The follicles are prominent and often hyperkeratotic. This girl was scratching at her occipital area, which led to further breakage and an erosion.

keratins, three have been associated with monilethrix and all are type II keratins.<sup>19</sup> Mutations in *KRT81* and *KRT86* are most common,<sup>20</sup> but a mutation in *KRT83* has been reported. Because keratins provide structural integrity to hair, abnormalities in these keratins lead to hair fragility with breakage occurring at the internodal sites. Mutations in hair keratins have also been linked to pure hair and nail ectodermal dysplasia (PHNED) (*KRT85*), woolly hair with hypotrichosis (*KRT71* and *KRT74*), and pseudofolliculitis barbae (*KRT75*). The majority of the hair keratins remain unlinked to human phenotypes but may impart variants in hair strength, texture, or curliness.<sup>21</sup>

Autosomal recessive monilethrix has been linked to mutations in *DSG4*, which encodes desmoglein 4, a transmembrane cell-adhesion molecule of the cadherin family that is predominantly expressed in the hair cortex and upper cuticle.<sup>22,23</sup> Desmoglein 4 is thought to integrate keratin filaments into desmosomes.<sup>24</sup> Desmoglein 4 mutations may also manifest as autosomal recessive hypotrichosis, which resembles monilethrix but lacks the characteristic beaded appearance of the hair shaft under light microscopy.<sup>25</sup>

**Pseudomonilethrix.** Pseudomonilethrix was originally described as an autosomal dominant developmental defect of fragile hair with irregularly shaped nodes.<sup>7,26</sup> In fact, the hair changes are artifactual and related to overlapping hairs under the pressure of an overlying glass slide.<sup>27</sup> Pseudomonilethrix is seen more commonly when fine hairs are handled by forceps.

**Trichorrhexis Invaginata.** Trichorrhexis invaginata (bamboo hair) is characterized clinically by dry, lusterless, easily fractured, sparse, and short hair. Under light microscopy, the hairs show a

peculiar intussusception or telescope-like invagination along the hair shaft, which microscopically resembles the ball-and-cup joints of bamboo.<sup>6,28</sup> Variations in trichorrhexis invaginata occur, most commonly “golf-tee hair,” presenting the expanded proximal end of an invaginate node.<sup>29</sup> The hair defect in trichorrhexis invaginata is thought to be abnormal keratinization of the hair shaft, which results in softening of the hair cortex and promotes intussusception of the distal portion of the hair shaft into the softer proximal portion.

Although trichorrhexis invaginata may occur as an isolated finding, this hair shaft abnormality is characteristic of Netherton syndrome (Fig. 7-5), an autosomal recessive genodermatosis that has been linked to mutations in *SPINK5* (see Chapter 5).<sup>30</sup> Neonates with this disorder characteristically show generalized exfoliative erythroderma and failure to thrive, often associated with hypernatremic dehydration, recurrent infections, and sepsis. Severely affected neonates may show extremely sparse and even absent hair, making the diagnosis based on hair shaft examination difficult. However, the eyebrows are almost always short and broken (see Fig. 7-5, A); eyebrow hairs should be examined in cases in which the abnormality cannot be demonstrated from scalp hair, and trichoscopy (dermoscopy) can be helpful.<sup>5,31–34</sup>

Beyond infancy, many affected individuals show the characteristic skin finding of ichthyosis linearis circumflexa, with walls of scale surrounding red patches, in addition to their dry, lusterless hair that breaks easily (see Fig. 7-5, B, and Figs. 5-20 and 5-21). Atopic conditions usually accompany the ichthyosis. Although spontaneous remission of the hair defect has been described (generally between 6 and 15 years of age), the vast majority show persistence.

**Pili Torti.** Pili torti hairs show three or four regularly spaced twists that occur at irregular intervals along the hair shaft.<sup>6,35</sup> The hair shaft appears flattened at the site of the twist, which is almost always

through 180 degrees. The dry, fragile hair is often lighter in color than expected and shimmers in reflected light with a “spangled” appearance because of the hair twisting. The hair tends to be short, especially in areas subject to trauma, and may extend out from the scalp. Pili torti must be distinguished from twisted hair, which has been described in association with anorexia nervosa.<sup>36</sup>

Pili torti may occur as an isolated phenomenon with onset at birth or early infancy. This genetic disorder shows both autosomal dominant and autosomal recessive inheritance patterns. The appearance of the hair in patients with pili torti may become more normal with time, although twisted hairs can still be found in the adult scalp; those who still manifest the disorder at puberty, however, are unlikely to show significant improvement with age. A late-onset autosomal dominant form has also been described, in which brittle hair and patchy alopecia develop after puberty. Mental retardation has been noted in some pedigrees. Pili torti has been associated with several mitochondrial disorders (see *Pili Torti* section).

Menkes syndrome (trichopoliodystrophy) is an X-linked recessive neurodegenerative disorder that affects male infants. Classic Menkes syndrome affects 90% to 95% of patients, with a less common mild form associated with long survival and occipital horn syndrome (previously called X-linked cutis laxa or Ehlers-Danlos syndrome type IX) showing largely connective tissue manifestations. Carrier females may exhibit pili torti. Classical Menkes syndrome is characterized by coarse facies; pili torti; temperature instability; seizures; psychomotor retardation; arterial intimal changes; soft, doughy skin; joint laxity; low or absent plasma copper and ceruloplasmin levels; growth failure; increased susceptibility to infection; and death, generally by age 3 or 4 years.<sup>37,38</sup> Clinical features often include premature birth, hypothermia, and relatively normal development until 2 to 6 months of age, when drowsiness and lethargy are noted, intractable seizures begin, and growth and development cease. Rarely neonates demonstrate erythroderma as an early sign.<sup>39</sup>

Usually the hair is fine, dull, sparse, and poorly pigmented in infancy; it stands on end and looks and feels like steel wool (Fig. 7-6). Additional features include tortuosity of cerebral and other medium-sized arteries; osteoporosis; frequent subdural hematomas; widening of the metaphyses with spurring; and frequent fractures, at times simulating the radiologic findings characteristic of patients with battered child syndrome. Although pili torti is generally a prominent feature of this disorder, other less commonly reported hair abnormalities include monilethrix and trichorrhexis nodosa.

**Figure 7-5** Netherton syndrome. (A) The characteristic microscopic features of Netherton hair (trichorrhexis invaginata) are often found in eyebrow hairs. Note the sparse, broken brows and lashes in this young girl who also shows the periorbital dermatitis. (B) Short, broken hair throughout the scalp. Note the desquamative scaling and excoriations.

**Figure 7-6** Menkes syndrome. The hair is fine, dull, hypopigmented compared with other family members, and stands on end. It looks and feels like steel wool.

Menkes syndrome results from mutations in *ATP7A*,<sup>40</sup> which encodes a copper-transporting adenosine triphosphatase (ATPase) that incorporates copper into copper-dependent enzymes and maintains copper levels by removing excessive copper from the cytosol.<sup>41</sup> The combination of clinical features, bone abnormalities, and low plasma copper and ceruloplasmin levels establishes the correct diagnosis. Parenteral administration of copper histidine occasionally prevents neurologic degeneration and pigmentation if initiated in the neonatal or infantile period<sup>42</sup> but often is ineffective.<sup>43</sup>

Crandall syndrome, an X-linked recessive disorder, consists of pili torti with alopecia, sensorineural deafness, and hypopituitarism.<sup>44</sup> Björnstad syndrome is characterized by sensorineural deafness, pili torti, and occasionally mental retardation. The syndrome is autosomal recessive, but families with an autosomal dominant pattern have been described.<sup>45</sup> The recessive form has more recently been linked to mutations in *BCS1L*, which encodes an ATPase needed to assemble complex III in the mitochondria. More severe defects in *BCS1L* markedly increase reactive oxygen species and are lethal to neonatal infants with multisystemic involvement (complex II deficiency and growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death [GRACILE] syndrome).<sup>46</sup>

Bazex–Dupré–Christol and Rombo syndromes are X-linked dominant traits characterized by congenital hypotrichosis with pili torti, number facial milia, trichoepitheliomas, vellus hair cysts, and an increased risk of the early development of basal cell carcinomas.<sup>28,47–50</sup> Distinguishing features are follicular atrophoderma, hypohidrosis, comedones and facial and neck pigmentation in Bazex–Dupré–Christol syndrome, and atrophoderma vermiculatum and photosensitivity in Rombo syndrome. Females often do not show the hypotrichosis, with normal and pili torti hairs intermingled.<sup>51</sup>

Hypotrichosis with juvenile macular dystrophy (HJMD) is characterized by the development of sparse, short hair from birth or in the first months of life. Fusiform beading and pili torti may be seen by microscopy. Macular degeneration first develops in the first or second decade, leading to blindness by early adulthood. Patients suspected of having HJMD should have annual ophthalmologic evaluations, because early retinal pigmentation and atrophy precede the decrease in visual acuity. The disorder is autosomal recessive and caused by mutations in *CDH3*, which encodes P-cadherin.<sup>52,53</sup> *CDH3* mutations also cause ectodermal dysplasia, ectrodactyly, and macular dystrophy (Table 7-1).

Individuals with mitochondrial enzyme abnormalities have shown a wide variety of abnormalities, predominantly failure to thrive and neuromuscular changes; however, skin or hair abnormalities have been described in 10% of affected children.<sup>54</sup> Hair abnormalities range from alopecia to dry, thick brittle hair to hypertrichosis, especially on the back. Syndromic disorders with hair abnormalities may also affect mitochondrial function (e.g., Björnstad syndrome and cartilage-hair hypoplasia). Light-microscopy examination of affected hair has shown a variety of hair shaft defects associated with increased fragility including pili torti, TTD, trichorrhexis nodosa, and diffuse longitudinal grooving with flattened hair shafts.<sup>54,55</sup> Patchy erythematous lesions have been described, and many of the patients with skin manifestations have shown mottled pigmentation.

**Pili Bifurcati.** Pili bifurcati is an uncommon anomaly of hair growth characterized by intermittent bifurcation of the hair shaft in which affected hairs divide into two separate shafts that subsequently become rejoined along the hair shaft.<sup>56,57</sup> This bifurcation is repeated at intervals, and the anomaly appears to be transitory, with only a small percentage of hairs exhibiting the bifurcation. This disorder should not be confused with pili multigemini, a disorder in which multiple hairs project from a single hair follicle.

**Trichothiodystrophy.** TTD is a heterogeneous group of autosomal recessive disorders in which patients have dry, brittle, cysteine-deficient hair as an isolated finding or in association with often-multisystemic disease.<sup>58</sup> To date, four genes have been linked to TTD: *ERCC2* (*XPD*), *ERCC3* (*XPB*), *p8* or *GTF2H5* (*TTDA*), and *C7orf11* (*TTDN1*). The function of *TTDN1* is not well understood, but it likely regulates cell cycling and transcription efficiency.<sup>59</sup> The other three genes encode subunits of transcription/repair factor IIH (TFIIH), a

multiprotein complex involved in transcription and nucleotide excision repair.<sup>60,61</sup> Unlike xeroderma pigmentosum, TTD is not prone to cancer, although squamous cell carcinoma has been described.<sup>62</sup>

Light microscopy of TTD hairs shows a wavy, irregular outline and a flattened shaft that twists like a folded ribbon. Two types of fracture may be seen: trichoschisis (clean transverse fracture) or an atypical trichorrhexis nodosa with only slight splaying of the cortical cells. Polarizing microscopy is critical to show the characteristic alternating light and dark bands, the “tiger-tail” appearance.<sup>63,64</sup> Although the severity of hair shaft defects is inversely proportional to the hair sulfur content, there is no association between the extent of systemic disease and percentage of abnormal hairs.<sup>64</sup> Sparse hair is often associated with the shaft defect. Some patients have described cyclic hair loss with fever, which may reflect a mutation leading to thermosensitive *XPD*.

A recent review of 112 published cases of TTD described the abnormalities beyond hair defects.<sup>65</sup> Ichthyosis has been noted in 65% and clinical evidence of photosensitivity in 24% of these patients. The ichthyosis may resemble autosomal recessive congenital ichthyosis (ARCI) or ichthyosis vulgaris (see Chapter 5), and some patients show marked depletion of the granular layer in skin-biopsy sections.<sup>66</sup> Of the patients who have TTD with ichthyosis, 37% show a collodion phenotype at birth.<sup>65</sup> Patients may also show xerosis, palmoplantar keratoderma, atopic dermatitis, and/or follicular keratosis.<sup>66</sup> Nail abnormalities have been described in 63% of patients overall, especially dystrophy with thickening or yellow discoloration.

Among the most common noncutaneous features are developmental delay/intellectual impairment (86%), short stature and low weight (73%),<sup>67</sup> and ocular abnormalities (51%, especially cataracts). Facial dysmorphisms are seen in 66% of patients, especially microcephaly, large or protruding ears, and micrognathia. Bone abnormalities are seen radiographically in 38%, particularly osteosclerosis and delayed bone age. Gonadal abnormalities were noted in 14% overall, most commonly hypogonadism and cryptorchidism. Recurrent infections have been noted in 46%, particularly involving the respiratory and gastrointestinal tracts and the inner ear, but were uncommonly associated with immunodeficiency or neutropenia.<sup>68,69</sup> Overall, mortality in the first decade of life is increased 20-fold. Complications during pregnancy are noted in 26% of patients, most commonly intrauterine growth retardation, but also preterm delivery; preeclampsia; hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome; and prematurity.<sup>70,71</sup>

Subgroups of TTD have been classified based on clinical characteristics (brittle hair, intellectual impairment, decreased fertility, and short stature [BIDS]; ichthyosis, brittle hair, infertility, developmental delay, short stature [IBIDS]/Tay syndrome, photosensitivity, ichthyosis, brittle hair, infertility, developmental delay, short stature [PIBIDS]). However, a new classification has been proposed that divides patients based on their mutations as group I (mutations in genes encoding subunits of TFIIH: *XPD*, *XPB*, *p8*), II (*TTDN1*), and III (no known molecular basis).<sup>66</sup> Group I includes patients with photosensitivity (either clinical or *in vitro*) and is the most common subtype. Most individuals in group II are not photosensitive and show an increased risk of delayed bone age, seizures, and autistic behavior.<sup>72</sup> Currently unclassified but nonphotosensitive patients (such as those with Pollitt and Sabinas syndromes)<sup>73</sup> are in group III. Using this classification, ichthyosis and the collodion-baby phenotype are most highly correlated with group I, whereas hypogonadism has been found more in groups II and III.

**Marie Unna Hypotrichosis.** Marie Unna hypotrichosis is an autosomal dominant disorder manifested by almost complete congenital absence of scalp hair, eyebrows, and eyelashes.<sup>74,75</sup> The hair regrows to normal density but is coarse, flattened, and twisted (Fig. 7-7). Beginning at puberty the hair becomes progressively sparser, particularly on the vertex and scalp margins, resulting in a high frontal and nuchal hairline. By adulthood, only a sparse fringe of hair at the scalp margin may remain, and eyelashes, eyebrows, and body hair, including secondary-sexual hair, tend to be sparse. Scattered follicular horny plugs may be associated. Other ectodermal structures are unaffected, except that 50% of affected individuals show exceptionally widely spaced upper incisor teeth. Mutations that cause Marie

AD, Autosomal dominant; AR, autosomal recessive; IKK, inhibitor of kappa light polypeptide gene enhancer in B cells kinase; TNF, tumor necrosis factor; TNFR, tumor necrosis factor receptor; XLD, X-linked dominant; XLR, X-linked recessive.

Unna hypotrichosis affect *U2HR*, an open-reading frame upstream of the hairless gene that inhibits hairless expression; as a result, hairless expression and Wnt signaling are increased.<sup>76,77</sup>

#### Hair Shaft Abnormalities Without Increased Fragility

**Pili Annulati.** Pili annulati (ringed hair) is an autosomal dominant condition with onset shortly after birth. The hair looks shiny with attractive highlights, but alternating bright and dark bands are seen on close inspection. The bright areas are the result of light scattering from clusters of air-filled cavities within the cortex that appear as dark areas under light microscopy, especially in more proximal hair

regions.<sup>78</sup> Pili annulati may increase the risk of developing AA<sup>79</sup> and has been reported to markedly improve or clear after the occurrence of alopecia totalis.<sup>80</sup> The gene mutated in pili annulati has been linked to chromosome 12q24.33, but no mutations in candidate genes have been found.<sup>81</sup>

Pseudopili annulati is an unusual variant of normal hair in which bright bands are seen at intervals along the hair shaft. Secondary to periodic twisting or curling of the hair shaft, this banding is conspicuous only in blond hairs and represents an attractive optical effect caused by reflection and refraction of light by flattened and twisted hair surfaces.

**Figure 7-7** Marie Unna hypotrichosis. This adolescent's hair is coarse and lusterless. Her hairline is receding at the frontal and nuchal areas, and she paints her sparse brows with eyeliner. Her progressive alopecia will leave her largely alopecic as an adult.

**Figure 7-8** Woolly hair in association with ulerythema ophryogenes. The woolly, curly hair and ulerythema ophryogenes in this boy prompted consideration of Noonan syndrome, but the 11-gene Noonan syndrome panel revealed no mutations.

### Woolly Hair

Woolly hair describes a tight, curly hair that is usually present from birth and shows abnormalities under light microscopy.<sup>6</sup> The individual scalp hairs are fine and dry, light-colored, and corrugated at intervals, resembling the wool of sheep. Recognition of woolly hair is important because of the many associated abnormalities. The autosomal recessive disorders characterized by generalized woolly hair, keratoderma and dilated cardiomyopathy (Naxos disease and Carvajal syndrome) have been linked to mutations in desmoplakin<sup>82,83</sup> and plakoglobin,<sup>84</sup> two desmosomal proteins; keratoderma and woolly hair without cardiomyopathy may also result from mutations in *KANK2* (see Chapter 5). Diffuse woolly hair has also been associated with ocular abnormalities, keratosis pilaris atrophicans and/or ulerythema ophryogenes (Fig. 7-8), keratosis follicularis spinulosa decalvans (KFSD),<sup>85</sup> giant axonal neuropathy (GAN) syndrome, and primary osteoma cutis.

Woolly hair without associated systemic manifestations can be inherited as either an autosomal dominant or autosomal recessive trait, both of which result from abnormalities of the inner-root sheath of the hair follicles. The entire scalp tends to be affected from birth, but nonscalp hair is normal. The hair grows slowly, is hypopigmented, and shows varying degrees of hypotrichosis. Plucked hair shows a dystrophic bulb and sometimes nonspecific shaft defects. The

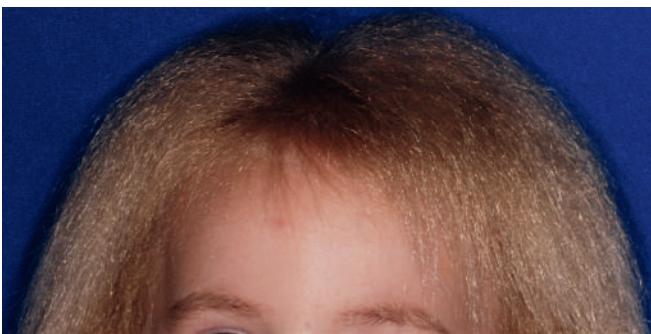

**Figure 7-9** Woolly hair nevus. The affected hair is lighter (**A**), sometimes sparser, and more "woolly" in consistency from the normal surrounding scalp hair (**B**).

dominant form results from mutations in *KRT71* or *KRT74*, encoding hair keratins 71 and 74, respectively.<sup>86,87</sup>

The recessive forms have now been explained by mutations in two interacting genes, *LPAR6* (encoding the lipophosphatidic acid [LPA] receptor 6/P2RY5) and *LIPH* (encoding lipase H).<sup>88,89</sup> Lipase H reduces phosphatidic acid to LPA,<sup>90</sup> which is involved in lipid and energy metabolism. *P2RY5* is thought to be a receptor for lysophosphatidic acid in the hair follicle.<sup>91,92</sup>

The woolly hair nevus is a sporadic condition characterized by the development of one or more patches of hair different in color, shape, and consistency from the normal surrounding scalp hair (Fig. 7-9). The hairs on the affected area are usually smaller in diameter, lighter in color, and sparser than those on the rest of the scalp.<sup>93</sup> When examined under a dissecting microscope, the individual hairs are noted to twist about their long axis. The majority of reported cases of woolly hair nevus have been recognized during the first few months of life, but some have appeared in young adulthood.<sup>94,95</sup> In about 50% of cases, woolly hair nevus coexists with a linear epidermal nevus in the same area or elsewhere.<sup>96,97</sup> Ocular involvement has been described as an associated feature. Epidermal nevi with woolly hair have recently been linked to mutations in *HRAS*.<sup>98</sup>

**Acquired Progressive Kinking of the Hair.** Acquired progressive kinking of the hair is a rare disorder of scalp hair, with onset in adolescence or in young adulthood.<sup>99</sup> The condition is characterized by a rapid onset of extreme curliness of the hair (mainly on the frontoparietal region of the scalp and vertex), often in association with an increased coarse texture, diminished luster, and striking unruliness. The disorder is more common in males than in females. Hair may become darker or remain unaltered in color, and the rate of growth may be decreased or unchanged.<sup>100</sup> Examination of abnormal hairs

**Figure 7-10** Uncombable hair syndrome. Blond hair that is dry and frizzy and does not lie flat on the scalp, thus making combing impossible. (Courtesy of Sarah Chamlin, MD.)

**Figure 7-11** Loose anagen syndrome. (A) The typical patient is a blonde preschool girl whose hair comes out easily and has become lusterless, fine, and sparse. When viewed under light microscope, the hairs that are easily able to be removed without plucking, show a ruffled cuticle (B) and distorted bulb (C).

by light microscopy reveals alterations in hair shaft diameter and partial twisting of the hair on its longitudinal axis.

Although the etiology of this disorder is unknown, it may follow treatment with systemic retinoids including isotretinoin. The localization of hair kinking, family history of androgenetic alopecia (AGA), pathologic features of affected scalp, and tendency to evolve into AGA suggest acquired kinking as a harbinger of AGA.<sup>101</sup> No therapy is effective, and application of topical minoxidil has not affected the progressive thinning of hair in the areas of kinking.<sup>101</sup> Spontaneous reversion to normal hair has been reported.<sup>102</sup> Coarse hair but not woolly hair is also a feature of Hajdu–Cheney syndrome, resulting from mutations in *NOTCH2*. Other features include craniofacial abnormalities, short stature, acroosteolysis with broad nails and digits, synophrys, coarse skin, and premature tooth loss with periodontitis.<sup>103</sup>

**Uncombable Hair Syndrome.** The uncombable hair syndrome (pili trianguli canaliculi, spun-glass hair syndrome) is a unique hair disorder characterized by very pale, silvery, blond, or straw-colored hair. The hair is dry, frizzy, and unruly, and it does not lie flat on the scalp, thus making combing impossible (Fig. 7-10).<sup>104,105</sup> The syndrome is thought to be autosomal dominant with variable penetrance, although no associated gene mutations have been identified. The onset is usually during infancy or early childhood, and eyebrows, lashes, and body hair are normal. Affected children may have minor nail abnormalities<sup>106</sup> and some show both uncombable hair and loose anagen hair (see *Loose Anagen Syndrome* section).<sup>107</sup> The characteristic structural defect, the presence of canalicular depressions along the hair shaft, can be demonstrated by scanning electron microscopy<sup>108</sup> or by routine microscopy of hair in cross-section.<sup>109</sup> Cross-sectional microscopy shows a variety of shapes, including triangular, quadrangular, and reniform. The longitudinal grooving and abnormal shape in cross-section, however, are not specific for uncombable hair syndrome and have been described in several other syndromes, among them Marie Unna hypotrichosis, the ectodermal dysplasias with clefting, hypohidrotic ectodermal dysplasia (HED), oral-facial-digital syndrome type I (OFD1), and progeria. The clinical appearance of the spun-glass hair requires a sizable proportion of abnormal hairs, and at least 50% of hairs are abnormal by scanning electron microscopy. The hair tends to become progressively more manageable by adolescence, and some patients have responded to biotin administration.<sup>106</sup>

Uncombable hair syndrome must be distinguished from extremely unruly hair, which is seen in 2% of individuals. Extremely unruly hair that tends to stand up from the area of the posterior parietal whorl toward the frontal hairline may be associated with microcephaly and is a potential indicator of abnormal brain growth and morphogenesis, similar to upsweep of anterior scalp hair and aberrant parietal whorl position.

#### Loose Anagen Syndrome

Loose anagen syndrome occurs in 10% of all children who have alopecia<sup>110</sup> and is characterized by actively growing anagen hairs that are

loosely anchored and can be easily and painlessly pulled from the scalp.<sup>111</sup> Although considered an autosomal dominant disorder, most cases are sporadic and occur in girls. A mutation in a hair keratin (*KRT75*, formerly called *K6hf*) has been found in some families, but its relevance is unclear because it does not reliably segregate with the loose anagen phenotype.<sup>19</sup> Most patients are blond girls above the age of 2 years (mean, 6 years of age). Affected children generally have sparse, short, scalp hairs that seldom require cutting (Fig. 7-11, A). Examination shows patchy or subtle diffuse thinning with hairs of uneven length. The hair often appears to be limp, and a matted texture has been noted, particularly in occipital hair. Of the actively growing anagen hairs, more than 80% show ruffled cuticles and pigmented misshapen bulbs (Figs. 7-11, B and C). Gentle pulling tends to yield several hairs, allowing the diagnosis to be made by light-microscopic

**Figure 7-12** Congenital triangular alopecia. This usually unilateral triangular patch of alopecia may not appear until 2 to 3 years of age or even later but then persists unchanged.

**Figure 7-13** Congenital atrichia. This boy lost his hair during the first year of life and has never regrown it. A mutation in the hairless gene was demonstrated.

examination of hair; forceful extraction of hairs may lead to misshaping of normal anagen hairs and thus should be avoided. Shedding of the hair is cyclic, and the inability to extract large amounts of hair by gentle pull test does not definitively rule out the diagnosis. Although no treatment is available for this disorder, it is reassuring for patients and their families to know that other abnormalities are not associated with this disorder and individuals with this condition tend to improve with time.

Loose anagen hair is also a feature of an autosomal recessive Noonan-like syndrome (Noonan-like syndrome with loose anagen hair)<sup>112</sup> that has been linked to mutations in *SHOC2*.<sup>113</sup> In addition to the fine, sparse hair, affected children show the Noonan syndrome facies and broad neck; macrocephaly; reduced growth with delayed bone age (often from growth hormone deficiency); variable cognitive defects, hyperactivity; hypernasal voice; darkly pigmented, thickened skin with dermatitis; and cardiac defects.

### NONSCARRING ALOPECIAS WITHOUT HAIR SHAFT ABNORMALITIES<sup>114</sup>

#### Congenital/Genetic Disorders

Congenital triangular alopecia is characterized by an area of alopecia that, although sometimes notable at birth in babies with abundant scalp hair, is usually detected at 2 or 3 years of age (Fig. 7-12).<sup>115,116</sup> Initial appearance during adulthood has been described.<sup>117</sup> The area is triangular and overlies the frontotemporal suture, with the base of the triangle directed forward. The triangular patch may extend to the hairline, but often a fringe of hair may separate it from the forehead. Generally measuring 3 to 5 cm from base to apex, the area may be completely bald or partially covered by vellus hairs and remains unchanged throughout life. Dermoscopy of the affected area shows normal follicular openings with vellus hairs, whereas dermoscopy of AA shows dystrophic and exclamation-point hairs.<sup>118</sup> Although unilateral in 80% of affected individuals, it may be bilaterally symmetric, and on rare occasions similar triangular patches may be noted on the nape of the neck.

The condition is almost always sporadic, although the association with developmental delay and seizures has been described in a mother and daughter.<sup>119</sup> Congenital triangular alopecia has been described in a patient each with phakomatosis pigmentovascularis, Down syndrome, and Dandy–Walker malformation.<sup>116</sup> Hair transplants have been used to repopulate the area of triangular alopecia.<sup>120</sup> Bilateral congenital localized patches of alopecia of the parietal area that resemble the alopecia of congenital triangular alopecia have been seen in patients with Gomez–Lopez–Hernandez syndrome

(cerebellotrigeminal–dermal dysplasia). Although the alopecia classically affects the parietal area, other sites have been reported to show symmetric alopecia.<sup>121</sup> Other features are skull defects (craniostenosis with brachycephaly, midfacial hypoplasia), neurologic abnormalities, short stature, hypertelorism, and corneal opacities.<sup>122</sup>

Individuals who initially have hair but lose it all with the first hair shedding shortly after birth likely have atrichia with papular lesions (APL; resulting from mutations in the hairless gene) or vitamin D-dependent rickets type IIA (caused by mutations in the vitamin D receptor).<sup>123,124</sup> Affected individuals never regrow scalp hair and tend to be nearly totally devoid of eyebrows, lashes, and axillary and pubic hair (Fig. 7-13). Follicular cysts and milia-like lesions may appear on the skin later in life (hence the nomenclature of *with papular lesions*). Scalp biopsies show disintegration of the lower two-thirds of the hair follicle, which is often replaced by cysts. Patients with vitamin D-resistant rickets are clinically and histologically identical to patients with APL<sup>125</sup> but show the additional manifestations of early-onset rickets, hypocalcemia, secondary hyperparathyroidism, and elevated 1,25-dihydroxyvitamin D<sub>3</sub>.<sup>126</sup> The similarity in phenotype reflects the direct regulatory effect of the vitamin D receptor and hairless gene on each other via a transcriptional mechanism.<sup>127,128</sup> This group of patients is often misdiagnosed as having alopecia universalis, and they must be also be distinguished from patients with PHNED, an autosomal recessive disorder resulting from mutations in *KRT85*, *KRT74*, or the *HOXC13* homeobox gene, which usually presents with congenital complete alopecia and uniformly small dystrophic nails.<sup>129–133</sup> Sometimes, very short, sparse, fragile hair may be present in PHNED and is easily visualized by trichoscopy.<sup>134</sup>

#### Hypotrichosis Simplex

Hypotrichosis simplex is a group of rare autosomal dominant and autosomal recessive nonscarring alopecias in which patients are usually born with normal hair. Hair loss can begin in the first months or even as late as the first decade (Fig. 7-14) and can progress to almost complete loss of scalp hair by adulthood. Graying has been reported to coincide with hair loss. Some individuals show sparse, fine, short hairs, especially at the crown, but hair on sites other than the scalp is normal. The disorder has considerable genetic heterogeneity. Autosomal dominant forms result from mutations in genes encoding corneodesmin, a protein of the corneocyte desmosomes and inner hair sheath (see Peeling Skin Syndrome section, Chapter 5)<sup>135,136</sup>; a protein of the pre-messenger-ribonucleic acid (mRNA) processing spliceosome (*SNRPE*)<sup>137</sup>; and *APCDD1*, an inhibitor of Wnt pathway signaling.<sup>138,139</sup> Autosomal recessive forms of hypotrichosis simplex can include hypotrichosis simplex with woolly hair (see Woolly Hair

**Figure 7-14** Hypotrichosis simplex. This girl began to lose hair in the first months of life. She has no other medical issues.

section) or be associated with scalp follicular keratosis, which can be confused with monilethrix.

Hallermann–Streiff, Sensenbrenner, Coffin–Siris, and growth retardation, alopecia, pseudoanodontia, and optic atrophy (GAPO) syndromes all show hypotrichosis in association with facial dysmorphism and other physical signs (see Online only).

In the Hallermann–Streiff syndrome (oculomandibulodyscephaly), hypotrichosis of the scalp, eyebrows, and eyelids is associated with dwarfism, beaked nose, and brachycephaly. The alopecia is most prominent at the frontal and parietal areas and is especially marked along suture lines. Axillary and pubic hair may also be scant, and cutaneous atrophy, largely limited to the scalp and nose, may appear as thin, taut skin and prominent underlying blood vessels. Other features include frontal and parietal bossing, mandibular hypoplasia, microphthalmia, low-set ears, thin and small lips, high-arched palate, atrophy of the skin of the face, congenital cataracts, blue sclerae, motor and occasionally mental retardation, and dental abnormalities.

Sensenbrenner syndrome, or cranoectodermal dysplasia, is a rare autosomal recessive disorder manifested by small stature, dolichcephaly, an unusual facies, and tubulointerstitial nephritis leading to early end-stage renal failure.<sup>140</sup> The typical facies show frontal bossing, hypertelorism, prominent epicantal folds, antimongoloid palpebral fissures, eversion of the lip, and full-rounded cheeks. Patients have small, gray, widely spaced teeth; short, fine, hair; and hypohidrosis.<sup>141</sup> Sensenbrenner syndrome is a ciliopathy that results from mutations in *IFT122*,<sup>142</sup> *WDR35*,<sup>143</sup> or *IFT43*.<sup>144</sup>

Patients with the Coffin–Siris syndrome most commonly show a constellation of severe mental retardation; a characteristic coarse-appearing facies; scalp hypotrichosis with hypertrichosis of the eyebrows, eyelashes, face, and back; hypotonia; hypoplastic to absent fifth fingernails and distal phalanges; and feeding problems with postnatal growth deficiency.<sup>145</sup> Coffin–Siris syndrome is autosomal dominant and results from mutations in one of several components of the SWI/SNF/sucrose nonfermenting (SWI/SNF; also called BAF) adenosine triphosphate (ATP)-dependent chromatin-remodeling complex.<sup>146,147</sup> Of these, mutations in *ARID1B* are most common (76% in one series).<sup>148,149</sup>

GAPO is an acronym for *growth retardation, alopecia, pseudoanodontia, and optic atrophy*.<sup>150</sup> Distinctive craniofacial features include frontal bossing, high forehead, mid-facial hypoplasia, hypertelorism, and thickened eyelids and lips. GAPO syndrome is autosomal recessive and results from mutations in *ANTXR1*, which encodes anthrax toxin receptor 1.<sup>151</sup>

Cartilage-hair hypoplasia syndrome is an autosomal recessive disorder that occurs primarily in inbred Amish or Finnish populations.<sup>152,153</sup> Patients have short limbs and sparse, fine scalp and body hair. Several patients with hyperextensible digits and soft, doughy skin, reflecting degenerated elastic tissue, have been described.<sup>154</sup>

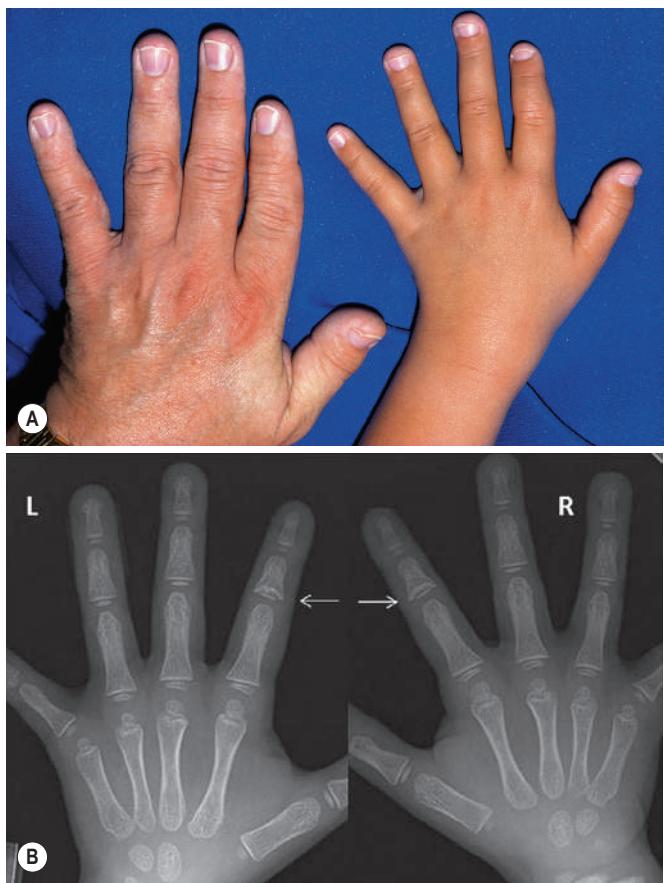

**Figure 7-15** Trichorhinophalangeal syndrome, type I. This 9-month-old boy shows the distinctive facies, including the pear-shaped nose and elongated philtrum, the thin upper lip, and the receding chin, as well as the sparse hair. He had hip dysplasia as well.

Defective cell-mediated immunity is seen in most patients and results in relative anergy, altered T-cell responses, and increased susceptibility to severe viral infections, particularly varicella.<sup>155</sup> Patients may have infantile neutropenia, Diamond–Blackfan anemia, severe combined immunodeficiency, celiac syndrome, and/or toxic megacolon. Mild to severe bronchiectasis has been noted in more than 50% of patients.<sup>156</sup> Approximately 10% develop malignancy, especially lymphoreticular; an increased prevalence of early basal cell carcinomas has also been described.<sup>157</sup> The disorder results from mutations in ribonuclease (RNase) *MRP*, which cleaves RNA in mitochondrial deoxyribonucleic acid (DNA) synthesis and preribosomal RNA in the nucleolus.<sup>158</sup> Alopecia is seen with macrocephaly, cutis laxa, and scoliosis in macrocephaly, alopecia, cutis laxa, and scoliosis (MACS) syndrome (see Chapter 6).

Trichorhinophalangeal syndrome (TRPS) type I is an autosomal dominant disorder characterized by a distinctive facies with pear-shaped nose, elongated philtrum, thin upper lip, supernumerary incisors, and receding chin (Fig. 7-15) and skeletal abnormalities including brachydactyly, deviation of the middle phalanges (Fig. 7-16, A), hip malformation, and short stature.<sup>159,160</sup> Most patients show fine, sparse, slow-growing hair, but almost-normal hair to complete baldness have been described. The underlying molecular basis is mutation in *TRPS1*, which encodes a transcription factor. Individuals with type II TRPS (Langer–Giedion syndrome) have associated multiple cartilaginous exostoses. The diagnosis is made by the demonstration of cone-shaped epiphyses of the fingers seen on plain radiography (Fig. 7-16, B). These findings may not be detectable until 3 years of age or older. The type II form is a contiguous gene syndrome, with deletion of both the *TRPS1* gene and the gene that is mutated in multiple exostosis type I (*EXT1*). Type III TRPS results from mutations in *TRPS1* but manifests with much more severe short stature and generalized shortening of all phalanges and metacarpals than TRPS type I.<sup>161</sup>

OFD1 is an X-linked dominant disorder limited to girls and thought to be lethal in boys.<sup>162</sup> Facial features occur in almost 70% of patients and include hypoplasia of nasal cartilages and hypertelorism with lateral displacement of the inner canthi (dystopia canthorum)<sup>163</sup> (Fig. 7-17). Among the oral anomalies described are tongue hamartomas, lobulated cleft tongue, cleft lip and palate, maldeveloped frenula, asymmetry of the lips and tongue, and maxillary gingival swelling.<sup>164</sup> Associated hand malformations are common and include brachydactyly, syndactyly, clinodactyly, and polydactyly. Almost half of affected individuals show central nervous system (CNS) involvement, most commonly retardation or selective cognitive impairment. Cutaneous abnormalities occur in the minority of patients but include numerous

**Figure 7-16** Trichorhinophalangeal syndrome, type I. **(A)** Brachydactyly in an affected father and daughter with short stature and typical facies. Note the deviation of the middle phalanges. **(B)** Cone-shaped epiphyses of the second finger of this child's left and right hands.

**Figure 7-17** Oral-facial-digital syndrome, type I. This infant girl shows the asymmetric hypoplasia of nasal cartilages and lobulated cleft tongue. Note the many facial milia on the cheek and eyelids. The hair continues to be sparse and dry.

milia at birth<sup>165</sup> and sparse fine or coarse, dry and lusterless hair to frank alopecia. Polycystic kidney disease with renal insufficiency is occasionally seen in children but more often occurs with advancing age (>50% after age 36 years).<sup>166</sup> The disorder results from mutations in *OFD1*, which encodes a centrosomal protein of primary cilia. Other "ciliopathies" share the CNS, skeletal, and cystic renal abnormalities of *OFD1*.

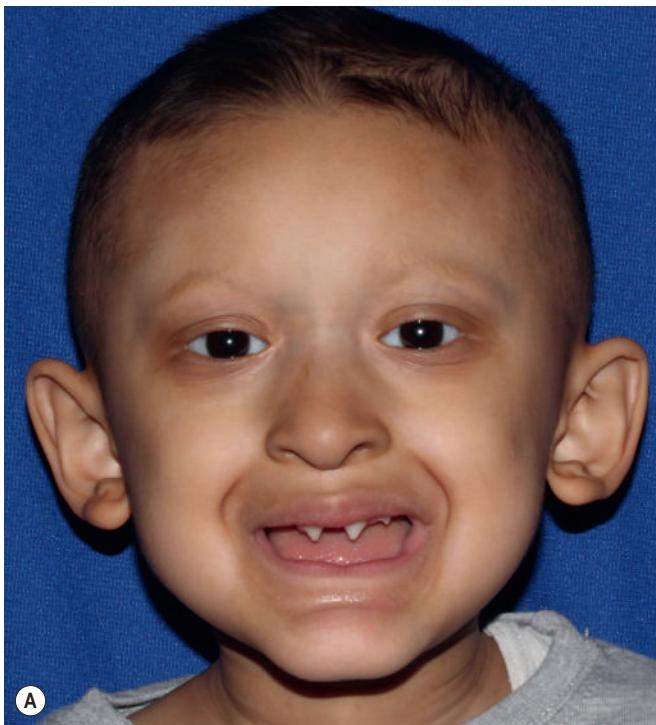

## Ectodermal Dysplasias

Ectodermal dysplasias are a complex group of approximately 200 developmental disorders that were traditionally classified based on their sites of abnormalities (hair, teeth, nails, and/or eccrine glands) and other ectodermal and nonectodermal features.<sup>167</sup> In 2009 Priolo suggested a new classification of ectodermal dysplasias that focuses on the molecular basis of these disorders (now known in approximately 80 of the ectodermal dysplasias),<sup>168</sup> the function of the affected proteins, and the clinical features.<sup>169</sup> As a result, ectodermal dysplasias are divided into two groups (see Table 7-1). The first group includes disorders in which ectodermal derivatives fail to develop or differentiate because of the absence of reciprocal signals from the ectoderm to the mesenchyme. This group can be further divided into: (1) abnormalities of the tumor necrosis factor (TNF)-like/TNF receptor pathway (including HED); (2) the nuclear factor κB (NF-κB), NF-κB essential modulator (NEMO), and inhibitor of κB (IkB) molecules (such as HED with immunodeficiency [HED-ID]); and (3) transcription factors such as p63 and DLX3. Inductive signals for normal differentiation are preserved in the second group, but tissues become dysplastic because abnormal regulation of transcription or expression leads to altered cell–cell interactions or disorganization of the cytoskeleton. Abnormalities in group 2 may affect nectins (e.g., cleft lip/palate–ectodermal dysplasia syndrome), connexins (as in Clouston syndrome and oculodentodigital dysplasia), desmosomal proteins (such as plakophilin in ectodermal dysplasia/skin fragility syndrome, also classified as a form of epidermolysis bullosa simplex, see Chapter 13), and molecules that interact with β-catenins (cadherins and *WNT10A*, as in odontoonychodermal dysplasia [ODDD]).

### Group 1 Ectodermal Dysplasia

**HYPOTHIDROTIC ECTODERMAL DYSPLASIA.** HED is characterized by the triad of reduced sweating, hypotrichosis, and defective dentition.<sup>170</sup> The majority of affected individuals are male, and overall 92% have a mutation in one of four genes (see Table 7-1): ectodysplasin-A1 (*EDA1* at Xq12-q13) in 58%; its ectodysplasin receptor (*EDAR* at 2q13) in 16%; *Wnt10A* (*WNT10A* at 2q35) in 16% (classified with group 2); and EDAR-associated death domain (*EDARADD* at 1q42.2-q43) in 2%.<sup>171</sup> HED may also result from a heterozygous mutation in *TRAF6*, which is upstream of NEMO and promotes NF-κB activity,<sup>172</sup> and in X-chromosome located *XEDAR*, encoding the receptor for *EDA2*, a different *EDA* isoform that binds to *Traf6*.<sup>173</sup> Female carriers with an *EDA1* mutation show random inactivation of the abnormal gene and can show manifestations ranging from none to extensive dental defects, alopecia, and patchy hypohidrosis following the lines of Blaschko, which are lines of embryologic development of skin. Mutations in the receptor (*EDAR*), the death domain (*EDARADD*), or *WNT10A* (*WNT10A*) may be inherited in a recessive or dominant pattern.<sup>169</sup> The phenotype with recessive mutations closely resembles those in X-linked recessive HED, whereas dominant mutations tend to be less severe with respect to sweating and hair loss.<sup>174</sup> Mutations in *WNT10A* can lead to a spectrum of ectodermal defects that can include isolated oligodontia, mild manifestations of HED,<sup>175,176</sup> ODDD, or Schöpf–Schulz–Passarge syndrome. The nail changes of ODDD (fragility, longitudinal ridging, splitting, koilonychias, onycholysis, and pterygium) begin in early childhood and are associated with palmoplantar keratoderma, agenesis of the permanent teeth, and sometimes facial erythema and atrophic tongue papillae. Schöpf–Schulz–Passarge syndrome may manifest solely with bilateral eyelid cysts and palmoplantar keratoderma but often includes nail, hair, and/or dental abnormalities.<sup>177</sup>

HED-ID affects 1:250,000 births<sup>178</sup> and is usually caused by hypomorphic mutations in *NEMO*,<sup>179</sup> an X-linked gene. Autosomal dominant HED-ID has been reported in six patients and results from hypermorphic (gain-of-function) mutations in *IKBA*.<sup>180</sup> *NEMO* mutations cause incontinentia pigmenti in girls (see Chapter 11) and amorphic (i.e., there is effectively no gene product) tend to be lethal in males. Features of HED have been described in 77% of boys with immunodeficiency and *NEMO* mutations; osteopetrosis and lymphedema have been noted in 8% with HED-ID.<sup>181</sup> Boys with HED-ID occasionally show the clinical vesiculopapules and histologic features of incontinentia pigmenti, but the distribution is not blaschkoid given the lack of mosaicism.<sup>182</sup> Most mutations in *NEMO* that lead to HED-ID occur in exon 10 and affect the C-terminal zinc finger domain,

**A****B**

**Figure 7-18** Hypohidrotic ectodermal dysplasia (HED). **(A)** This boy shows the short, sparse hair; large conspicuous nostrils; wide cheekbones with flat malar ridges; periorbital wrinkling; a thick everted lower lip; prominent chin; and low-lying, anteriorly placed, pointed ears. **(B)** Conical incisors in a toddler with HED.

which is critical for normal dendritic cell immune stimulation,<sup>183</sup> but mutations leading to HED-ID are scattered throughout the *NEMO* gene.<sup>184</sup>

**FEATURES OF ECTODERMAL DYSPLASIA.** Affected persons often appear more like each other than like their own unaffected siblings<sup>185</sup>; classic features are usually obvious by infancy. Most have a distinctive pathognomonic facies: a square forehead with frontal bossing, large conspicuous nostrils, wide cheekbones with flat malar ridges, a thick everted lower lip, and a prominent chin. Ears may be small, satyr-like (pointed), low-lying, and anteriorly placed (Figs. 7-18, A, and 7-19). Alopecia is often the first feature to attract attention but is seldom complete; overall 80% of males with the X-linked type have sparse hair.<sup>186</sup> The hair also tends to be lightly pigmented and short. The skin is soft, thin, and light-colored but shows fine wrinkling and sometimes darkening of the periorbital areas. Many affected neonates are born with red, peeling skin, but collodion-like thickening has occasionally been described.<sup>187,188</sup> Atopic dermatitis and other atopic conditions occur with increased incidence, and periorbital dermatitis is particularly common. The paucity of nail changes helps to distinguish HED

**Figure 7-19** Hypohidrotic ectodermal dysplasia (HED). This girl is a carrier for a mutation in ectodysplasin but shows all of the characteristic facies features. Girls with HED may also have a mutation in a gene encoding the receptor for ectodysplasin, inherited as an autosomal disorder.

from other ectodermal dysplasias, although nail changes were described in up to 50% of males and female carriers in a recent self-reported survey.<sup>186</sup>

The decreased capacity for perspiration occurs in virtually all affected males and has a profound effect on life quality.<sup>189</sup> Hypohidrosis often results in hyperthermia, and patients manifest with intermittent fevers, especially during hot weather or after exercise or meals. These recurrent fevers of unknown origin may be the presenting manifestation in affected infants. Hypoplastic lacrimal and mucous glands can lead to decreased tearing or epiphora, chronic nasal discharge, and an increased risk of otitis media and respiratory tract infections.<sup>190</sup> Females and female carriers may have breast hypoplasia. Dentition is generally delayed, and dental anomalies vary from complete to partial absence of teeth with peg-shaped or conical incisors (see Fig. 7-18, B).

**FEATURES OF IMMUNODEFICIENCY.** Boys with HED-ID usually have recurrent infections. Serious pyogenic infections occur in 86% of affected individuals, and mycobacterial infections (especially atypical *Mycobacterium avium*) in 44%.<sup>185,191,192</sup> Pneumocystis and viral and candidal infections occur less often. Bacteremia or sepsis is common,<sup>185,193</sup> and the most common sites of infection are the lungs, sometimes leading to bronchiectasis, and the skin, sometimes with abscesses. Inflammatory colitis affects 21% of boys and presents as intractable diarrhea and/or failure to thrive. Some patients develop autoimmune hemolytic anemia. Natural killer-cell dysfunction has been described in all patients, but otherwise a range of immune defects have been described, largely reflecting the functional impairment in CD40, interleukin (IL)-1, TNF- $\alpha$ , and toll receptor signaling.<sup>185,194</sup> Almost 60% of affected boys show hypogammaglobulinemia, with high levels of immunoglobulin (Ig) M in 15%. Hyper-IgM syndrome much more commonly results from mutations in *CD40L* ligand (*CD40L*)<sup>195</sup> and may manifest with *CD40L* deficiency as oral aphthae and warts.<sup>196</sup> Individuals with HED-ID are at high risk for early death from infections without transplantation.<sup>197-200</sup>

Therapy for patients with all forms of HED is directed toward temperature regulation; cool baths and drenching with water, air conditioning, light clothing, cooling suits, and the reduction of the causes of normal perspiration are beneficial.<sup>201</sup> Lubricating eye drops and nasal irrigation can compensate for the decreased glandular secretion. Minoxidil may promote some hair growth with long-term use.<sup>202</sup> Dental intervention should begin by 2 years of age and can include dental prostheses and dental implants in older adolescents and adults to improve mastication, encourage normal speech development, and

**Figure 7-20** Ankyloblepharon-ectodermal dysplasia-clefting syndrome. Scalp dermatitis with secondary staphylococcal infection is a chronic problem and leads to cicatricial alopecia.

reduce cosmetic disfigurement. In mouse and dog models of X-linked HED, the prenatal or perinatal administration of recombinant Fc-EDA protein or ligand replacement using an *EDAR*-agonist antibody can improve dentition, lacrimation, sweating, and bronchopulmonary gland function,<sup>203–205</sup> whereas postnatal administration in affected adult mice only improves sebaceous gland activity.<sup>206</sup> Most recently, a single injection of *EDA1* replacement protein into the amniotic fluid of pregnant *eda1*-mutant mice provided a depot for recurrent oral ingestion of affected offspring without maternal absorption; treatment led to darker, denser coat; normal eye opening, tail shape, and teeth; and functional sweat glands.<sup>207</sup> Prenatal diagnosis has been made noninvasively by tooth-germ ultrasound.<sup>208</sup> The National Foundation for Ectodermal Dysplasias (NFED) provides excellent education materials on management of the hypohidrosis and dental abnormalities.

**P63-RELATED FORMS OF ECTODERMAL DYSPLASIA.** Mutations in *p63*, a gene that plays a critical role in maturation of ectodermal, orofacial, and limb development, lead to an autosomal dominant disorder with ectodermal dysplasia, orofacial clefting, and limb malformations as key characteristics. These clinical manifestations have traditionally been used to classify subtypes, but significant clinical and genotypic overlap is now recognized.<sup>209–211</sup> Included are Rapp–Hodgkin syndrome (clefts of the lip, palate, and/or uvula; small narrow dysplastic nails; hypodontia with small conical teeth; and maxillary hypoplasia)<sup>212</sup>; ankyloblepharon-ectodermal dysplasia-clefting (AEC or Hay–Wells syndrome; ankyloblepharon or congenital fusion of the eyelids in association with facial clefting and midfacial hypoplasia)<sup>213,214</sup>; ectrodactyly, ectodermal dysplasia, and cleft lip/palate (EEC) syndrome; limb-mammary syndrome (ectrodactyly, cleft palate, and mammary gland abnormalities); acrodermatoganglular-lacrimo-tooth (ADULT) syndrome syndrome; and nonsyndromic split hand/foot malformation.

The skin, hair, teeth, nails, and glands (eccrine, sebaceous, lacrimal, mammary) are abnormally developed.<sup>215</sup> The skin tends to be dry, itchy and hypopigmented. Extensive erosions have been described in 80% of neonates with the AEC phenotype. The hair is often sparse and wiry, and nails tend to be dystrophic. Scalp dermatitis and erosions with secondary chronic staphylococcal infection may be recurrent in the first few years of life and lead to cicatricial alopecia, especially of the vertex and frontal scalp (Fig. 7-20). Teeth are often decreased in number with malformations and enamel hypoplasia.<sup>216</sup> Hypohidrosis may be present, tearing is often decreased, and nipple hypoplasia has been described. Patients may show split hand/foot malformations (lobster claw deformity; ectrodactyly) and/or syndactyly.<sup>217</sup> Short stature, poor weight gain, and hypospadias are other commonly described characteristics.<sup>218</sup> Ectodermal dysplasia with clefting and/or ectrodactyly/syndactyly can be caused by mutations in a variety of other genes, i.e., other disorders (see Table 7-1). Disorders with *p63* mutations also should be distinguished from CHAND syndrome or

**Figure 7-21** Trichodental syndrome (Witkop syndrome). Slow-growing, small, spoon-shaped nails are a characteristic feature, in addition to the slow-growing lusterless hair, sparse outer eyebrows, and small, sometimes absent, teeth.

CHANDS, characterized by curly hair from birth, ankyloblepharon, nail dysplasia and, variably, ataxia<sup>219,220</sup>; the underlying genetic basis is unclear.

The trichodentosseous syndrome is an autosomal dominant disorder characterized by kinky, curly hair at birth that tends to become straighter during childhood; small, widely spaced, pitted, eroded, and discolored teeth with early caries as a result of defective enamel; thickness and splitting of the nails; dolichocephaly, frontal bossing, and a square jaw, giving affected persons a distinctive facies; normal physical development; and increased bone density, especially of the cranial bones. The condition results from mutations in *DLX3*, a crucial regulator of hair follicle differentiation and cycling.<sup>221</sup>

The trichodental syndrome, also known as *Witkop syndrome* or the tooth-and-nail syndrome, is an autosomal dominant disorder characterized by fine, dry, slow-growing lusterless hair; sparseness or absence of the lateral halves of the eyebrows; congenitally missing and small teeth; and slow-growing, small, spoon-shaped nails (especially toenails) (Fig. 7-21).<sup>222,223</sup> Mutations have been described in *MSX1*, which directs the formation of teeth and nails.<sup>224</sup> The other ectodermal dysplasia with mucocutaneous features included in group 1 is Ellis van Creveld syndrome. This autosomal recessive disorder features nail dysplasia in association with chondrodyplasia, polydactyly, orofacial abnormalities, and sometimes cardiovascular malformations.<sup>225</sup> The mutated genes, *EVC* and *EVC2*, localize to cilia and are thought to be involved in hedgehog signaling.<sup>226</sup>

### Group 2 Ectodermal Dysplasia

**CLOUSTON SYNDROME (HIDROTIC ECTODERMAL DYSPLASIA).** The most common hidrotic type of ectodermal dysplasia is Clouston syndrome, an autosomal dominant disorder characterized by nail dystrophy, hyperkeratosis of the palms and soles, and hair defects.<sup>227</sup> Most cases have been reported in French-Canadian families. Unlike HED, individuals with the hidrotic form have a normal facies and show no abnormality of sweating, although eccrine syringofibroadenomas have been described.<sup>228</sup> The teeth develop normally but are prone to caries. The predominant feature is congenital nail dystrophy, which may be the only manifestation in about one-third of affected individuals. The nails are thickened or thinned, striated, and often discolored (Fig. 7-22). They may resemble the nails of pachyonychia congenita (PC) and are difficult to distinguish without genotyping until other features develop such as the painful character of the plantar keratoderma of PC, which is often present by 5 years of age, and the alopecia of hidrotic ectodermal dysplasia. The nails grow slowly and commonly show chronic paronychial infections that may result in partial to complete destruction of the nail matrix. Typically the skin and soft tissue surrounding the nail and at the finger pad appear thickened and swollen, leading to the term *drumstick fingers*. The palmoplantar keratoderma can extend to the dorsal aspects of the hands and feet. Hair may be normal during infancy and childhood but thereafter often becomes sparse, fine, and brittle and may eventuate in total alopecia (Fig. 7-23). Body hair may

**Figure 7-22** Hidrotic ectodermal dysplasia (Clouston syndrome). Nail dystrophy, accentuation of ridging on the digital tips, and bulbous swelling of the soft tissue surrounding the nail and at the finger pad are the most typical manifestations of this syndrome. The nails can be confused with pachyonychia congenita, but the hair changes of hidrotic ectodermal dysplasia and the characteristic discomfort of the plantar keratoderma of pachyonychia congenita help to distinguish the disorders.

**Figure 7-23** Hidrotic ectodermal dysplasia. This child shows the fine, sparse, brittle hair of Clouston hidrotic ectodermal dysplasia. Not uncommonly the hair abnormality does not develop until after puberty.

be sparse; eyebrows and eyelashes may be thinned or absent. The skin may show a mottled hyperpigmentation with thickening and hyperpigmentation over the knees, elbows, and knuckles. Ocular abnormalities may include strabismus, conjunctivitis, and premature cataracts. Clouston syndrome has been attributed to mutations in *GJB6*,<sup>229</sup> encoding connexin 30, a structural component of the intercellular gap junction. One patient with Clouston syndrome and bigenic mutations (one of each allele) of *GJB6* and *GJA1* (encoding connexin 43) have also been described.<sup>230</sup> Mutations in *GJB6* have also been noted in patients with keratitis, congenital ichthyosis, and neurosensory deafness (KID) syndrome (see Chapter 5), who share the palmoplantar keratoderma and sometimes early alopecia with thickening of the scalp. Clouston syndrome should also be distinguished from an autosomal recessive disorder that results from mutations in encoding grainyhead-like 2 (*GRHL2*); in addition to nail dystrophy or loss and marginal palmoplantar keratoderma, patients show hypodontia and enamel hypoplasia, oral hyperpigmentation, dysphagia, and sometimes deafness or asthma.<sup>231</sup> The combination of tretinoin and minoxidil has reportedly caused hair growth in Clouston syndrome.<sup>232</sup>

**OCULODENTODIGITAL DYSPLASIA.** Oculodentodigital dysplasia (ODDD), an autosomal dominant disorder, results from mutations in *GJA1*, which encodes connexin 43<sup>12,13</sup>; mutations in *GJA1* have also been linked to erythrokeratoderma variabilis (see Chapter 5). In addition to abnormalities of the eyes, teeth, and digits, patients show curly hair (sometimes with trichorrhexis nodosa), focal keratoderma, a

**Figure 7-24** Keratosis pilaris. Keratotic, follicular-based plugs with variable associated erythema are common on the lateral cheeks of young children.

**Figure 7-25** Keratosis pilaris. The lateral thighs are a common site. The follicular lesions can be inflamed papules or even pustules, resembling bacterial folliculitis.

characteristic facies with hypoplastic ala nasi, and neurologic, cardiac, and hearing defects. Cleft lip/palate-ectodermal dysplasia features spoon-shaped, slow-growing fingernails and toenails, pili torti, mental retardation, malformed ears, and partial syndactyly. It results from mutations in neitin 1, encoded by *PVRL1*.<sup>233,234</sup> Mutations in neitin 4, encoded by *PVRL4*, lead to ectodermal dysplasia-syndactyly syndrome (EDSS), characterized by alopecia, tooth abnormalities, and syndactyly.<sup>235,236</sup>

## DISORDERS OF FOLLICULAR PLUGGING

### Keratosis Pilaris

Keratosis pilaris is a common skin condition characterized by keratinous plugs in the follicular orifices surrounded by a variable degree of erythema (see Chapter 3).<sup>237</sup> These small follicular-based papules are most commonly distributed on the cheeks (Fig. 7-24), extensor areas of the upper arms, and anterior and lateral thighs (Fig. 7-25) but may be widespread. Children with keratosis pilaris tend to have xerosis and sometimes atopic dermatitis and/or ichthyosis vulgaris. Occasionally, facial keratosis pilaris overlies intense erythema (keratosis pilaris rubra)<sup>238</sup> and may also be pigmented (erythromelanosis follicularis faciei et colli).<sup>239</sup> Keratosis pilaris does not tend to be symptomatic but may be cosmetically distressing, especially if quite inflammatory or extensive. Treatment is difficult but usually requires application of keratolytic agents such as creams or lotions containing lactic acid, glycolic acid, salicylic acid, or urea, and gentle exfoliation by a pumice stone, washcloth, loofah sponge, or Buf-Puf. Responsive

**Table 7-2** Classification of Keratosis Pilaris Atrophicans

	<b>Atrophoderma Vermiculata</b>	<b>Ulerythema Ophryogenes</b>	<b>Keratosis Follicularis Spinulosa Decalvans</b>
Skin lesions	Erythematous papules, follicular plugs, horn cysts, atrophic	Follicular papules, plugging, scarring	Milia, thorn-like follicular projections, atrophic scars
Sites	Cheeks, neck, limbs	Lateral eyebrows, extending medially	Scalp, eyebrows, eyelashes, cheeks, nose, neck, dorsal hands, fingers
Alopecia	Absent	Minimal eyebrows	Scarring alopecia of the scalp
Photophobia	Absent	Absent	Marked, corneal opacities
Inheritance	Sporadic or autosomal dominant	Sporadic or autosomal dominant	X-linked recessive or autosomal dominant

**Figure 7-26** Ulerythema ophryogenes. Extensive keratosis pilaris with alopecia and scarring of the eyebrow in an adolescent boy.

patients must maintain therapy to achieve continued remission or improvement. The intense erythema of keratosis pilaris rubra may be lessened by pulsed-dye laser therapy<sup>240</sup> or photopneumatic (vacuum-assisted pulsed-light) therapy.<sup>241</sup> The erythema is sometimes decreased by treatment with low-strength topical steroids or calcineurin inhibitors.<sup>242</sup>

### Keratosis Pilaris Atrophicans

Numerous terms have been used to describe a group of interrelated syndromes characterized by inflammatory keratotic follicular papules and later by atrophy. Commonly described as atrophic variants of keratosis pilaris, these include ulerythema ophryogenes, atrophoderma vermiculata, and KFSD (keratosis pilaris decalvans)<sup>243,244</sup> (Table 7-2).<sup>245</sup> This group of disorders has been attributed to abnormal keratinization of the follicular infundibulum, resulting in obstruction of the growing hair shaft, chronic inflammation, and scarring. No therapy is terribly effective,<sup>246</sup> although topical keratolytic and anti-inflammatory agents (topical corticosteroids and calcineurin inhibitors) may reduce the keratotic and inflammatory components, respectively. In general, systemic retinoids have not been helpful. Durable eyebrow reconstruction using individual hair follicle micrografts in an adult with quiescent disease has been reported.<sup>247</sup>

Ulerythema ophryogenes (keratosis pilaris atrophicans faciei) is characterized by persistent reticular erythema, small horny papules, atrophy, and scarring of the outer half of the eyebrows (see Fig. 7-8; Fig. 7-26).<sup>248</sup> The disorder is more common in boys and usually starts in the first months of life. Occasionally the disorder extends to include the adjacent skin, adjacent scalp, and cheeks.

Ulerythema ophryogenes and keratosis pilaris have been described in patients with two similar but distinct "RASopathies" of the RAS-MAPK signaling pathway, the cardiofaciocutaneous (CFC) syndrome<sup>249</sup> and Noonan syndrome. Patients with CFC syndrome often show widespread keratosis pilaris-like lesions of the face, ears,

scalp, and extensor surfaces of the extremities that may be more lichenoid and prominent than keratosis pilaris.<sup>250</sup> Sometimes patients with CFC and Noonan syndromes have alopecia of the eyelashes and eyebrows with follicular hyperkeratosis but lack the atrophy and scarring of ulerythema ophryogenes. Both CFC and Noonan syndromes share features of short stature, congenital cardiac abnormalities (particularly pulmonary valve stenosis), retardation, macrocephaly, hypertelorism, a high forehead, pectus carinatum, curly hair, and many pigmented nevi.<sup>251</sup> Lymphedema and a low posterior hairline are more typical features of Noonan syndrome. Patients with CFC syndrome often show hypoplastic supraorbital ridges, bitemporal constriction, and an antimongoloid slant, features not described in Noonan syndrome.<sup>250</sup>

As with clinical features, there is overlap in genes that are mutated in Noonan and CFC syndromes (*BRAF*, *KRAS*, *MEK1*, and *MEK2*).<sup>252–255</sup> However, the genes most commonly altered in Noonan syndrome are *PTPN11* (50%) and *SOS1* (10% to 13%).<sup>253</sup> Individuals with Noonan syndrome associated with loose anagen syndrome exclusively have a unique mutation in *SHOC2*, a scaffold protein required for the RAS-MAPK signaling cascade.<sup>256</sup> A recent study noted genotype–phenotype correlation during the first year of life, with thin hair linked to mutations in *SHOC2* and *BRAF*, whereas keratosis pilaris was associated with mutations in *SOS1*, *BRAF*, and *SHOC2*.<sup>257</sup> Other RASopathies with skin features are lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness (LEOPARD) syndrome; neurofibromatosis; neurofibromatosis–Noonan syndrome; Legius syndrome; the newly described *CBL*-mutation-associated syndrome (café-au-lait spots, see Chapter 11); and Costello syndrome (see Chapter 6). Ulerythema ophryogenes has also been associated with Cornelia de Lange<sup>258</sup> and Rubenstein–Taybi<sup>259</sup> syndromes, as well as with woolly hair (see Fig. 7-8).<sup>260</sup>

Atrophoderma vermiculata (folliculitis ulerythema reticulata, atrophoderma vermicularis) usually has its onset between 5 and 12 years of age.<sup>243</sup> This disorder is characterized by the formation of numerous tiny symmetric atrophic and at times erythematous pits on the cheeks, periauricular areas, and occasionally the forehead and eyebrows. These cribriform lesions generally measure 1 to 2 mm across and 1 mm deep and are separated from each other by narrow ridges of normal-appearing skin. Laser and dermabrasion have been advocated to improve the cosmetic appearance of affected individuals when the condition is stable, usually after puberty. Low-dose isotretinoin (0.5 mg/kg per day) for two 6-month courses has been reported to cause cosmetic improvement.<sup>261</sup>

KFSD is characterized by atrophic keratotic follicular papules of the scalp, eyebrows, and eyelashes that eventuate in scarring alopecia (Fig. 7-27). Associated features are palmoplantar keratoderma, corneal dystrophy, photophobia, and atopy.<sup>262</sup> KFSD is usually an X-linked recessive disorder, and female carriers may show milder manifestations. The initial signs are photophobia with tearing, ophthalmitis, and conjunctival and corneal inflammation, which occur in the first weeks or months of life; congenital glaucoma and cataracts have been noted in association. Extensive keratosis pilaris of the face, extremities, and trunk tends to begin during early childhood, often in association with facial erythema. Cicatricial alopecia of the scalp begins around puberty and slowly progresses in association with follicular inflammation and fibrosis; eyebrows also tend to be affected.

**Figure 7-27** Keratosis follicularis spinulosus decalvans. This patient showed widespread spiny follicular-based keratoses, photophobia, and abnormal hair with cicatricial alopecia.

Some patients show palmoplantar keratoderma and marked xerosis. Acne keloidalis nuchae (see [Acne Keloidalis](#) section) and tufted hair folliculitis has been described in several patients.<sup>263</sup> Ichthyosis follicularis, congenital atrichia, and photophobia (IFAP) is another X-linked condition in which affected neonates show keratotic follicular papules with a sandpaper feel to the skin, atrichia or severe hypotrichosis, and photophobia from birth (Fig. 7-28).<sup>264–266</sup> In contrast to KSFD, the alopecia of patients with IFAP does not scar. Mental retardation and developmental delay have been described in both KSFD and IFAP syndromes. Other features are gingival hyperplasia and angular stomatitis, psoriasiform plaques, palmoplantar erythema with thickening, short stature, and seizures.

IFAP and KSFD are allelic and result from mutations in a zinc metalloprotease (*MBTPS2*) that is important for cholesterol homeostasis, handling endoplasmic reticulum stress, and cell differentiation.<sup>267,268</sup> Mutations in *MBTPS2* also cause X-linked Olmsted syndrome (see Chapter 5) and BRESEK/BRESHECK syndrome. The latter disorder is characterized by brain anomalies, retardation (intellectual, associated with microcephaly), ectodermal dysplasias (atrichia and photophobia, but not ichthyosis follicularis), skeletal deformities (especially vertebral and hand anomalies), Hirschsprung disease, eye or ear anomalies, cleft lip/palate or cryptorchidism, and kidney

**Figure 7-28** Ichthyosis follicularis, congenital atrichia, and photophobia syndrome. **(A)** Note the total alopecia and the erythematous, scaling skin. **(B)** Note the spiny keratotic follicular papules of the eyebrows and lashes and the atrichia. The patient's photophobia prevents him from looking at the camera and has led to tearing. **(C)** Periungual erythema and marked nail yellowing and thickening; note the psoriasiform plaques at the ankle and on the dorsal aspect of the foot.

anomalies.<sup>269</sup> The most common features are included in the BRESEK acronym.

KFSD may also be autosomal dominant in inheritance,<sup>49,270</sup> although the underlying molecular defect is unclear.<sup>271</sup> Marked facial erythema, extensive folliculitis, onychodystrophy, and multiple caries have been described in these patients.

Ichthyosis in association with hair abnormalities may also be seen in ichthyosis hypotrichosis syndrome, ichthyosis-hypotrichosis-sclerosing cholangitis syndrome, Netherton syndrome (see Chapter 5) and TTD. Another disorder with nonscarring partial alopecia that must be distinguished is hereditary mucoepithelial dysplasia.<sup>272</sup> In addition to extensive keratosis pilaris and psoriasisiform plaques, affected individuals show fiery red mucosal inflammation (hard palate, gingival, tongue, perianal, and perineal), and ocular photophobia with keratitis, cataracts, and corneal opacities.

The follicular scarring of these disorders should be distinguished from disorders of follicular atrophoderma without keratotic plugs. These include perifollicular atrophoderma of acne scarring (see Chapter 8), Conradi-Hünermann syndrome (see Chapter 5), Rombo syndrome, and Bazex syndrome. Treatment of these disorders of follicular plugging is challenging, with most patients refractory to systemic and topical steroids, systemic antibiotics, dapsone, methotrexate, and systemic retinoids.<sup>265,270</sup>

## OTHER SCARRING ALOPECIAS

Scarring or cicatricial alopecia is the end result of a wide number of inflammatory processes in and around the pilosebaceous units, resulting in irreversible destruction of tissue and consequent permanent scarring alopecia.<sup>114,273</sup> The scarring may be the result of a developmental defect (aplasia cutis) (see Figs. 2-34 and 2-35); inflammatory changes due to severe bacterial, viral, or fungal infection; physical trauma (halo alopecia from caput succedaneum<sup>274</sup> [see Chapter 2], irradiation, long-term trichotillomania, thermal or caustic burns); neoplastic or infiltrative disorders (including severe alopecia mucinosa); various dermatoses (lichen planus, lupus erythematosus, localized or systemic scleroderma [see Chapter 22]); keratosis pilaris atrophicans, a group of disorders of hair plugging; or various dermatologic syndromes such as folliculitis decalvans, dissecting cellulitis of the scalp, acne keloidalis, and pseudopelade.

### Follicular Mucinosis

Follicular mucinosis (alopecia mucinosa) is an inflammatory disorder characterized by sharply defined follicular papules or infiltrated plaques with scaling, loss of hair, and accumulation of mucin in sebaceous glands and the outer root sheaths of affected hair follicles.<sup>275-277</sup> A relatively uncommon condition affecting children as well as adults, the disorder is characterized by often pruritic, grouped follicular papules that often coalesce into scaling plaques or nodular boggy infiltrated plaques with overlying erythema and scaling (Fig. 7-29). Lesions usually measure 2 to 5 cm in diameter. Distributed primarily on the face, scalp, neck, and shoulders (occasionally the trunk and extremities), lesions are usually devoid of hair. Except in the scalp or eyebrows, the alopecia is generally not conspicuous.

The cause of follicular mucinosis is unknown. In the majority of cases (in those <40 years of age), it is a benign idiopathic condition.<sup>278</sup> In persons older than age 40, however, the presence of boggy infiltrated plaques of alopecia mucinosa may be the first sign of cutaneous T-cell lymphoma. Cutaneous T-cell lymphoma has rarely been described in children with follicular mucinosis,<sup>279</sup> so affected children must be monitored carefully.<sup>280-282</sup>

Follicular mucinosis must be differentiated from lichen spinulosus,<sup>283</sup> pityriasis rubra pilaris, tinea infection, pityriasis alba, granulomatous diseases, and the papulosquamous group of disorders. When the diagnosis remains in doubt, cutaneous biopsy of an affected area is generally confirmatory, showing accumulation of mucin within the hair and sebaceous glands.

Solitary or few lesions usually clear spontaneously within 2 years. More numerous and widely distributed plaques tend to be more chronic. Destruction of follicles may give rise to permanent alopecia, and the disorder may persist with new lesions continuing to appear over years. Although some cases appear to benefit from topical or

**Figure 7-29** Alopecia mucinosa. An erythematous, mildly scaling, infiltrated hairless plaque. Biopsy shows mucin in the follicular area. Alopecia mucinosa tends to be a benign condition in children but has been associated with cutaneous T-cell lymphoma in adults.

intralesional corticosteroids, such claims are difficult to evaluate because spontaneous healing is the rule.

### Folliculitis Decalvans

Folliculitis decalvans is characterized by successive crops of patchy, painful folliculitis leading to progressive hair loss and scarring.<sup>284</sup> The disorder must be distinguished by culture from bacterial folliculitis caused by *Staphylococcus aureus*, although the two forms often coexist, leading to the hypothesis that folliculitis decalvans results from an abnormal host response to staphylococcal toxins.<sup>285</sup> Folliculitis decalvans may begin during adolescence in male patients but is rarely seen in female patients before 30 years of age. Although the scalp is the most commonly affected site, hair-bearing areas of the trunk, axillae, and pubic region may be affected. Typical lesions show round to irregular bald, atrophic patches, each surrounded by crops of follicular pustules. Tufted folliculitis is a variant in which tufts of hair emerge from dilated follicular openings amid areas of scarring.<sup>285</sup>

Treatment of folliculitis decalvans is difficult. Systemic antibiotics that penetrate the follicle well (tetracyclines, clindamycin, erythromycin) with or without rifampicin often prevent disease extension, but continued administration is required to prevent relapse.<sup>286</sup> Many individuals develop severe alopecia and scarring despite long-term and intensive therapy.

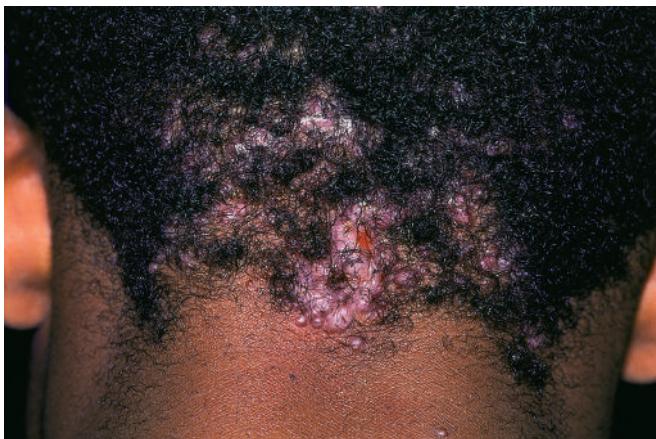

### Dissecting Cellulitis of the Scalp

Dissecting cellulitis of the scalp, also termed *perifolliculitis capitis abscedens et suffodiens*, is characterized by painful fluctuant nodules and abscesses of the scalp connected by tortuous ridges or deep sinus tracts with cicatricial alopecia.<sup>5</sup> The connection can often be demonstrated by applying pressure to one nodule and observing purulent drainage emerging from another. Lesions are usually first noted at the occipital area or vertex but may progress to involve the entire scalp. The disorder occurs most commonly in African-American male teenagers and young adults.<sup>287</sup> An association with acne conglobata and hidradenitis suppurativa has been described ("follicular occlusion triad"), suggesting an inflammatory reaction to *Propionibacterium acnes*. Other pustular disorders of the scalp, including bacterial folliculitis and inflammatory tinea capitis (kerion), must be considered.<sup>288,289</sup>

The disorder has a chronic, relapsing course. Although use of oral tetracyclines or erythromycin with or without surgical drainage of lesions may be effective, many studies suggest systemic administration of isotretinoin to be the treatment of choice.<sup>290</sup> Laser ablation has also been advocated.<sup>291</sup>

### Acne Keloidalis

Acne keloidalis (folliculitis keloidalis) is a chronic scarring folliculitis and perifolliculitis of the nape and occipital scalp.<sup>292-294</sup> Initial lesions tend to be inflammatory papules and occasionally pustules that evolve

**Figure 7-30** Acne keloidalis. Scarring folliculitis with keloidal scarring at the nape and occipital scalp in this 17-year-old African-American adolescent.

**Figure 7-31** Telogen effluvium. Hair shedding is increased and, if a significant amount, a detectable increase in sparsity of hair may be noted. The loss is diffuse across the scalp but tends to stabilize after a few months and usually returns to normal within about 6 months.

into firm keloidal, often coalescent papules and plaques (Fig. 7-30). Severe cases may show abscesses and sinus formation. Patients may complain of pruritus and discomfort. The disorder is seen most commonly in postpubertal males, especially African-Americans between the ages of 14 and 25 years, but is occasionally described in females.<sup>295</sup>

Acute inflammation of the follicle is thought to be the primary pathologic process, followed by a granulomatous foreign body reaction to released hair, and subsequent fibrosis; a variety of triggers have been proposed, among them irritation from shirt collars or helmets, bacterial folliculitis, or ingrown hairs after a short haircut. Treatment of this disorder is difficult and consists of long-term systemic antibiotics and intralesional corticosteroids. Patients should avoid close “clipper” haircuts and scratching of the area. Laser and excision with second-intention healing have been helpful for selected patients, especially with fibrotic nodules.<sup>296,297</sup> Targeted ultraviolet B (UVB) light therapy has shown promise.<sup>298</sup>

#### Pseudofolliculitis Barbae

Pseudofolliculitis barbae, commonly called *razor bumps* or *ingrown hair*, is an inflammatory condition of hair follicles of the beard area that is particularly common in adolescent males of African ancestry with curly, coarse hair (see Chapter 14).<sup>293,294,296,299,300</sup> The condition can affect adolescent girls with tightly curled hair, however, especially if shaving occurs on the face because of hirsutism or because of hair removal elsewhere (waxing plucking or shaving of the axillae or pubic area). Erythematous, 2- to 4-mm, flesh-colored or often hyperpigmented, follicular-based papules are characteristic. The shape of the hair follicle, hair cuticle, and direction of hair growth predispose the patient to the inflammatory response when hair is shaved or plucked.<sup>301</sup> A single-nucleotide polymorphism (SNP) in *KRT75*, encoding hair keratin 75, has been linked with a much greater tendency to develop pseudofolliculitis barbae, especially in individuals with curly hair.<sup>302</sup> It is theorized that the pressure and traction exerted by close and regular shaving destabilizes the hair keratin.<sup>302</sup>

Pseudofolliculitis barbae is thought to represent a foreign-body reaction around an ingrown hair. Therapy largely involves prevention, particularly by temporarily discontinuing shaving or other forms of hair removal and then instituting alternative techniques that decrease the closeness of the shave such as use of an electric razor (avoiding the “closest” shave setting), the Bumpfighter razor (American Safety Razor Company, Staunton, VA),<sup>303</sup> or chemical depilatories. The condition tends to clear 4 to 8 weeks after discontinuation of triggers. Shaving should always be in the direction of hair growth, and pre-treatment with an antibacterial soap or benzoyl peroxide wash may decrease the potential inflammation from bacterial overgrowth. Adjunctive topical agents are retinoids, low-potency topical steroids, topical antibiotics, and depigmenting agents. Nonlaser epilation is not recommended and may exacerbate pseudofolliculitis barbae; however, the neodymium:yttrium-aluminum-garnet (Nd:YAG) 1064 nm and

diode (800 to 810 nm) lasers have been used to epilate the curly hairs and can cause significant improvement.<sup>304–306</sup> Elflornithine cream, which inhibits hair growth, may also be helpful but may be associated with the development of local irritation.

#### Pseudopelade

Pseudopelade is a nonspecific scarring form of slowly progressive alopecia of the scalp generally seen in adults, although it has been described rarely in children. It may represent the end result of discoid lupus erythematosus (see Chapter 22) or lichen planopilaris (see Chapter 4). It is characterized by multiple small round, oval, or irregularly shaped hairless cicatricial patches of varying sizes. Affected areas are shiny, ivory white or slightly pink, and atrophic. Lesions commonly coalesce to form finger-like projections and have been compared to footprints in the snow. Lesions generally appear at the vertex of the scalp. A few hair-containing dilated hair follicles may be interspersed between the patches. The condition tends to resolve spontaneously after several years, leaving the alopecia. Therapy is often unsuccessful, although intralesional injections of triamcinolone have temporarily benefited some patients. Cosmetic improvement has also been achieved by the multiple-punch autograft technique of hair transplantation.

#### Telogen Effluvium

The normal cyclic pattern of anagen and telogen hair phases may be interrupted by a variety of different stimuli, resulting in telogen effluvium. Telogen effluvium represents the most common type of alopecia in children and is characterized by diffuse thinning of scalp hair to varying degrees (Fig. 7-31).<sup>4</sup> The average individual who shampoos at least every other day loses 50 to 100 telogen hairs per day, but 25% of scalp hair (25,000 hairs) must be shed before unmistakable thinning becomes apparent.<sup>307–309</sup>

Several stimuli are capable of producing an interruption in the anagen phase of the hair follicles (Box 7-5). Telogen effluvium may be suggested by a history of a stressful event preceding the onset of alopecia by 6 to 16 weeks that shifts more hairs into telogen phase. Most common are acute illnesses, especially with fever, major trauma, surgery, or childbirth. Initiation of medications (Box 7-6) or discontinuation of medications, particularly oral contraceptives, isotretinoin, anticonvulsants, cimetidine, and terbinafine, has also been implicated.<sup>310,311</sup> More chronic telogen effluvium has been associated with chronic illness, thyroid abnormalities, iron deficiency anemia, malabsorption (e.g., celiac disease), malnutrition (e.g., anorexia nervosa),<sup>36</sup> systemic lupus erythematosus,<sup>312</sup> and zinc deficiency. The proportion of follicles affected and the severity of the subsequent alopecia depend on the duration and severity of the trigger and individual variations in susceptibility.

The diagnosis may be confirmed by both counting the number of hairs shed each day and determining the percentage of telogen hairs

### Box 7-5 Potential Triggers of Telogen Effluvium

- Emotional stress
- Fever (high)
- Medications (see Box 7-6)
- Nutritional disorders
  - Biotin deficiency
  - Dieting, crash; anorexia
  - Essential fatty acid deficiency
  - Iron deficiency
  - Hypervitaminosis A
- Physiologic telogen effluvium of the newborn
- Parturition
- Severe chronic illness
- Severe infection
- Surgery
- Thyroid disease (hyperthyroidism or hypothyroidism)

### Box 7-6 Pediatric Medications That May Be Associated with Telogen Effluvium

- Albendazole
- Amphetamines
- Angiotensin converting enzyme inhibitors (e.g., captopril, enalapril)
- Anticoagulants (e.g., heparin, warfarin)
- Anticonvulsants (e.g., valproic acid, carbamazepine)
- $\beta$ -Blockers (e.g., propranolol)
- Cimetidine
- Danazol
- Interferon- $\alpha$
- Lithium
- Oral contraceptives (during use or with discontinuation)
- Retinoids (e.g., isotretinoin)

in the scalp. Telogen hair represents approximately 15% and anagen 85% of scalp hair. If 25% or more of gently pulled hairs are telogen, telogen effluvium can be diagnosed. Anagen hair roots can be recognized by their intact outer and inner hair sheaths, with or without a portion of the dermal papilla adherent to the tip of the root (see Fig. 7-1, A). Telogen hair roots have uniform shaft diameters, contain no pigment, and are club shaped (see Fig. 7-1, B), much like the tip of a cotton-tipped applicator.

Increased telogen hair loss can also be seen in children with short anagen syndrome, in which the short, fine hair does not require haircuts and is present from birth. The shortening of the anagen phase, despite a normal rate of growth, leads to the decrease in the maximal hair length and an increase in the number of hairs in telogen. The disorder tends to resolve spontaneously during puberty and adulthood.<sup>313</sup> Elongation of the anagen phase has also recently been described as a result of mutations that deplete fibroblast growth factor 5 (FGF5), a regulator of hair length.<sup>314</sup> Because anagen hairs are already the majority of scalp hair but represent the minority of hairs of the eyelashes and extremities, trichomegaly (very long eyelashes) and longer extremity hair are the clinical manifestations in this recessive disorder that is homologous to the "angora" mutation in several species.

There is no effective treatment for telogen effluvium, but complete regrowth almost invariably occurs within months unless the stressful event is repeated or the underlying trigger is sustained. Careful explanation of the cause of this disorder and its favorable prognosis, with careful instructions to the patient to avoid unnecessary manipulation, tends to suffice. Blood tests for underlying disorders should be performed based on personal and family history and on examination, especially if no trigger is obvious. Adolescents predisposed to AGA may show incomplete regrowth after telogen effluvium with a residual pattern of hair loss consistent with AGA. Rarely, prolonged illness with high fevers destroys some follicles completely and only partial recovery ensues. Telogen effluvium occasionally occurs more than once in an individual, suggesting a predisposition to more significant hair loss with stress.

**Figure 7-32** Alopecia areata. Individuals with this common hair disorder suddenly develop one or more round or oval well-circumscribed, clearly defined patches of hair loss.

### Anagen Effluvium

In anagen effluvium, hair shaft production is markedly reduced, leading to tapering of the shaft and shedding.<sup>315</sup> Given that more than 80% of scalp hair is in anagen phase, hair loss is usually profound. Anagen effluvium usually occurs in patients administered radiation or chemotherapy for malignancy. Most commonly implicated are cyclophosphamide, methotrexate, 6-mercaptopurine, and doxorubicin.<sup>310,311</sup> In addition, anagen effluvium may be associated with exposure to colchicine and toxic levels of boric acid, lead, thallium, arsenic, bismuth, and warfarin.<sup>310</sup>

The clinical features of anagen effluvium depend on the degree of toxicity created by the causative agent. With lower doses of the toxic agent, only segmental thinning or narrowing may occur without actual fracture of the hair shaft. Gentle hair pulls yield "pencil point" dystrophic hairs with proximal tips tapered to a point.<sup>308</sup> With extensive anagen effluvium, the remaining hairs are telogen, and the hair plucks late in the course may show as many as 100% telogen hairs. A careful history, documented evidence of hair loss, microscopic examination of spontaneously shed and manually epilated hairs, and appropriate physical and toxicologic examinations help to establish the correct diagnosis. Cessation of the responsible drug or toxin generally results in regrowth of hair.

### Alopecia Areata

Alopecia areata (AA), one of the most common hair loss disorders with a prevalence of 0.1% to 0.2% of the population, is characterized by the sudden appearance of sharply defined round or oval patches of hair loss.<sup>316–318</sup> Alopecia totalis (loss of all scalp hair) or alopecia universalis (loss of all body hair) develops in approximately 5% of cases. The cumulative lifetime risk of developing AA is 2.1%, with the peak incidence occurring during young adulthood.<sup>319</sup> Prepubertal onset occurs less often than onset during adolescence but is not uncommon and is associated with a family history of AA and a poorer prognosis. Occurrence in young infants is unusual, and the disorder is very rare in neonates.<sup>320</sup>

There is a strong association between AA and atopic dermatitis, which is greatest among prepubertal children and in individuals with alopecia totalis and alopecia universalis.<sup>321–324</sup> Loss-of-function mutations in *FLG* (encoding filaggrin) have been associated with a more severe course and associated atopy but not a higher risk.<sup>325</sup> There is no sexual predilection for the disorder. Familial occurrence is reported in 8% to 52% of children, with an estimated lifetime risk of 7.1% in siblings, 7.8% in parents, and 5.7% in offspring.<sup>326</sup> Occurrence in both identical twins is 55%, emphasizing the importance of genetic as well as environmental factors.

The typical clinical picture of AA generally consists of a sudden (overnight or several days) appearance of one or more round or oval, well-circumscribed, clearly defined patches of hair loss (Fig. 7-32). Overall 83% of children have this patchy loss involving less than 50%

**Figure 7-33** Alopecia areata. Regrowing hair may be vellus hair or appear hypopigmented but is eventually replaced by normally pigmented terminal hair.

**Figure 7-35** Alopecia areata. The ophiasis pattern involves hair loss in a band extending from the occiput bilaterally along the hair margin toward the region above the ear and sometimes circling to the anterior scalp.

**Figure 7-34** Alopecia areata. "Exclamation-point hairs" in a girl with an ophiasis pattern of hair loss. Under the microscope, these hairs demonstrate a tapered shaft to an attenuated bulb (the "dot" of the exclamation point).

**Figure 7-36** Alopecia universalis. All hair is lost on the scalp and elsewhere. This is associated with a much poorer prognosis for hair regrowth.

of the scalp. Occasionally the initial patches may lack a regular outline and at times may demonstrate scattered long hairs within the bald areas. In other instances the initial loss may be diffuse, with discrete patches of alopecia being apparent only after 1 or 2 weeks, if at all. The primary patch may appear on any hairy cutaneous surface but usually occurs on the scalp. The skin is smooth, soft, and almost totally devoid of hair. Rarely, slight erythema or edema may be found at an early stage. Depigmented or hypopigmented hair shafts, simulating poliosis, may be seen (Fig. 7-33). Discrete islands of hair loss sometimes are separated by completely uninvolved or partially involved scalp. Around the margins of patches of alopecia, pathognomonic "exclamation-mark" hairs may be detected (Fig. 7-34). These loose hairs, with attenuated bulbs and short stumps, are easily plucked out of the scalp. Examination of such hairs under a low-power microscope reveals an irregularity in diameter and a poorly pigmented hair shaft that tapers to an attenuated bulb. The hair bulb represents the dot of the exclamation point. Dermoscopic evaluation of affected scalp can be very helpful, showing the tapered hairs and sometimes yellow perifollicular dots, demarcating the hyperkeratotic follicular plugs.<sup>327,328</sup>

The ophiasis pattern of hair loss begins as a bald spot on the posterior occiput and extends anteriorly and bilaterally in a 1- to 2-inch wide band encircling the posterior scalp, usually extending above the ear but occasionally to the anterior aspect of the scalp (Fig. 7-35). The ophiasis pattern is generally associated with a poor prognosis.<sup>329</sup> Progression to the totalis or universalis forms (Fig. 7-36) occurs more slowly but more often in children than in adults. Alopecia may involve

**Figure 7-37** Alopecia areata. The alopecia may involve the eyebrows and eyelashes, even without hair loss on the scalp; in this situation, trichotillomania must also be considered.

any hair; eyebrows and eyelashes may be lost with or without patches of hair loss on the scalp (Fig. 7-37).

Nail defects are seen in 10% to 20% of cases. Although more extensive disease is associated with more nail involvement, some patients may have extensive nail dystrophy with little hair change. The most

**Figure 7-38** Alopecia areata with nail changes. **(A)** The nails in this boy with alopecia areata are covered with shallow pits resulting from alteration in the proximal matrix. **(B)** Punctate opacification, proximal shedding (onychomadesis), Beau lines (horizontal dells), and serration of the free edges are all seen in the nails of this young girl with alopecia universalis.

characteristic nail abnormality is a fine, grid-like stippling, regularly arranged in horizontal and/or vertical rows with smaller and shallower pits than those seen in patients with psoriasis (Fig. 7-38, A). Proximal shedding (onychomadesis), opacification, and serration of the free edges may also be seen (Fig. 7-38, B). Longitudinal ridging (trachonychia) is another associated finding. Nail dystrophy tends to occur more often and be more severe in patients with alopecia totalis and universalis.

The diagnosis of AA is based on its clinical picture. The sudden appearance and circumscribed nonscarring, patterned nature of hair loss distinguish it from other disorders of alopecia. Trichotillomania is typically associated with bizarre, irregular patches of hair loss with areas of broken hairs of different lengths. The absence of signs of inflammation and scaling will generally help distinguish this disorder from that of tinea capitis. When the diagnosis is in doubt, microscopic examination of hairs, potassium hydroxide mounts, fungal cultures, and cutaneous punch biopsy will generally establish the proper diagnosis. Alopecia universalis beginning in infants must be distinguished from congenital alopecias such as atrichia with papules.<sup>330</sup> The AA spectrum can be a feature in 33% of children with autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED; see Chapter 23) syndrome because of mutations in AIRE.<sup>331</sup> Although associated autoimmune disorders in affected children are quite rare, a family history of other autoimmune disorders, especially thyroiditis, is common, and autoantibodies may be detected in patient sera.<sup>332</sup> An increased incidence has also been noted in patients with trisomy 21.

The course of AA is variable and difficult to predict.<sup>333</sup> New patches of hair loss may appear for 4 to 6 weeks and occasionally for several months. Spontaneous regrowth may occur. In general, when the process is limited to a few patches, the prognosis is good, with complete

regrowth occurring within 1 year in 60% to 80% of patients; progression to total loss of scalp hair is unusual (<10%) and portends a considerably worse prognosis. About 30% of patients with patchy AA will have future episodes once regrown. In general, the earlier the onset, the poorer the prognosis. Other prognostic indicators of a worse outcome are family history of autoimmune disease, personal history of atopy, and nail abnormalities. Therapy for AA at best controls the condition but does not cure it or prevent development of new areas.<sup>334-336</sup> Because of the chronic nature of the condition and the slow growth of hair, any trial of a treatment modality requires at least 4 months. The sudden hair loss, cosmetic ramifications, and unpredictable course make AA a frightening disorder for affected patients and families<sup>337</sup>; psychological support and counseling are required for all patients and parents. Adequate camouflage of alopecic areas may be achieved by hats, headbands, or hairstyle changes. In children with severe involvement, wigs can be helpful. Locks of Love is an organization that provides hair prostheses to financially disadvantaged children under the age of 18 years ([www.lockslove.org](http://www.lockslove.org)).<sup>338</sup> The National Alopecia Areata Foundation ([www.alopeciaareata.com](http://www.alopeciaareata.com)) is a national support group for affected children and their families. Given the high percentage of children with patchy AA who show spontaneous remission within a year, some physicians prescribe no therapy for this condition. In general, patients with more extensive AA or with limited involvement unresponsive to topical corticosteroids should be referred to a dermatologist.

The most commonly used therapy for more limited AA in children is topical corticosteroids, with or without occlusion (such as may be achieved under a wig, bathing cap, or Saran Wrap); class II (potent) steroids are usually administered. Because the regrowth rate without medications is high, it has been hard to demonstrate clear evidence of the efficacy of steroids. If a class I (ultrapotent) steroid is employed, its use should be limited to intermittent pulse therapy; longer use may result in significant local atrophy and systemic absorption. In one study, clobetasol cream was more effective than 1% hydrocortisone in decreasing extent of hair loss by 12 weeks of twice daily use when used for 6 weeks on and 6 weeks off for a total of 24 weeks.<sup>339</sup> Intra-dermal corticosteroid injections commonly result in regrowth in tufts at injection sites within 4 to 6 weeks but are too uncomfortable for most children, even with the use of topical anesthetic creams. When an intralesional corticosteroid is used, a syringe with a 30-gauge needle or jet injection is best. Triamcinolone acetonide is injected in concentrations of 2.5 mg/mL (eyebrow area) to 10 mg/mL (scalp). Dosage should be limited to 0.1 mL per site, spaced at least 1 cm apart, with injections at intervals of at least 4 to 6 weeks.<sup>317</sup> Transient local atrophy may occur. Efficacy appears to be greatest in those who have less than 75% hair loss and with a relatively short duration of hair loss.

Minoxidil has been shown to stimulate follicular DNA synthesis. Although largely used for AGA, 2% to 5% topical minoxidil solution has been shown to cause cosmetically acceptable hair regrowth in approximately 20% to 45% of patients when used twice daily for 2 months.<sup>340</sup> Best results occur in patients with limited hair loss and when used concurrently with topical corticosteroids or anthralin. Cutaneous side effects may include local irritation, allergic contact dermatitis, and hypertrichosis, especially on the forehead (Fig. 7-39). Although quite rare, three children treated with topical minoxidil developed tachycardia, palpitations, and dizziness.<sup>341</sup> Prostaglandin F2a analogues (e.g., latanoprost, bimatoprost, travoprost) have not been helpful for alopecia of the eyelashes or brows<sup>342</sup> and have been linked to periorbital hyperpigmentation.<sup>343</sup>

Anthralin cream is an alternative therapy that seems to elicit hair growth by nonspecific immunostimulation. The 1% cream is usually applied as short-contact therapy, initially for 30 minutes with a gradual increase in exposure as tolerated to a maximum of 2 hours before shampooing of the scalp. A mild dermatitis is often required for regrowth, so concurrent use of topical corticosteroids is not recommended. New hair growth is usually seen in 3 months, but 6 months or more may be required for an acceptable response. Scalp irritation, folliculitis, and staining of the skin or clothes are potential adverse effects.

Two studies have demonstrated significantly low levels of vitamin D in individuals with AA,<sup>344,345</sup> and a boy with AA responded to topical

**Figure 7-39** Hypertrichosis induced from topical medications. Children who apply both topical corticosteroids and minoxidil are at particularly high risk for developing localized hypertrichosis, especially on the forehead (**A**) and nape (**B**).

calcipotriol,<sup>346</sup> but no causal relationship with vitamin D deficiency has been confirmed. Excimer laser therapy twice weekly is painless and caused hair regrowth in 60% of recalcitrant patches of AA in children in less than 3 months; only 22% of responders relapsed after 6 months.<sup>347</sup>

Treatment of more extensive AA (>50%), alopecia totalis, and alopecia universalis is very difficult. Topical application of corticosteroids is generally not helpful, but anthralin has shown greater responses. Topical immunotherapy is considered the treatment of choice for chronic, severe AA<sup>318</sup> and has been shown to decrease the T-cell infiltration.<sup>348</sup> Patients are initially sensitized to the contact allergen (2%); then increasing concentrations of the allergen beginning at 0.001% (occasionally stronger) are applied to the scalp until mild erythema and scaling develop. Squaric acid dibutyl ester and diphenylcyclopropane are used most commonly, because they are effective but not mutagenic or carcinogenic. Contact dermatitis at the sensitization site (about 20% of treated children)<sup>349</sup> or treatment site and regional lymphadenopathy are the risks of this therapy but only occasionally lead to discontinuation.<sup>350,351</sup> Immunotherapy may be performed weekly by the physician or administered with careful monitoring by responsible parents at home on a daily basis, gradually increasing the frequency of application and dosing. Up to 40% respond to immunotherapy with complete regrowth, although 70% to 80% show some response.<sup>352,353</sup> Unfortunately, relapse occurs in 81% of responders.<sup>354,355</sup> In patients who are atopic with extensive AA, the addition of oral fexofenadine to the contact allergen treatment may increase the response.<sup>356</sup> Although photochemotherapy with systemic psoralen followed by ultraviolet A (PUVA) light and cyclosporine therapy have been successful in some adults with this disorder, their efficacy and potential toxicity probably do not justify their use in children.

Although not recommended for general use, systemic corticosteroids may be considered for carefully selected patients with severe involvement and rapidly progressive hair loss who are psychologically

handicapped by their disorder. In such instances, prednisone may be administered in dosages of 0.5 to 1 mg/kg per day for 4 weeks until hair loss ceases and then tapered to alternate-day therapy for a few months. It must be emphasized that close follow-up evaluation is indicated in such cases and that the potential side effects associated with systemic corticosteroid therapy must be explained to the patient and parents. Pulse therapy with intravenous methylprednisolone has also been administered at a dosage of 250 mg twice daily for three sequential days with cessation of hair loss,<sup>357</sup> but the long-term outcome after corticosteroid therapy is poor.<sup>358</sup> In one retrospective study of 24 children with multifocal disease to alopecia universalis, 5 to 6 monthly treatments on 3 consecutive days of 8 mg/kg intravenous methylprednisolone led to a complete response in 38% and no response in 33%, but 81% relapsed within a mean of 9.5 months after therapy.<sup>359</sup> Not surprisingly, patients with duration of less than 6 months and an onset at younger than 10 years of age and multifocal vs. diffuse disease responded better. Continuing application of topical minoxidil after a steroid taper has been shown to decrease hair loss. Methotrexate (0.3 to 0.6 mg/kg per week) led to greater than 50% hair regrowth in 5 of 12 children (>40%) with recalcitrant AA in whom it was used for more than 2 months. The mean time to regrowth was 4.4 months, and all responders experienced improvement within 6 months.<sup>360</sup> Sulfasalazine has shown cosmetically acceptable improvement in about 25% of treated adults<sup>361</sup> when used at a dosage of 1.5 g twice daily (starting instead with 0.5 g/dose and then 1 g/dose for the first and second month, respectively). Trials with TNF inhibitors have been disappointing,<sup>362,363</sup> and AA has developed during TNF inhibitor therapy.<sup>364</sup>

Recent studies, including a genome-wide association study (GWAS) of more than 1000 affected individuals,<sup>365</sup> have shed light on the underlying pathomechanism of AA.<sup>365-373</sup> Whereas most of the linked genes involve the immune system, a receptor for stress-induced proteins (NKG2D) is also strongly linked, which is of interest because a stressful event precedes the onset of AA in 9.5% to 58% of patients.<sup>374,375</sup> These mechanistic studies have led to the discovery that systemic administration of Janus kinase (JAK) inhibitors (ruxolitinib, tofacitinib) prevent the development of AA in the C3H/HeJ-grafted mouse model and in pilot studies lead to almost complete hair regrowth after up to 5 months of 20 mg ruxolitinib twice a day orally in adults with severe AA.<sup>376</sup> Topical administration of ruxolitinib and tofacitinib to established mouse AA also led to full hair regrowth within 12 weeks, suggesting the applicability of topical therapy for pediatric AA.<sup>376</sup>

### Androgenetic Alopecia

Androgenetic alopecia (AGA) occurs in both males (common baldness or male-pattern baldness) and females (hereditary thinning or female-pattern hair loss) and is the most common cause of hair loss in adolescents<sup>377</sup> and adults. In many cases, it begins in teenage years with onset as young as 7 years<sup>378,379</sup>; in general, the earlier the onset, the more profound the subsequent alopecia. The disorder is characterized by patterned, progressive hair loss from the scalp and results from the effects of circulating androgens in genetically susceptible individuals. Dihydrotestosterone is the primary androgen implicated, converted from testosterone by the enzyme 5- $\alpha$ -reductase. These androgens gradually decrease the size of scalp hair follicles, resulting in miniaturized hairs. In addition, the anagen growth phase is shortened, leading to more hairs in telogen phase. The condition is inherited as a polygenic trait influenced by both maternal and paternal genes<sup>380</sup>; in one study, 83% of adolescents with AGA had an affected first-degree relative.<sup>377</sup>

Most patients with AGA note thinning of scalp hair rather than shedding, although shedding may occur early in the course and be confused with telogen effluvium or diffuse AA. AGA during adolescence occurs twice as often in males as in females and is generally more severe. The mildest and often earliest form of androgenetic male-pattern alopecia in males is thinning at the vertex, often in conjunction with symmetrical bitemporal triangular recession of the hairline (Fig. 7-40). In girls, the frontal hairline is relatively unaffected and there is either just vertex thinning or more commonly, diffuse thinning, particularly from the frontal scalp to the vertex (see Fig. 7-38). Widening of the central hair part is often seen, leading to scalp

**Figure 7-40** Androgenetic alopecia. The scalp hair is thinned progressively but most notably between the frontal region of the scalp and the vertex.

**Figure 7-41** Androgenetic alopecia. Widening of the central hair part is often seen, leading to scalp visibility.

visibility (Fig. 7-41). This female pattern of more diffuse hair loss is observed in 20% to 33% of adolescent males.<sup>377,379</sup>

The diagnosis of AGA can be suspected by the patterning of the scalp hair loss. Dermoscopy is a useful adjunctive measure to visualize the miniaturized hairs in affected areas.<sup>3</sup> If confirmation is required, scalp biopsy can be performed, particularly with horizontal sectioning to determine the ratio of terminal to vellus hairs (>7:1 is normal; <4:1 is diagnostic). Other supporting histologic features are the perifollicular inflammation and fibrosis. Hormonal evaluation and endocrinologic consultation for female patients should be considered, especially in the presence of menstrual irregularities, moderate to severe acne, seborrhea, and evidence of virilization such as hirsutism. Laboratory evaluation should include testing for thyroid disease, iron deficiency, free and total testosterone, dehydroepiandrosterone sulfate (DHEA-S), 17-OH-progesterone (to consider late-onset congenital adrenal hyperplasia) and if appropriate, prolactin levels. In one study 37.5% of 19 affected adolescent girls had increased levels of androgens, and 47% showed at least one additional clinical feature of hyperandrogenism. Laboratory testing should also be considered in boys

who have diffuse thinning (more of a female pattern) or abnormal pubertal development.

The occurrence of AGA during teenage years can be quite disturbing to both young men and women. Careful examination and repeated reassurance are required to discourage expensive and ineffective therapeutic regimens. Without treatment, AGA is progressive; the aim of treatment is to retard the further thinning of the hair and to promote hair growth.

Topical minoxidil and oral finasteride are US Food and Drug Administration (FDA)-approved treatments (minoxidil is over-the-counter) but are only approved for use in patients over the age of 18 years. Minoxidil promotes hair growth and decreases hair loss in approximately 60% of male and female patients when applied twice daily.<sup>381–383</sup> Evidence of hair growth requires at least 3 to 6 months. The mechanism of action of topical minoxidil most likely involves its stimulation of follicular proliferation and vascularization of the follicle. Although 2% has been approved for women and 5% for men, the 5% strength can be initiated off-label in either girls or boys, with 2% as an alternative should any issue arise. Application of minoxidil must be continued to maintain hair growth, and hair loss resumes 4 to 6 months after discontinuation. The most common side effect of topical minoxidil is irritation, usually from the propylene glycol in the solution, although orthostatic hypotension has rarely been described. Hypertrichosis has been described on nonscalp sites, possibly from transfer of the solution.<sup>384</sup> The addition of weekly microneedling, which stimulates hair follicle stem cells but may also improve minoxidil penetration, markedly increased the hair count and improved the patient evaluation during a 12-week period in comparison with minoxidil alone.<sup>385</sup> Oral finasteride (1 mg daily) is often combined with the minoxidil for treatment in males, given their different mechanisms of action. Finasteride specifically inhibits type II 5- $\alpha$ -reductase, leading to reduction in both serum and scalp levels of dihydrotestosterone. The only statistically significant side effect of finasteride is sexual dysfunction, and decreased libido or erectile or ejaculatory dysfunction have each been described in 1% to 2% of patients. Postmarketing reports suggest that these adverse sexual effects sometimes persist more than 3 months after discontinuation, but a causal relationship has not been demonstrated. Although sometimes used in boys with AGA, finasteride is known to cause feminization of the male fetus and thus should be used with caution, if at all, for adolescent girls.<sup>386</sup> Oral dutasteride 0.5%, which inhibits both type I and type II 5- $\alpha$ -reductase and is available outside of the United States, has been shown to be more effective than finasteride with the same side effect profile.<sup>387</sup>

Spirostanolactone has shown some benefit in girls with AGA at doses of 50 to 200 mg/day<sup>388</sup>; similarly, cyproterone acetate in doses of 50 to 100 mg/day in combination with ethynodiol has been successful in inducing hair regrowth and preventing progression but is not currently available in the United States. Food supplements with plant extracts including of *Serenoa repens*, a treatment of benign prostatic hyperplasia, have been proposed as a "natural" alternative for treating male AGA.<sup>389</sup> A report of hot flashes in an 11-year-old girl linked to oral ingestion of *Serenoa repens* for telogen effluvium warns of their danger in pediatric patients.<sup>390</sup>

Randomized, double-blind, controlled office- or home-based studies have suggested efficacy of office-based low-level laser therapy, either as monotherapy or with other interventions.<sup>391–393</sup> Surgical procedures, such as scalp reduction with or without tissue expansion, scalp flaps, and multiple-punch autografting hair transplantation, may also be considered in patients with advanced AGA but is inappropriate for use in adolescents, given that the course of the AGA is unpredictable.<sup>394</sup>

### Traumatic Alopecia

Traumatic alopecia results from the forceful extraction of hair or the breaking of hair shafts by friction, pressure, traction, or other physical trauma. The usual causes are cosmetic practices and trichotillomania. Other causes of traumatic alopecia include pressure, such as occurs in neonates who develop caput succedaneum with a scalp ring from birth trauma or use of suction at delivery<sup>474</sup> (see Chapter 2) and as is seen in association with the habit of head banging; prolonged bed rest in one position such as may be seen in chronically ill patients; postoperative alopecia (as a result of pressure-induced ischemia during long

**Figure 7-42** Traction alopecia. Hair loss can be seen at the margins where hair is pulled most tightly through use of barrettes.

surgical procedures); thermal or electric burns; repeated vigorous massage; a severe blow to the scalp; occipitoparietal alopecia such as may be induced by spinning on the crown of the head during break dancing; pressure from orthodontic headgear<sup>395</sup>; or prolonged use of wide-strapped heavy headphones such as those commonly used by individuals while jogging. Prolonged or forceful trauma may cause scarring alopecia.

Alopecia from cosmetic practices most often results from traction but has been described as resulting from pulling, frequent brushing with nylon bristles, the use of hot combs and oils, and hair-straightening practices such as teasing. Traction alopecia is characterized by oval or linear areas of hair loss at the margins of the hair line, along the part, or scattered through the scalp, depending on the type of traction or trauma.<sup>396,397</sup> Peripheral scalp hair loss may occur in individuals who wear their hair in pony-tails or braids or use hair extensions<sup>398</sup> or barrettes (Fig. 7-42). Overall, 17.1% of school-aged African girls showed traction alopecia, with the percentage increasing toward the end of high school and with a history of braids on relaxed hair.<sup>399</sup> In one study, traction alopecia occurred 3 times more often in girls with cornrows versus ponytails or braids.<sup>400</sup> Hair loss from hair rollers is usually most conspicuous in the frontocentral area or around the margins of the scalp. Hot-comb alopecia, seen primarily in African-American individuals who straighten their hair for cosmetic purposes, generally occurs on the vertex or marginal areas of the scalp. In severe chronic forms, however, the entire scalp may be involved. Traction folliculitis may present as perifollicular erythema and pustules at sites of traction.<sup>401</sup>

Trichotillomania is a self-limiting, self-induced form of traction alopecia produced either consciously or by habitually plucking, pulling, or cutting the hair in a bizarre manner.<sup>402–404</sup> Trichotillomania-by-proxy has also been described, in which a parent with trichotillomania pulls the hair of a child as part of the overwhelming urge to depilate.<sup>405</sup> Seen in both sexes, it more commonly occurs in adolescents, although the condition may occur in preschool children. The scalp is the most common site of involvement, but the eyebrows, eyelashes, and even pubic hair may also be affected as the patient plucks, twirls, or rubs hair-bearing areas, resulting in the epilation or breakage of hair shafts (Fig. 7-43).

The habit is usually practiced in bed before the child falls asleep (when the parent does not notice the habit) or when the child is reading, writing, or watching television. In young individuals the condition is commonly associated with a habit of finger or thumb sucking (Fig. 7-44). In older children, other compulsive behaviors such as nail biting (onychophagia), skin picking, picking at acne (acne excoriée), nose picking, lip biting, and cheek chewing may be seen as well. In 2013 the American Psychiatric Association changed trichotillomania in its *Diagnostic and Statistical Manual of Mental Disorders (DSM) 5* classification tool from an impulse-control disorder not elsewhere classified to an obsessive-compulsive disorder.

Trichotillomania usually begins insidiously as an irregular linear or rectangular area of partial hair loss. Affected areas are generally single; often frontal, frontotemporal, or frontoparietal; and commonly

**Figure 7-43** Trichotillomania. The eyebrows and eyelashes may be pulled out or broken by repetitive plucking, twirling, or rubbing.

**Figure 7-44** Trichotillomania. In younger children trichotillomania is often a habit of twirling or plucking associated with finger or thumb sucking and does not reflect significant psychologic disturbance.

appear on the contralateral side of right- or left-handed individuals. The affected patches have irregularly shaped angular outlines and are never completely bald (Fig. 7-45). Within the involved regions, the hair is short or stubby and broken off at varying lengths (Fig. 7-46).

If one maintains a high index of suspicion, trichotillomania can generally be distinguished from other forms of hair loss by its characteristic configuration and distribution. Trichoscopy can be helpful, showing the irregularly broken hairs as well as a variety of other specific signs (such as the V sign, flame hairs, and coiled hairs).<sup>406</sup> Occasionally the diagnosis can be confirmed by the finding of wads of hair under the pillow or bed or by observation of the habit by a parent, teacher, or physician. When the diagnosis is suspected, regrowth of hair in a carefully shaved or occluded patch of scalp in the involved area (to prevent manipulation) may confirm the correct diagnosis. The possibility of associated trichophagia and trichobezoar should be also be entertained.<sup>407</sup>

Trichotillomania should be distinguished from AA, although both have been described in the same individuals, often with the AA as the trigger to the trichotillomania.<sup>408</sup> Clinical differentiation from AA is usually based on the bizarre configuration, irregular outline, and presence of short, stub-like, broken hairs. Differentiation from tinea capitis may require microscopic examination of plucked hairs with potassium hydroxide and fungal culture (see Chapter 17). Of particular significance is the fact that the broken hairs of trichotillomania, unlike those of certain forms of tinea capitis, remain firmly rooted in the

**Figure 7-45** Trichotillomania. The affected areas have irregularly-shaped, angular outlines and are never completely bald. They tend to be sites that are easy to reach.

**Figure 7-46** Trichotillomania. This boy tried to cover a patch of trichotillomania with eyebrow pencil but continued to pluck hairs.

scalp, and the cutaneous surface is normal and stubbled rather than erythematous or scaly. If the diagnosis remains in doubt, biopsy of the involved area may be helpful.

The management of trichotillomania is often difficult and requires a strong relationship among the doctor, patient, and parents. Although patients occasionally will admit to touching the affected areas, they commonly will deny plucking, rubbing, or excessive manipulation. Blunt accusation is often detrimental, but gentle suggestion of the cause may lead to dialog that is important for reversal. Psychopathologic changes are reported to be present in some 50% to 75% of affected individuals. These changes are usually mild, but severe psychologic disturbance occurs in approximately 5% of patients with trichotillomania, most commonly in older children and teenagers. In general, the disorder is limited in preschool-age children and may be more episodic in children than in affected teenagers.

If patients are reassured, given an opportunity to express their emotional needs, and offered a reasonable therapeutic regimen such as a mild shampoo, mild topical steroid (e.g., hydrocortisone 1%) lotion, and behavioral modification techniques, the habit will sometimes disappear, especially in young children. For those individuals with persistent or severe obsessive-compulsive or emotional problems, however,

**Figure 7-47** Vellus hair cysts. Size 1- to 3-mm, skin-colored to hyperpigmented follicular papules on the anterior chest.

psychiatric intervention should be considered. Cognitive behavioral therapy with relapse prevention can reduce trichotillomania severity by 64% at 6-month follow-up evaluation.<sup>409,410</sup> For habitual trichotillomania in young children, substitution therapy (such as with a soft tag to stroke or a long-haired doll) and provision of rewards can be helpful.<sup>411</sup> Olanzapine, clomipramine, or a highly selective serotoninergic reuptake inhibitor (SSRI) (e.g., fluvoxamine, fluoxetine, paroxetine, sertraline, or citalopram) may be of benefit. Despite the value of oral N-acetylcysteine in a large trial of adults with trichotillomania, a recent trial of 39 children ages 8 to 17 years did not show benefit during 12 weeks of treatment.<sup>412</sup> A trichotillomania support group, the Trichotillomania Learning Center, is available at [www.trich.org](http://www.trich.org).

## Eruptive Vellus Hair Cysts

Eruptive vellus hair cysts are characterized by 1- to 3-mm, skin-colored to hyperpigmented follicular papules, most commonly on the anterior chest (Fig. 7-47).<sup>413</sup> Lesions usually are not grouped and tend to be smooth-surfaced with a round or domed shape. Vellus hair cysts have less commonly been described on the upper and lower extremities, face, neck, abdomen, axillae, posterior trunk, and/or buttocks. If darker blue in color and on the face, they have been confused with nevus of Ota.<sup>414</sup> Although usually seen in children between 4 and 18 years of age, these cysts can occur at any age.

The histologic picture of eruptive vellus hair cysts shows small, mid to upper dermal keratinizing cysts filled with lamellar keratin and small-diameter nonpigmented or lightly pigmented hair shafts. Vellus hair cysts can be distinguished from steatocystoma multiplex by the inclusion of sebaceous glands in the cyst wall of steatocystoma multiplex.<sup>415</sup> However, lesions with features of both types of cysts have been described; both types of lesions have been seen in the same individuals, and kindreds with the autosomal dominant inheritance of both vellus hair cysts and steatocystoma multiplex have been reported with keratin 17 mutations, suggesting a common causation for the two types of cystic lesions.<sup>416,417</sup> An alternative diagnostic technique to biopsy is to perform a tiny incision at the top and examine the expressed contents microscopically for vellus hairs.<sup>418</sup>

Vellus hair cysts are most commonly confused with comedonal acne, milia, molluscum contagiosum, syringomas, folliculitis, keratosis pilaris, steatocystoma multiplex, and other adnexal tumors; dermoscopic evaluation can be helpful in making the diagnosis.<sup>419</sup> The cysts may resolve spontaneously during a few months to years by transepidermal elimination. Patients desiring therapy can be treated by incision of individual cysts and expression of their contents followed by gentle curettage, light electrodesiccation with expression of contents,<sup>420</sup> therapy with topical vitamin A acid (tretinoin), lactic acid (12% lotion), or laser.<sup>421</sup>

## Hypertrichosis and Hirsutism

Excessive hairiness may be localized or diffuse, congenital or acquired, and normal or pathologic.<sup>312</sup> Hair in the pubic area of infants may be benign and often resolves spontaneously by 1 year of age, especially if on the scrotum in boys and labia majora or mons in girls without other evidence of virilization or sexual development.<sup>422</sup> The terms *hypertrichosis* and *hirsutism* are commonly and inappropriately used synonymously to describe excessive hair on the body.<sup>423,424</sup> *Hirsutism* implies an excessive growth of body hair in women or children (mostly girls) in an androgen-induced hair pattern (upper lip, chin, sideburn areas, neck, anterior chest, breasts, linea alba, abdomen, upper inner thighs, and legs).<sup>425</sup> *Hirsutism* most commonly represents a physiologic variant of hair growth, often seen in several family members, which comes to medical attention only because of societal pressure to remove excessive hair (Fig. 7-48). *Hypertrichosis*, conversely, refers to a generalized or localized pattern of non-androgen-dependent excessive hair growth in a male or female without evidence of masculinism or menstrual abnormality.

### ACQUIRED GENERALIZED HYPERTRICHOSIS

Generalized hypertrichosis may be associated with neurologic disorders (postencephalitic hypertrichosis, multiple sclerosis), anorexia nervosa, acrodynia, hypothyroidism, porphyria, dermatomyositis, gross malnutrition, and various forms of drug-induced hypertrichosis. Drug-induced hypertrichosis (Fig. 7-49) is most commonly seen in children who are administered phenytoin or cyclosporine, usually after 2 or 3 months of treatment, but other medications have been implicated as well (Box 7-7; see Fig. 22-21). Reversible generalized hypertrichosis has also been described in an infant exposed to topical minoxidil from her caregiver grandfather who held her extensively on his shoulders.<sup>426</sup> Localized hypertrichosis can be acquired from topical application as well, including with minoxidil (see Fig. 7-39) and topical corticosteroids (Fig. 7-50). In adults but not in children, acquired forms of hypertrichosis lanuginosa are strongly associated with internal malignancy, especially adenocarcinoma.

### CONGENITAL HYPERTRICHOSIS

The original fine, soft, unmedullated, and usually unpigmented lanugo hairs are shed *in utero* during the seventh or eighth month of gestation. Premature infants, however, commonly display this fine coat of lanugo hair, particularly on the face, limbs, and trunk. In these

**Figure 7-48** Familial hirsutism. This 6-year-old girl has excessive terminal hair on the upper lip, which led to embarrassment. Her mother and maternal grandmother experienced the same increase in mustache hair.

**Figure 7-49** Drug-induced hypertrichosis. This infant girl developed hypertrichosis from administration of diazoxide for hyperinsulinemia.

**Figure 7-50** Drug-induced hypertrichosis. Overgrowth of terminal hair was noted strictly at the site at which this boy's parents continued to apply a medium-strength topical corticosteroid for many months after clearance of his nummular dermatitis.

### Box 7-7 Medications That May Cause Hypertrichosis

- Adrenocorticotropic hormone (ACTH)
- Corticosteroids
- Cyclosporine
- Danazol
- Diazoxide
- Glucocorticosteroids
- Hexachlorobenzene (drug-induced porphyria cutanea tarda)
- Minoxidil
- Penicillamine
- Phenytoin
- Psoralens and ultraviolet light exposure
- Streptomycin
- Testosterone
- Valproic acid

infants the fine lanugo hairs are shed during the first 3 months of life and replaced by normal terminal hair growth, generally before the first 6 months.

Hypertrichosis lanuginosa is a rare inherited disorder in which lanugo hairs persist or are overproduced throughout life.<sup>427</sup> Affected infants may be unusually hairy at birth or may develop hypertrichosis during early childhood. In some children, the hair will be spontaneously lost during childhood; in others, it will remain into adulthood. Generalized hypertrichosis can be very disfiguring. Affected children have been called *monkey-men*, *dog-face*, and *human Skye terriers*. Sporadic, autosomal recessive, and autosomal dominant cases have been described. Congenital glaucoma, skeletal abnormalities, and missing teeth have been described in association.

Ambras syndrome is a generalized condition of hypertrichosis in which the hair appears to be vellus rather than lanugo hair.<sup>428–430</sup> The hypertrichosis is most evident on the face, ears, and shoulders, and persists throughout life. Dysmorphic facial features have been associated. Ambras syndrome has been linked to a rearrangement in chromosome 8q that downregulates the expression of *TRPS1* (mutated in trichorhinophalangeal syndrome).<sup>431</sup>

Hypertrichosis with gingival hyperplasia is a distinct autosomal dominant disorder in which affected individuals have excessive body and facial hair in an identical distribution to that of hypertrichosis lanuginosa, but patients tend to have terminal hair and have associated gingival hyperplasia (Fig. 7-51). Although the hypertrichosis is most commonly present at birth or in infancy, in up to half of reported cases the hypertrichosis begins at puberty. The gingival hyperplasia is usually noted with delayed tooth eruption and has been described as pink, firm, and pebbly. The disorder is complicated by interference with chewing, respiration, and speech, and periodontal abscesses have been described because of difficulty in dental eruption. Gingival debulking may be required. A large deletion on 17q24.2-q24.3 has been found to be responsible for congenital generalized hypertrichosis, with or without gingival hyperplasia.<sup>432</sup> Whole exome sequencing in a girl with congenital generalized hypertrichosis and gingival hyperplasia showed a homozygous intronic mutation in the ABC lipid transporter gene *ABCA5*, which is within the deleted region on chromosome 17; the mutation caused aberrant splicing of the transcript and decreased follicular protein levels.<sup>433</sup> Generalized hypertrichosis can also be a manifestation of a “potassium channelopathy,” resulting from heterozygous activating mutations in *ABCC9*, which encodes the sulfonyl-

urea receptor *SUR2*. In addition to the hypertrichosis, affected individuals have a spectrum of features ranging from acromegalic facies (with or without gingival hypertrophy)<sup>434</sup> to Cantú syndrome with its neonatal macrosomia, coarse facial features, osteochondrodysplasia, and cardiomegaly.<sup>435</sup> *SUR2* is expressed in the dermal papilla and is stimulated by minoxidil in inducing hair growth.<sup>436</sup>

X-linked dominant hypertrichosis has been described in a Mexican pedigree. Affected males show excessive generalized terminal hair growth, especially on the face and upper torso; female individuals are less severely affected and can show asymmetric hairiness thought to represent random inactivation (lyonization) of the affected chromosome. This condition sometimes improves after puberty.<sup>437</sup> In another Mexican kindred, congenital universal hypertrichosis was associated with deafness and dental anomalies as an X-linked recessive disorder.<sup>438</sup>

Generalized hypertrichosis is also a feature of several syndromes (Box 7-8), among them congenital erythropoietic porphyria (see Chapter 19) and most commonly, the Cornelia de Lange syndrome.<sup>439</sup> This congenital, genetically heterogeneous disorder features marked hypertrichosis; cutis marmorata; hypoplastic genitalia, nipples, and umbilicus; prenatal and postnatal growth retardation; malformation of the limbs, gastrointestinal tract, diaphragm, heart, and genitourinary systems; mental retardation; and a characteristic low-pitched and growling cry. The face of afflicted individuals is characterized by overgrowth of the eyebrows, long eyelashes, high upper lip, saddle-nose, and a cyanotic hue about the eyes, nose, and mouth. Children with this disorder often have recurrent respiratory-tract infections and gastrointestinal reflux; seizures have been observed in about 20% of reported cases, and most patients die before the age of 6 years. To date, heterozygous mutations in five genes have been described, most commonly *NIPBL* (60%).<sup>439</sup> These genes all encode structural or regulatory proteins involved in cohesin, a protein complex that regulates the separation of sister chromatids during cell division.<sup>440</sup>

## LOCALIZED FORMS OF HYPERTRICHOSIS

### Nevoid Hypertrichosis

Growth of hair abnormal in length, shaft diameter, or color may occur in association with other nevoid abnormalities or as isolated circumscribed developmental defects.<sup>441</sup> Abnormal tufts of hair in the lumbarosacral and, at times, the posterior cervical or thoracic areas (the

**Figure 7-51** Hypertrichosis. Generalized terminal hair growth in this girl with gingival hyperplasia.

- Barber-Say syndrome
- Cantu syndrome (hypertrichosis with osteochondrodysplasia)
- Coffin-Siris syndrome
- Cornelia de Lange (Brachmann-de Lange) syndrome
- Craniofacial dysostosis
- Hemimaxillofacial dysplasia
- Lipodystrophies
  - Berardinelli-Seip syndrome
  - Donohue syndrome (leprechaunism)
- Mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome
- Mucopolysaccharidoses
  - Hunter syndrome
  - Hurler syndrome
  - Sanfilippo syndrome
- Rubinstein-Taybi syndrome
- Schinzel-Giedion syndrome
- Porphyrrias (see Chapter 19)
  - Erythropoietic porphyria (Gunther disease)
  - Familial porphyria cutanea tarda
  - Hepatoerythropoietic porphyria
- Stiff skin syndrome
- Toxin exposure
  - Fetal alcohol syndrome
  - Fetal hydantoin syndrome
- Winchester syndrome (see Chapter 6)

**Figure 7-52** Faun-tail deformity. Abnormal tufts of hair in the lumbosacral area suggest an underlying tethered cord or diastematomyelia.

**Figure 7-54** Nevoid circumscribed hypertrichosis. This hair follicle hamartoma shows congenital growth of thicker, darker, and longer hairs without associated hyperpigmentation or associated follicular prominence.

**Figure 7-53** Anterior cervical hypertrichosis. A form of nevoid hypertrichosis, this patch of hair at the anterior aspect of the neck is usually not associated with other pathology.

faun-tail nevus, Fig. 7-52) may be associated with an underlying kyphoscoliosis, duplication of a portion of the spinal cord (diastematomyelia), or tethered cord. Although neurologic signs of this disorder generally appear during early childhood, they may be delayed until the affected person's teenage or adult years. Early detection by imaging allows neurosurgical intervention and prevents the potential neurologic sequelae. Symmetric localized hypertrichosis has also been described at the elbows (hypertrichosis cubiti)<sup>442,443</sup> and anterior cervical area (anterior cervical hypertrichosis) (Fig. 7-53). Hypertrichosis cubiti and anterior cervical hypertrichosis are usually isolated disorders. However, anterior cervical hypertrichosis has been described as an autosomal recessive disorder in association with developmental delay, peripheral neuropathy with or without retinal abnormalities,<sup>444</sup> and hypertrichosis cubiti with short stature, facial asymmetry, intrauterine growth retardation, developmental and speech delay, and infantile spasms.<sup>445</sup>

Hypertrichosis is often a characteristic of melanocytic nevi, smooth muscle hamartomas and Becker nevus, plexiform neurofibromas, and linear epidermal nevus. Nevoid circumscribed hypertrichosis (Fig. 7-54), a hair follicle nevus, presents as an isolated patch of hypertrichosis. Increased local hair growth may be seen after wearing a cast or at sites of thrombophlebitis, stasis dermatitis, X-ray or ultraviolet light irradiation, chemical irritation, or local hormonal stimulation. Extensive congenital smooth muscle hamartomas may show hypertrichotic and skin-colored to lightly hyperpigmented patches in association with excessive skin folds and follicular dimpling (sometimes called *Michelin baby syndrome*).<sup>446</sup> Multiple patches of congenital hypertrichosis in association with blaschkoid streaks of hypopigmentation have spontaneously cleared shortly after birth.<sup>447</sup>

Symmetric, large, hypertrichotic, indurated hyperpigmented patches on the middle and lower body first appear during the first or second decade in autosomal recessive H syndrome.<sup>448</sup> In addition to hyperpigmentation and hypertrichosis, patients show hepatosplenomegaly, heart anomalies, hearing loss, hypogonadism, hallux valgus, low height, camptodactyly and occasionally hyperglycemia. Mutations have been found in the nucleoside transporter hENT3, encoded by SLC29A3.<sup>449</sup>

### Idiopathic Hirsutism

Idiopathic hirsutism describes the presence in girls of excessive body hair in a male sexual pattern (the face, particularly the upper lip, chest, abdomen, arms, and legs) in the absence of clinical evidence of disturbed endocrine or metabolic function (see Fig. 23-13).<sup>450,451</sup> Idiopathic hirsutism is assumed to relate to increased stimulation of the hair follicles of genetically predisposed girls by normal levels of androgenic hormones. Hirsutism is quantified by the Ferriman-Gallwey scale, with scores of 6 to 8 considered mildly hirsute, 8 to 15 serious, and greater than 15 overt hirsutism. Other signs of hyperandrogenism are acne, oligomenorrhea or amenorrhea, and AGA.

The incidence of hirsutism in any population is difficult to assess, because the range of normal is quite wide and subject to individual acceptance and includes that which is not always socially acceptable in a particular culture. Hispanic, Jewish, and Welsh women in general have more hair than their counterparts of Northern European, Japanese, and Indian heritage. The physician should be cognizant of what is normal and acceptable to some individuals, yet unacceptable and a source of anguish to others. Performing a history and physical

examination (including body mass index [BMI] and waist circumference) will determine the need for full endocrinologic investigation. When hirsutism is observed in a postpubertal girl without other signs of masculinity (receding hairline, deepening of the voice, or evidence of menstrual disturbance), endocrine disease is unlikely. When the disorder does not appear to be physiologic and particularly if associated with other signs of androgen excess or premature puberty (sexual hair before 8 years of age in girls), abnormalities of the pituitary, adrenals, and ovaries must be ruled out. These include “exaggerated adrenarche,” late-onset congenital adrenal hyperplasia, virilizing tumors,<sup>452,453</sup> Cushing syndrome, hyperprolactinemia, acromegaly, Achard-Thiers (diabetes, hypertension, and hirsutism) syndrome, and polycystic ovary syndrome (PCOS) (see Chapter 8).<sup>454,455</sup> Of these, PCOS is by far the most common and is increasing in prevalence in parallel to the increasing trend toward obesity in teenagers (3% of unselected adolescents in one study).<sup>456</sup>

In addition to signs of hyperandrogenism,<sup>457</sup> the presence of oligomenorrhea or amenorrhea and acanthosis nigricans are a clue to PCOS.<sup>458</sup> Oligomenorrhea is defined as menstrual cycles of more than 35 days, with fewer than eight menstrual cycles defined as chronic anovulation. It is harder to diagnose oligomenorrhea in adolescents, but persistent irregularity more than 2 years after the onset of menses should be considered abnormal. Obesity is a significant risk factor for PCOS, and 40% to 60% of women with PCOS are overweight or obese, especially with abdominal adiposity.

If an endocrine abnormality is suspected, minimal laboratory testing for excessive androgen production should include levels of 17-ketosteroids (for mild adrenal hyperplasia), free plasma testosterone, dehydroepiandrosterone sulfate levels, and morning and evening cortisol; luteinizing hormone (LH) and follicle-stimulating hormone (FSH) ratios and transabdominal ultrasound (to rule out small ovarian cysts) may be useful. Hormonal evaluations are best carried out in the morning during the third to fifth day of menstruation. If PCOS is suspected, fasting levels of glucose and insulin should be obtained.<sup>459</sup> A proposed definition of PCOS in adolescents includes four of the following criteria: (1) clinical hyperandrogenemia; (2) biochemical hyperandrogenemia (serum testosterone >50 ng/dL and LH/FSH ratio of greater than 2); (3) insulin resistance and hyperinsulinemia (acanthosis nigricans, visceral adiposity, and impaired glucose tolerance); (4) oligomenorrhea persisting 2 years after menarche; and (5) polycystic ovarian morphology on ultrasound.<sup>460</sup>

### Treatment of Hypertrichosis and Hirsutism

The appearance of excessive hair may be modified in several ways.<sup>450</sup> Cutting with scissors or shaving with a razor or electric shaver, although occasionally not psychologically acceptable to the patient, are the simplest methods and least likely to irritate the skin. These techniques do not stimulate faster or thicker growth.<sup>423</sup> Bleaching with hydrogen peroxide may make excessive hair less conspicuous for up to 4 weeks and works best for light-skinned children, because yellow bleached hair may be emphasized when viewed against darkly pigmented skin. Plucking and wax epilation (essentially a form of widespread plucking) by application of a warm wax preparation to the affected areas are too painful for children but may be an option for older adolescents. Chemical depilatories that contain sulfides, thioglycolates, or enzymatic depilatory agents destroy the projecting hair shafts, causing minimal damage to underlying skin. Of these, the sulfide-containing preparations are more effective but more irritating and produce a disagreeable hydrogen sulfide odor. The thioglycolate-containing agents are less irritating but slower in action and less effective on coarse hairs. Enzymatic agents are less offensive but not as effective as other types. Children with extensive hypertrichosis must limit treatment with chemical depilatories to localized sites because of the risk of systemic absorption and toxic reactions.

Electrolysis and laser are more permanent hair removal techniques that are uncomfortable and thus their use may be limited for prepubertal children. In electrolysis, an electric current is delivered to the hair follicle, destroying it. In contrast, laser and intense pulsed light remove unwanted hair through the selective photothermolysis of the melanin-rich hair follicles with minimal absorption by surrounding tissues.<sup>461,462</sup> Laser systems used for the treatment of hirsutism include the ruby laser (694 nm), the long-pulsed diode laser (800 or 810 nm),

the alexandrite laser (755 nm) and the Nd:YAG laser (1084 nm); broad-spectrum intense pulsed light (570 to 1200 nm) has also been used.<sup>463</sup> The diode, alexandrite, and Nd:YAG laser are safest for treatment of hirsutism in dark-skinned patients.<sup>464,465</sup> Application of topical anesthesia may be required. By 4 years of age, 20 sessions of diode laser depilation beginning at 9 months of age reduced facial and body hair by 80% in a girl with hypertrichosis lanuginosa congenita.<sup>466</sup> Eflornithine cream 15% is prescription medication for twice-daily application that inhibits ornithine decarboxylase, a hair follicle enzyme that participates in hair growth. As a result, eflornithine may decrease further growth, although it does not minimize existing hair. Local irritation may occur.

If an adolescent has hirsutism and hyperandrogenemia, therapy should be specific to the underlying trigger under the guidance of a gynecologist or endocrinologist. For example, dexamethasone 0.25 to 0.5 mg at night generally reverses the hyperandrogenic signs of adrenal hyperplasia.<sup>467</sup> For PCOS in adolescents, the most important intervention is lifestyle modification with increasing exercise and controlling dietary intake. In PCOS, loss of at least 10% of initial body weight improves menstrual function and metabolic abnormalities.<sup>468</sup> The administration of metformin or other insulin sensitizers is adjunctive to lifestyle changes but can improve insulin resistance, adiposity, oligomenorrhea, and serum androgen levels as well as hirsutism.<sup>469,470</sup>

Antiandrogens and oral contraceptives are the traditional treatment for management of hirsutism. The combination of ethynodiol and drospirenone, for example, reduces the Ferriman-Gallwey score in adolescents by approximately 50% over a 12-month period.<sup>471</sup> Spironolactone in doses of 50 to 200 mg/day; cyproterone acetate, 50 to 100 mg/day (available in Europe); and cimetidine have antiandrogenic activity. Intermittent low-dose finasteride (2.5 mg every 3 days) for 6 months has recently been shown to be effective in reducing the hirsutism score in teenaged girls with idiopathic or PCOS-related hirsutism.<sup>472</sup>

## Pigmentary Changes of Hair

### PREMATURE GRAYING

Graying of human hair is caused by a reduction in the activity of melanocytes within hair follicles. Premature graying of hair, termed *canities*, refers to a loss of color, especially of scalp hair, at an age earlier than that generally accepted as physiologic (before the age of 20 in Caucasians and 30 in African-Americans). It most commonly occurs in children with vitiligo or AA. Canities have also been described in children with pernicious anemia, hyperthyroidism and other thyroid disorders, progeria, Werner syndrome, ataxia-telangiectasia, Rothmund-Thomson syndrome, tuberous sclerosis, neurofibromatosis, and the Waardenburg and Vogt-Koyanagi syndromes. Premature graying may be readily masked, if desired, by chemical rinses and dyes. Chloroquine interferes with pheomelanin synthesis and may lead to lightening of hair with a silvery discoloration in blonde and red-haired persons.<sup>473</sup>

### GREEN DISCOLORATION

The spontaneous appearance of green discoloration in the hair of light-haired individuals may occur as a result of exposure to copper used as an algae-retardant in swimming pools or household tap water containing excessive amounts of copper.<sup>474,475</sup> The introduction of fluoride into a town water supply may acidify water and cause copper to be leached from the plumbing system. Sometimes a ground wire connects a faulty electric apparatus to the copper water pipes, thus diverting sufficient flow of electric current through the water system to dissolve copper.

If resulting from swimming, the use of a copper-based algicide should be discontinued. In cases related to household tap water, electric grounding of household plumbing and adjustment of the pH of the tap water will help to prevent recurrences. Copper-induced discoloration of the hair can be treated in several ways: bleaching with 3% hydrogen peroxide for 2 to 3 hours; washing with the chelating agent edetic acid (EDTA-Metalex) for 30 minutes; use

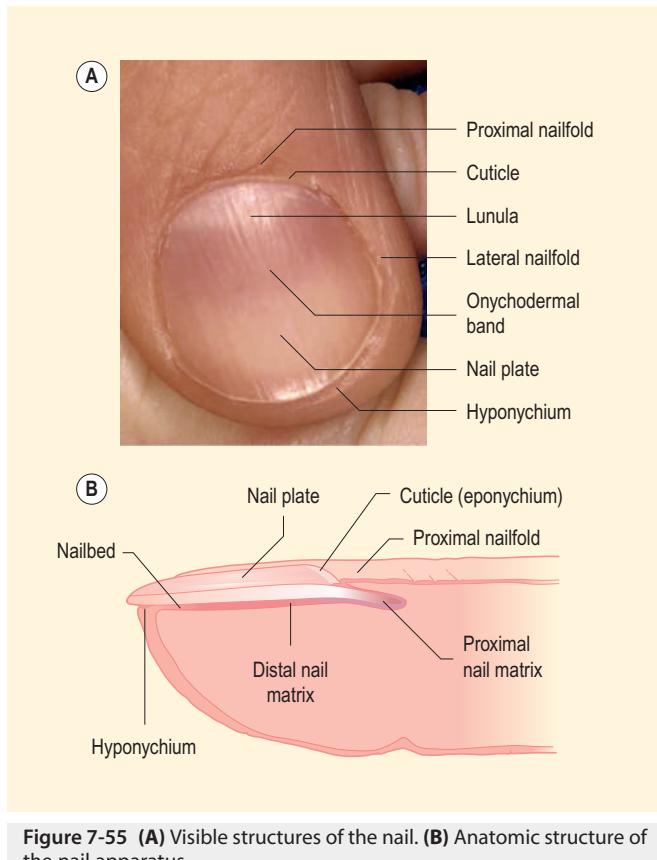

of a penicillamine-containing shampoo; or application of 1.5% 1-hydroxethyl diphosphonic acid.

## Nails

The nails are convex horny structures originating from a matrix that develops from a groove formed by epidermal invagination on the dorsum of the distal phalanges at 9 weeks' gestation. At 10 weeks' gestation, a smooth, shiny quadrangular area can be recognized on the distal dorsal surface of each digit, and formation is completed by 20 weeks' gestation. The nail apparatus consists of a nail matrix of proliferating epidermal cells (Fig. 7-55), largely located under the proximal nailfold. In the thumbs and in a variable number of digits, a white crescent-shaped lunula is usually seen projecting from under the proximal nailfolds, and represents the distal portion of the matrix. The cells of the lunula form the lower surface of the nail plate, whereas the more proximal matrix forms the exposed surface of the nail plate. Although the nail plate is translucent and essentially colorless, most of the exposed nail appears pink as the result of transmission of color from the adherent richly vascular underlying nailbed. The lateral borders of the nail plate lie under the edge of the lateral nailfolds. The hyponychium is the area of skin where the distal border of the nail plate becomes detached from the nailbed.

Unlike hair, nails grow continuously throughout life and normally are not shed. Although the nails of individual fingers grow at different rates, the normal rate of growth of fingernails varies between 0.5 and 1.2 mm per week; the rate of toenail growth is slower than that of the fingernails. Nails grow more quickly in children than in adults.

Many dermatoses that characteristically involve the skin and hair may also affect the nails. Among these are atopic dermatitis, psoriasis, lichen planus, Darier disease, AA, onychomycosis, dyskeratosis congenita (DC) and other ectodermal dysplasias, and certain forms of epidermolysis bullosa.<sup>476</sup> Some nail deformities require surgical correction for cosmetic or functional improvement.<sup>477</sup>

**Figure 7-55** (A) Visible structures of the nail. (B) Anatomic structure of the nail apparatus.

## MEDIAN NAIL DYSTROPHY AND HABIT-TIC DYSTROPHY

Median nail dystrophy (also termed *solenonychia* or *dystrophia unguium mediana canaliformis*) and habit-tic dystrophy (also termed *onychotilomania* or *habit-tic deformity*) are uncommon disorders that usually affect the thumbs. Both disorders have a central canal-like depression or split of varying severity with cracks or lines extending from the central longitudinal lesion toward the lateral nail edges (Fig. 7-56). In median nail dystrophy the lines are typically described as feathery cracks resembling a Christmas tree, and in habit-tic dystrophy they are described as more horizontally arrayed and irregularly spaced; however, the two disorders can look identical, leading to their grouping by some experts as one disorder. A temporary defect in the matrix that interferes with nail formation is thought to be the cause, leading to the depression or split initially appearing at the cuticle and proceeding outward as the nail grows. Median nail dystrophy has been described during administration of isotretinoin<sup>478,479</sup> and with habitual use of smartphones and tablets,<sup>480</sup> whereas habit-tic dystrophy is commonly linked to continuous picking of the nail cuticle of the affected digit and has been described in association with guitar playing.<sup>481</sup> The disorder may at times improve spontaneously after years, especially after the causative trauma ceases. Other than avoidance of trauma, there is no effective treatment, although 4 months of tacrolimus 0.1% ointment led to significant improvement in a 19-year-old man with median nail dystrophy.<sup>482</sup>

**Figure 7-56** Median nail dystrophy/habit-tic dystrophy. (A) and (B) Central depression to varying degrees and fine tree-like or irregularly spaced horizontal splits extending toward the lateral margins. Neither boy admitted to any trauma to the nail, although scaling and swelling of the periungual area can be seen in (B).

## ONYCHOSCHIZIA

Lamellar splitting of the nail plate at its distal free edge, or onychoschizia, is a common complaint of girls and women. The condition usually results from repeated trauma, frequent exposure to nail polish, or excessive immersion in water with detergents. The defect is aggravated by excessive manicuring and the frequent use of solvents to remove nail polish, which further dehydrates the nail. The regular use of an emollient hand cream to the nail and its cuticles, the avoidance of excessive manipulation, the use of several layers of nail polish in an effort to splint the nail, and avoidance of all but oily polish removers are beneficial.

## NAIL PITTING

Pitting of the nails is a common problem of children and most commonly is associated with the nail involvement of psoriasis,<sup>483</sup> atopic dermatitis, or AA. Less common associations are lichen planus, vitiligo, reactive arthritis, and chronic renal failure. The punctate depressions result from alterations in the proximal matrix and may vary from small to large and deep. One nail or several may be affected. Clustered pits may be seen in children who have experienced localized trauma, whereas shallow, randomly distributed pits are usually seen in children with psoriasis or atopic dermatitis. Transverse rows of regularly spaced pits have been described in children with AA (see Fig. 7-38, A). The pathomechanism for nail pits likely involves pinpoint areas of aberrant epidermis and inflammation of the nail matrix.

## NAIL MATRIX ARREST (BEAU LINES AND ONYCHOMADESIS)

Nail matrix arrest develops as a nonspecific reaction to any stress that temporarily interrupts nail formation and become visible on the surface of the nail plate several weeks or more after onset of the disease that caused the condition. Beau lines are transverse grooves or furrows that originate under the proximal nailfold (Table 7-3). They first appear at the cuticle and move forward with the growth of the nail. Because normal nails grow at a rate of approximately 1 mm per week, the duration and time of the illness often can be estimated by the width of the furrow and its distance from the cuticle. Onychomadesis (proximal complete separation of the nail) results from full but temporary arrest of growth of the nail matrix (Fig. 7-57).<sup>484,485</sup> Triggers are similar for Beau lines and onychomadesis and involve stressful events (see Table 7-3) such as birth trauma,<sup>486,487</sup> chemotherapy and other drugs,<sup>488,489</sup> infections and febrile illnesses,<sup>484,490,491</sup> and prolonged intensive-care hospitalization.<sup>492</sup> Of these, nail matrix arrest after Coxsackie infection is most common in children<sup>484,493,494</sup>; in one study of 28 pediatric patients with Coxsackie A16 infection, nail matrix arrest was noted on average 52 days after onset of signs, and the nail changes correlated with the presence of mouth ulcers.<sup>493</sup>

## SPOON NAIL

Spoon nail (koilonychia) is a common deformity in which the normal contour of the nail is lost. The nail is thin, depressed, and concave from

side-to-side, with turned-up distal and lateral edges. Koilonychia of the hallux nails is common in newborns and young infants and resolves spontaneously during childhood. The condition may be a secondary feature of several dermatologic disorders. It occurs in association with nail thickening in psoriasis, onychomycosis, and PC, in which subungual thickening from the hyponychium changes the direction of nail growth. Koilonychia can also be seen in disorders with nail thinning or ridging such as in lichen planus, trachonychia, and focal dermal hypoplasia. Spoon nails have been described in individuals with severe iron-deficiency anemia, although the pathomechanism is unclear. Koilonychia may also be inherited as an isolated autosomal dominant trait. Koilonychia can be confused with platonychia, or flattened nails, which have been described primarily in patients with cirrhosis, and with pincer nails, characterized by excessive curvature at the lateral aspects of the nail plate, leading to an appearance of ingrown nails. Pincer nails are usually a congenital deformity but can be acquired in individuals with epidermolysis bullosa, digital epidermoid cysts, and distal phalangeal exostosis. Because they can be quite painful, pincer nails are often corrected surgically.

## RACKET NAIL

Racket nails, or brachyonychia, are short, wide nails that show loss of curvature. Most commonly found on the thumb and halluces, racket nails are associated with short, stubby phalanges, presumably reflecting an arrest in distal phalangeal formation. This disorder may be inherited in an autosomal dominant mode as an isolated entity but has been described in association with several pediatric syndromes such as acrodyostosis, acroosteolysis, cartilage-hair hypoplasia syndrome, Larsen syndrome, pyknodysostosis, and Rubinstein-Taybi syndrome. Racket nails may be confused with nail clubbing or acropachy (Table 7-4), which results from overgrowth of the fibrovascular support stroma of the distal phalanx. Increased flexibility of the distal

**Figure 7-57** Onychomadesis. Nails showed this deep transverse groove and nail separation.

**Table 7-3** Associations with Nail Matrix Arrest

Conditions	Infection	Medications	Trauma

\*Broad distal phalanges with normally shaped nails.

nail plate because of edematous tissue is an early sign of clubbing. Also typical is the angle greater than 180 degrees (Lovibond angle) formed by the proximal nailfold and nail plate when viewed from a lateral position. Clubbing in children is usually a sign of internal disease.

### TRACHYONYCHIA

Trachyonychia is characterized by excessive ridging, longitudinal grooves and striations, opalescent discoloration, a rough sandpaper-like quality of the nails, a tendency toward breakage and fragmentation (onychorrhexis), and splitting at the free margins<sup>495</sup> (Fig. 7-58). When all nails are involved, the condition has been called *twenty-nail dystrophy*. Trachyonychia is usually an isolated entity but has been described primarily in association with psoriasis, atopic dermatitis, and AA, but the trachyonychia may occur months to years before other signs of cutaneous disease. The course of trachyonychia is variable, but spontaneous improvement may occur in months to years; in one study 50% showed total resolution or marked improvement in the first 6 years.<sup>496</sup> Application of potent topical corticosteroids to the base of the nail, particularly in the form of flurandrenolide tape, may reverse the changes of trachyonychia after several months of nightly usage. Filing the nails and application of clear nail polish may reduce the tendency toward snagging and tearing of the nail plates.

**Figure 7-58** Twenty-nail dystrophy (trachyonychia). Opalescent discoloration, excessive ridging, longitudinal striations, and a rough texture of all 20 nails in a school-age child (A) and in an adolescent (B). Note the rough edges associated with the longitudinal striations in (B).

### ONYCHOGRYPHOSIS

Onychogryphosis is a hypertrophic nail deformity most commonly seen in the toenails. Some cases of nail hypertrophy are developmental. The nails become thick and circular in cross-section instead of flat (thus resembling a claw). The disorder is most commonly seen in elderly individuals but may occur in children with poor hygiene. Management requires regular paring or trimming and when severe, treatment by a podiatrist using files, nail clippers, or mechanical burrs. Onychogryphosis is commonly associated with secondary onychomycosis but may be seen in a variety of forms of ichthyosis, such as Haim-Munk syndrome (see Chapter 5) and in severe epidermolysis bullosa simplex (see Chapter 13).

### CONGENITAL MALALIGNMENT OF THE GREAT TOENAILS

Congenital malalignment of the great toenails is a disorder in which lateral rotation of the nail matrix leads to lateral deviation of the great toenail from the longitudinal axis of the distal phalanx and, at times, thickening, discoloration, and shortening of the nail plate (Fig. 7-59).<sup>497,498</sup> Resultant onychodystrophy may lead to onychogryphosis and chronic ingrown toenails. The disorder may be inherited as an autosomal dominant disorder<sup>499</sup> and often improves spontaneously.<sup>500</sup> If improvement is not seen during the first year and the deviation is

**Figure 7-59** Congenital malalignment of the great toenails. Lateral rotation of the nail matrix leads to lateral deviation of the great toenail from the longitudinal axis of the distal phalanx and at times, thickening, discoloration, and shortening of the nail plate. Note the secondary severely ingrown toenails and overgrowth of the medial nailfold.

severe, surgical realignment of the nail with local anesthesia can be performed, preferably before age 2 years.<sup>477</sup>

### INGROWN NAILS

Ingrown toenails (onychocryptosis) are a common disorder in which the lateral edge of the nail is curved inward and penetrates the underlying tissue with resulting erythema, edema, pain, and in chronic forms, the formation of granulation tissue. Generally seen on the great toes of affected individuals, the main cause of the deformity is compression of the toe from side-to-side by ill-fitting footwear and improper cutting of the nail (in a half-circle rather than straight across). Pseudo-ingrown toenails, also seen as a transient deformity in newborns, are a common phenomenon (2.4% of infants)<sup>501</sup> and are generally self-corrected by the time the child reaches the age of 12 months. Treatment, if required, consists of the wearing of properly fitting footwear, allowing the nail to grow out beyond the free edge, control of acute infection by compresses, topical and at times systemic antibiotics, and in many instances (once the infection has subsided), surgical treatment. The traditional therapy for recurring cases has been excision of the lateral aspect of the nail (wedge resection) with the use of local anesthesia followed by curettage or chemical destruction (e.g., with phenol) of the nail matrix to prevent regrowth of the offending portion of the nail.<sup>502–504</sup> An alternative technique uses a flexible tube secured with a suture (FTSS) was associated with a lower recurrence rate than matricectomy and faster recovery.<sup>505</sup> Alternatively, one can excise the nailfold itself rather than the matrix. In one study in children, excellent cosmesis was achieved with no recurrences.<sup>506</sup>

*Retronychia* refers to inflammation of the proximal nailfold and occurs when the new nail growing from the matrix pushes the old nail upwards, interrupting longitudinal nail. It usually results from trauma and can be treated initially in children with clobetasol ointment nightly for a few months. Alternative therapy for recalcitrant or recurrent retronychia is complete nail-plate avulsion, although permanent nail dystrophy results in approximately one-third of treated patients.<sup>507</sup>

### NAIL ATROPHY

Atrophic nails range from complete absence of the nail (anonychia) to nails that are poorly or partially developed (micronychia). Congenital anonychia is an autosomal recessive disorder characterized by isolated congenital anonychia or hypoplasia, usually of all the fingernails and toenails. The disorder results from mutations in the R-spondin 4 (*RSPO4*) gene, which is only expressed in the mesenchymal tissue underlying the digit tip epithelium and activates Wnt/β-catenin signaling.<sup>508,509</sup> Anonychia can be associated with junctional epidermolysis bullosa, trauma, infectious paronychia, and inflammation (e.g., Stevens–Johnson syndrome, chronic graft-versus-host disease, and

lichen planus). Micronychia has been described in patients with ectodermal dysplasias, teratogen exposure (e.g., fetal hydantoin syndrome), and chromosomal abnormalities (e.g., Turner syndrome, Noonan syndrome, and trisomies of chromosomes 3, 8, 13, and 18). Micronychia is a prominent feature of the nail-patella syndrome and congenital onychodysplasia of the index fingers (COIF).

### NAIL-PATELLA SYNDROME

The nail-patella syndrome, also termed *osteonychodysplasia*, is an autosomal dominant disorder that results from mutations in *LMX1B*. *LMX1B* encodes a transcription factor (LIM homeobox) that regulates dorsoventral polarity in the developing limb (including nail development), as well as bone, eye, and glomerular basement-membrane development.<sup>510,511</sup> Nail changes are seen in 98% of affected individuals.<sup>512,513</sup> They vary from a triangular lunula (most consistent feature), especially of the thumbs and index fingers, to severe dysplasia and micronychia to absence of the medial and distal aspects of the index and thumb nails. Nail involvement is symmetric and often shows progression from index to fifth fingernails. Occasionally the toes are affected. Softening, spooning, discoloration, central grooving, splitting and cracking, narrowing, and less commonly, thickening of nails have been described.

The knees have a flattened profile with a small or absent patella and the elbows show radial head dysplasia. Both are subject to recurrent dislocation, flexion contractures, and arthritis. The pathognomonic iliac horns extend from the center of the iliac bones. Renal involvement occurs in 30% to 60% of patients and presents with (often asymptomatic) proteinuria and/or microscopic hematuria, edema, and hypertension. Progression to nephrotic syndrome occurs in fewer than 20% of patients, and renal failure requiring dialysis or transplantation occurs in 10%.<sup>514</sup> Affected patients also risk the development of glaucoma and dystrophic dental enamel. An increased risk of attention-deficit/hyperactivity disorder and depression has been described, perhaps related to the role of *LMX1B* in the development of mesencephalic dopaminergic neurons and the serotonergic system.<sup>515</sup> Support groups are available at: [www.nailpatella.org](http://www.nailpatella.org), [www.npsw.org](http://www.npsw.org), and [www.npsuk.org](http://www.npsuk.org).

### CONGENITAL ONYCHODYSPLASIA OF THE INDEX FINGERS

Congenital onychodysplasia of the index fingers (COIF), also known as *Iso* and *Kikuchi* syndrome, is characterized by asymmetric, ulnar-deviated micronychia of the index fingers. Involvement may be unilateral or bilateral, and polyonychia may be associated. X-rays of the underlying phalangeal bone show a characteristic Y-shaped bifurcation or a sharp distal phalangeal tip. Deformities of other fingers are rarely present.<sup>516</sup> Usually a sporadic condition, autosomal dominant inheritance and occurrence in twins have been described.<sup>517</sup> Use of a new device to correct that deviation (and treat ingrown nails as well) has been described.<sup>518,519</sup>

### PACHYONYCHIA CONGENITA

*Pachyonychia congenita* (PC) describes a group of autosomal dominant conditions characterized by a characteristic nail dystrophy (see Chapter 5); in association with painful plantar keratoderma.<sup>520</sup> Mutations occur in one of five keratins: *KRT6a*, *KRT6b*, *KRT6c*, *KRT16*, and *KRT17*,<sup>521–525</sup> and a new classification is now based on the underlying affected gene (i.e., PC-6a, PC-6b, PC-6c, PC-16, and PC-17). Of these, PC-6a (41%) and PC-16 (31%) are most common. The historical terms PC-1 (Jadassohn–Lewandowsky syndrome) and PC-2 (Jackson–Lawlor syndrome) are no longer used, given their overlapping features and lack of concordance with underlying gene changes. At this time, genotyping is being performed free of charge through the Pachyonychia Congenita Project ([http://www.pachyonychia.org/pc\\_data.php](http://www.pachyonychia.org/pc_data.php) and [www.pachyonychia.org](http://www.pachyonychia.org)).

At birth, fingernail and toenail changes are present in almost 70% and 60% of patients, respectively (Fig. 7-60), but the plantar keratoderma is in only 7%. By 5 years of age, however, more than 75% of patients have toenail and fingernail dystrophy, as well as plantar

**Figure 7-60** Pachyonychia congenita. The nails may be thickened or discolored at birth but often show changes first on the toenails and during infancy.

**Figure 7-61** Pachyonychia congenita. Nails show progressive discoloration, tenting, and thickening, particularly owing to accumulation of a horny, yellowish-brown material of the undersurface that causes the nail to project upward from the nailbed at the free margin.

keratoderma. Ultimately, 98% of affected individuals show toenail dystrophy, and fingernail dystrophy occurs in 76%. Typical nails have marked subungual hyperkeratosis with a pinched V-shape (Fig. 7-61), but premature nail termination is common. Most individuals have dystrophic changes of all 10 toenails. Periungual infection (especially staphylococcal and candidal) is reported by most affected individuals, and nails may be shed. The keratoderma tends to be predominantly at pressure points but can be exquisitely painful with a profound impact on quality of life and functioning (see Chapter 5). The pain in part results from underlying bullae.<sup>526</sup> Hyperhidrosis of the palms and soles may be associated.

Additional clinical manifestations include cysts, follicular keratoses, hoarseness, and oral leukoplakia. The steatocysts and pilosebaceous cysts, formerly thought to be specific to PC-6b and PC-17, are now known to be common in PC-6a as well. These cysts usually first manifest at early puberty, particularly on the head, neck, upper chest, and upper arms. Pinhead-sized follicular papules may appear in areas of trauma on the extensor surfaces of the extremities, popliteal fossae, lumbar region, buttocks, and less commonly, on the face and scalp. Early oral lesions are often present in the form of opaque white plaques

(leukokeratosis) on the dorsum of the tongue or the buccal mucosa at the interdental line and are often confused with thrush (candidal infection) in the infant. Less common associated findings include cheilitis, scrotal tongue, corneal dystrophy, and hoarseness, the latter specific for PC-6a.

Differences that distinguish PC subtypes include: (1) later onset and less frequent occurrence of nail dystrophy and keratoderma in PC-K6b, PC-K6c, and PC-K16; (2) concurrent fingernail and toenail thickening in PC-K6a and PC-K17; (3) more palmar (vs. plantar) keratoderma in PC-K16; (4) cysts primarily in PC-K17 and follicular hyperkeratoses primarily in PC-K6a; (5) hoarseness and/or oral leukokeratoses in the first year of life, most often in PC-K6a; and (6) natal teeth exclusively in PC-K17. Among pediatric patients, PC affects the social interactions and function of adolescents more profoundly than younger children, related to the highly visible nail changes and painful plantar thickening.

In the young child, PC must be distinguished from hidrotic ectodermal dysplasia (Clouston syndrome, see *Group 2 Ectodermal Dysplasia* section), which can show similar nail alterations at birth and painful keratoderma.<sup>527</sup> The presence of alopecia and if present, hearing loss can distinguish hidrotic ectodermal dysplasia. Indeed, alopecia is not a feature of PC except in the rare situation in which biallelic mutations in *KRT17* are inherited.<sup>528</sup> Hypertrophic nail dystrophy at birth is also a feature of biallelic mutations in *FZD6*, encoding frizzled 6, a Wnt-signaling pathway receptor in the nail matrix.<sup>529,530</sup>

The subungual hyperkeratosis persists for life, and treatment is directed toward relief of the painful hyperkeratosis of the soles and the nail dystrophy.<sup>531</sup> Mechanical nail treatment (filing, grinding, and trimming) is particularly effective after soaking the nails.<sup>532</sup> As for the nails, mechanical intervention can improve the keratoderma, but topical agents (retinoids, steroids, keratolytics, emollients) are not very helpful, and pain control management is key. Administration of systemic retinoids has been successful for some but not all patients but is rarely appropriate in pediatric patients.<sup>533</sup> As a last resort, surgical avulsion and matrix destruction followed by scarification of the nailbed to prevent regrowth can be performed. Plantar sweating has been shown to increase the painful blistering of at hyperkeratotic sites and can be controlled by oral administration of glycopyrrolate or injections of botulinum toxin.<sup>534</sup> Oral rapamycin decreased painful plantar thromboses and keratoses in patients with *K6a* mutations (based on suppression of *K6a* expression) but led to unacceptable gastrointestinal and mucocutaneous adverse events.<sup>535</sup> Interestingly, chemotherapy in an adult with lifelong painful plantar keratoderma led to complete resolution.<sup>536</sup> *K16* small interfering ribonucleic acid (siRNA) injections into the palmoplantar keratoderma have resulted in clearance but are too painful to sustain.<sup>537</sup> A support group is available for affected families ([www.pachyonychia.org](http://www.pachyonychia.org)).

## DYSKERATOSIS CONGENITA

Dyskeratosis congenita (DKC) is characterized in 80% to 90% of patients by the triad of nail dystrophy, reticular pigmentation, and oral leukoplakia, but many additional features have been described (Table 7-5).<sup>538–540</sup> Most cases have been in males, consistent with an X-linked disorder, but carrier females may show mild to complete clinical features. The median age of diagnosis is 15 years, because many patients first seek treatment as teens or young adults.

The disorder may also be inherited as autosomal dominant or recessive, and nine mutated genes have been described to date, accounting for 60% of studied individuals with DKC (Table 7-6).<sup>541,542</sup> The protein products of these genes affect the maintenance of telomeres, which are repetitive base pairs at the ends of chromosomes to prevent the loss of genetically encoded information. Telomerase catalyzes DNA synthesis to maintain telomere length; when too short, cells become senescent or apoptotic. This is particularly important in rapidly dividing cells. DKC is considered a “telomeropathy,” because most patients show severe shortening of telomeres. The most common cause of DKC is mutations in *DKC1* (a gene on the X chromosome that encodes dyskerin, a nucleolar protein that stabilizes telomerase), but features of DKC have been described from mutations affecting other components of the telomerase complex (*TINF2*, *TERT*, *TERC*, *C16orf57*, *NOLA3*, *NOLA2*, *WRAP53/TCAB1*, and *RTEL1*). Although DKC is

**Table 7-5** Complications of Dyskeratosis Congenita and Suggested Monitoring

System	Findings	Potential Complications	Monitoring/Treatment
Skin	Nail dystrophy* Reticulated pigmentation* Hyperhidrosis Early graying or sparse hair Telangiectasia Acrocyanosis Cutaneous atrophy Palmoplantar keratoderma Absent dermatoglyphics	Cutaneus SCCs	Annual skin examination Sun protection
Oral	Leukoplakia* Erythematous patches Dyspigmentation Taurodontism Tooth decay and loss	Oral cancer	Biannual dental examinations
Growth and development	Short stature Developmental delay		
Head and neck		SCC	Annual otolaryngology examinations
Eyes	Epiphora Ectropion, entropion Trichiasis, sparse lashes	Corneal abrasion Infections	Annual eye examinations
Gastrointestinal	Esophageal stenosis Hepatic fibrosis	Dysphagia	Esophageal dilatation Annual liver function tests Liver ultrasounds
Genitourinary	Urethral stenosis Epithelial malignancy		
Lungs	Pulmonary fibrosis	High risk with transplant	Annual PFTs
Bones	Osteoporosis Avascular necrosis hips, shoulder	Fractures	Ca <sup>++</sup> , Vitamin D <sub>3</sub>
Hematologic	Low blood counts*	Bone marrow failure* Myelodysplastic syndrome Leukemia	Biannual blood counts Baseline bone marrow Chemotherapy as appropriate

Ca<sup>++</sup>, Calcium; PFT, pulmonary function test; SCC, squamous cell carcinoma.

\*Present in more than 75% of patients.

AD, Autosomal dominant; AR, autosomal recessive; RNA, ribonucleic acid; XLR, X-linked recessive.

**Figure 7-62** Dyskeratosis congenita. Shortened nails with pterygium formation.

sometimes classified among disorders of aging, patients do not appear old and have no increased risk of atherosclerosis.

The thin, dystrophic nails usually appear first between the ages of 5 and 13 years. Mildly affected nails show ridging and longitudinal grooving; severely affected nails are shortened and show pterygium formation, resembling the nails of lichen planus or graft-versus-host disease (Fig. 7-62). Cutaneous changes usually develop after the onset of nail changes, most commonly during late childhood to teenage years. A fine reticulated grayish-brown hyperpigmentation, sometimes surrounding hypopigmented, atrophic, telangiectatic

**Figure 7-63** Dyskeratosis congenita. Reticulated hyperpigmentation surrounding hypopigmented, atrophic, telangiectatic patches.

**Figure 7-64** Dyskeratosis congenita. Leukoplakia of the oral mucosa.

patches, on the face, neck, shoulders, upper back, and thighs is characteristic (Fig. 7-63). The poikilodermatosus change is sometimes confused with Rothmund-Thomson syndrome (*RECQL4* mutations), epidermolysis bullosa simplex with mottled pigmentation (usually *KRT5* mutation), Naegeli–Franceschetti–Jadassohn syndrome/dermatopathia pigmentosa reticularis (*KRT14* mutation) or Clericuzio-type poikiloderma with neutropenia (another *C16orf57* mutation).<sup>543</sup> Other cutaneous changes may include telangiectasia of the trunk; redness and atrophy of the face with irregular macular hyperpigmentation; acrocytosis; palmoplantar hyperkeratosis; hyperhidrosis and bullae of the palms and soles; wrinkled atrophic skin over the elbows, knees, and penis; and a diffuse atrophic, transparent, and shiny appearance on the dorsal aspects of the hands and feet. The hair of the scalp, eyebrows, and eyelashes is often sparse and lusterless, and patients with this disorder commonly have atrophic changes of the muscles and bones of the feet and hands, giving a “cupped” appearance to the palms.

Mucous membrane changes consist of leukoplakia and rarely, blisters and erosions of the oral (Fig. 7-64) and anal mucosae, esophagus, and urethra. Similar changes of the tarsal conjunctiva may result in atresia of the lacrimal ducts, excessive lacrimation, chronic blepharitis, conjunctivitis, and ectropion. The teeth tend to be defective and subject to early decay. Periodontitis may develop, and affected persons have an increased incidence of cutaneous malignancy, predominantly squamous cell carcinoma in the areas of leukoplakia.

Overall, approximately 90% of patients develop life-threatening bone marrow failure characterized by severe aplastic anemia with neutropenia, splenomegaly, and a hemorrhagic diathesis. Acute myeloid leukemia and myelodysplastic syndrome have also been described. Pulmonary fibrosis and hepatic cirrhosis are other life-threatening complications. Epithelial tumors often first develop by the mid-teens, commonly in areas of mucosa with leukoplakia. Squamous cell carcinoma of the tongue is most common, but cutaneous squamous cell carcinoma, acute myeloid leukemia, and myelodysplastic syndrome are not uncommon. Variants of DCK include Hoyeraal-Hreidarsson syndrome, which is DCK with cerebellar hypoplasia, developmental delay, and intrauterine growth retardation<sup>544</sup> and Revesz syndrome with bilateral exudative retinopathy, cerebellar hypoplasia and growth retardation.<sup>545</sup> The average life expectancy is 44 years. Patients usually die of bone marrow failure (≈60% to 70%), pulmonary disease (≈10% to 15%) or malignancy (≈10%).

Screening for DCK is best performed by flow cytometry and fluorescence *in situ* hybridization (flow-FISH) of leukocyte subsets<sup>540</sup> to detect telomere shortening. Recommended disease surveillance includes biannual blood counts, bone marrow evaluations annually, hepatic ultrasounds, annual pulmonary functional tests, and skin cancer screening. Treatment of bone marrow failure is recommended with a hemoglobin persistently below 8 g/dL, platelets less than 30,000/mm<sup>3</sup>, and neutrophils less than 1000/mm<sup>3</sup>. If a matched donor without genetic and clinical evidence of DCK is available, stem cell transplantation should be considered but carries substantial risk. The 10-year survival rate probability is 30% with mortality generally attributed to pulmonary fibrotic or vascular complications related to disease progression or toxicity related to myeloablative regimens.<sup>546</sup> Long-term survival after transplantation has been poor. A trial of androgens such as oxymetholone may be considered before transplantation from an unrelated donor and has improved blood counts in 60% of treated patients<sup>547</sup>; however, androgens may cause hepatic tumors, and the combination of androgen and granulocyte colony stimulating factor (G-CSF) has led to splenic rupture. Management of patients otherwise consists of bougienage for esophageal stenosis; fulguration, curettage, and surgical excision of leukokeratosis of the buccal and anal mucosae; and lifelong, regular supervision for early detection of mucosal or cutaneous carcinomas. A support group called *Dyskeratosis Congenita Outreach* is available at <http://www.dcoutreach.org/>.

## DISORDERS OF THE NAILBED

**Onycholysis** refers to separation of the nail plate from the underlying hyponychium and can occur for a wide variety of reasons (Box 7-9).<sup>548,549</sup> Vigorous cleaning of the subungual debris that tends to accumulate exacerbates this condition. Onycholysis may result from exposure to sunlight (photoonycholysis)<sup>550</sup> in individuals administered tetracyclines, especially doxycycline (see Fig. 8-16),<sup>551</sup> griseofulvin,<sup>552</sup> or thiazides.

Abnormalities of the nailbed may be seen through the transparent nail plate. Onycholysis that occurs proximal to the hyponychium may resemble a yellow-brown oil spot, a nail change that is considered pathognomonic of psoriasis but is rarely seen in children. Notching of the distal nail plate may be seen in Darier disease in association with longitudinal red and white streaks (Fig. 7-65) (see Disorders of Nail Coloration section and Chapter 5). Nailbed hemorrhages are usually the result of trauma. As the hemorrhage ages, it changes color from red to purple to brown and moves more distally. Larger hematomas may resemble melanocytic nevi, although more commonly melanocytic nevi of the nailbed manifest as longitudinal pigmented streaks of the nail.

Injuries to fingers or toes may result in nail avulsion, painful subungual hematoma, or nailbed laceration, which are often managed in the emergency room. Nailbed removal results in scarring and deformity and is generally not necessary when the nail plate is intact and well adherent, especially with just a minimally displaced underlying distal phalanx fracture.<sup>553</sup> Hematomas should be decompressed through trephining, in which a hole is created in the nail plate by electrocautery or rotating a hot paperclip to drain the blood, thereby reducing pain and pressure.<sup>554</sup> Nailbed lacerations are repaired with 6-0 sutures or octyl-2-cyanoacrylate.<sup>555,556</sup>

### Box 7-9 Underlying Causes of Onycholysis

#### Chemical Irritants

Cosmetics, especially with formaldehyde  
Depilatories  
Detergents  
Nail polish removers  
Organic solvents

#### Inflammatory Disorders

Alopecia areata  
Atopic dermatitis  
Contact dermatitis  
Lichen planus  
Psoriasis

#### Infectious Disorders

Bacterial paronychia  
Candidiasis  
Herpes simplex (whitlow)  
Onychomycosis  
Verrucae

#### Medications

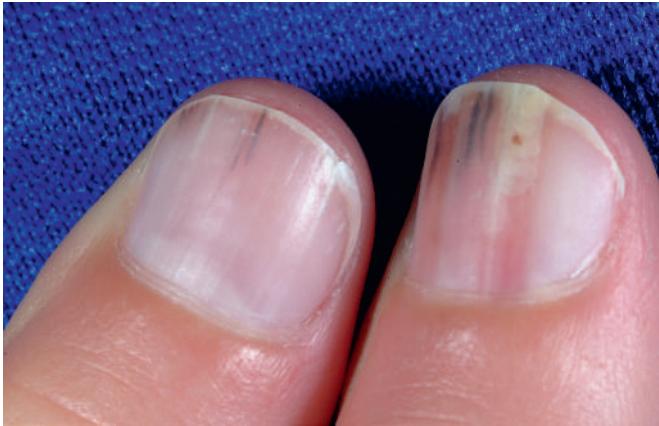

Anticonvulsants (valproic acid)  
Chemotherapeutic agents (especially taxanes)  
Griseofulvin  
Retinoids (isotretinoin)  
Tetracyclines (photoonycholysis)  
Thiazides (photoonycholysis)

#### Systemic Disorders

Iron-deficiency anemia  
Rheumatic disease  
Thyroid disease (hyperthyroidism or hypothyroidism)

#### Trauma

Compulsive subungual cleaning  
Sportsman toe

**Figure 7-65** Darier disease. Longitudinal reddish-purple and white streaks of the nail.

## PARONYCHIA

*Paronychia* refers to inflammation surrounding the nail, generally after breakdown in the barrier between the nail plate and the adjacent nailfold.<sup>557,558</sup> At times, the cuticle is obscured, and the nailfold is replaced by granulation tissue. Acute paronychia, characterized by painful, erythematous, indurated swelling of the proximal or lateral nailfolds, often with purulent draining, is usually caused by *S. aureus* infection; bacterial cultures can be performed to consider a bacterial etiology (see Chapter 14). Abscesses associated with acute staphylococcal infections may spontaneously decompress or may require drainage and local wound care along with a course of appropriate antibiotics. Chronic paronychia with nail dystrophy presenting with

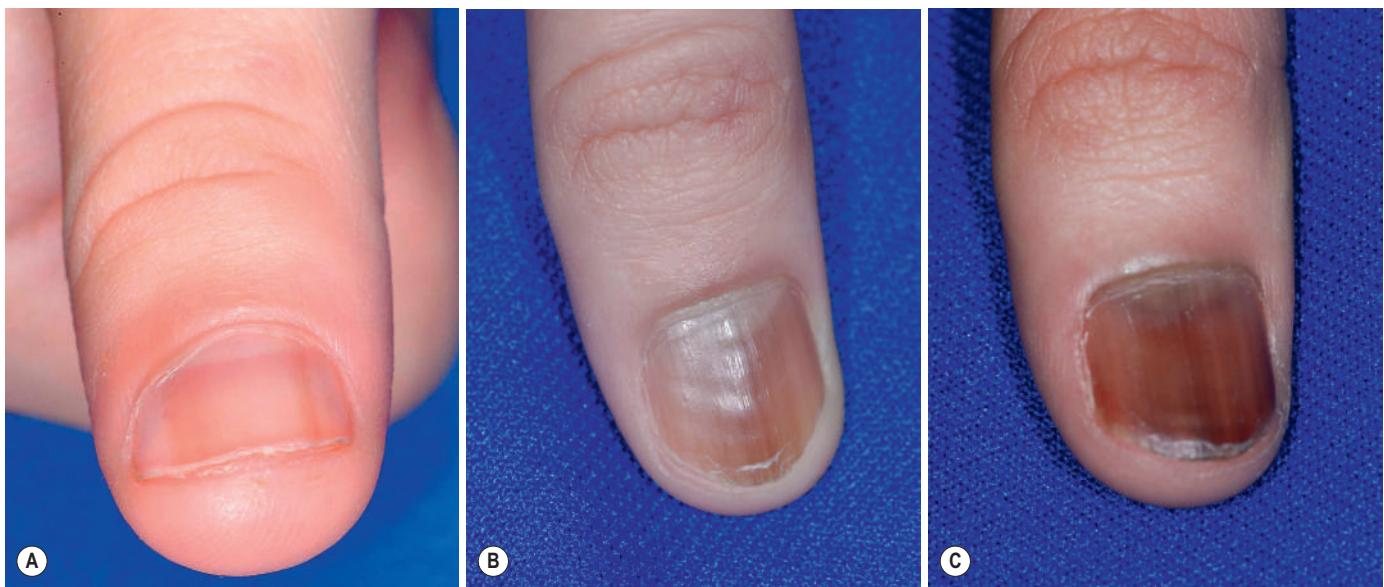

nonpurulent erythema of the periungual areas, nail ridging, and cuticle loss, is more commonly owing to candidal infection. Candidal paronychia is often associated with repeated exposure of the fingers to wetness (see Figs. 17-41 and 17-45). Toddlers who suck their fingers or thumb usually have candidal paronychia, but a more acute process with purulence and crusting overlying the erythema and swelling may also reflect a herpetic whitlow of the finger or toe. Infants with sucking blisters show blisters filled with clear fluid. Potassium hydroxide scrapings to detect the pseudohyphae of *Candida albicans* (see Chapter 17) and direct fluorescence assays and cultures to consider herpes simplex infection (see Chapter 15) should be performed to distinguish these disorders. Treatment of paronychia should be directed toward clearance of the infecting organism. In individuals beyond the age of infancy, efforts to keep the fingers dry, including avoidance of sucking and wet work, are critical for clearance. Paronychia is rarely seen with tinea unguium (see Chapter 17).

Periungual inflammation may also result from noninfectious causes. These include psoriasis and acropustulosis (see Chapter 4), medications (particularly isotretinoin<sup>549</sup> and indinavir<sup>550</sup>), and chemical irritants including nail cosmetics.<sup>560</sup>

## DISORDERS OF NAIL COLORATION

A longitudinal streak of brown pigmentation of the nail (melanonychia striata), which may even extend to involve the entire nail (Fig. 7-66), almost always represents a benign melanocytic nevus in children (see Chapter 9), as opposed to melanoma, the concern with new onset of melanonychia striata in an adult. Melanonychia can also be horizontally arrayed (transverse melanonychia) or involve the entire nail. Abnormal nail pigmentation may be seen in systemic diseases<sup>561</sup> or in association with the ingestion of various chemicals or medications. Brown pigmentation of multiple nails may be associated with the ingestion of phenolphthalein, as a reaction to antimalarials, minocycline, gold therapy, cancer chemotherapy, or zidovudine in pediatric human immunodeficiency virus (HIV) infection.<sup>562</sup> Brown-black pigmentation of the nailfold and nail matrix can be seen as a sign of melanoma of the nailbed (Hutchinson sign), Peutz–Jeghers syndrome, and Laugier–Hunziker syndrome (see Chapter 11). Brown nail pigmentation has also been described as a manifestation of Addison disease or Graves disease.<sup>563</sup> Orange-brown chromonychia has been observed in Kawasaki disease, including in 72% of 40 pediatric patients from India in a recent series.<sup>564</sup> The transverse discoloration of the acral nail begins 5 to 8 days after the onset of fever and clears entirely 2 to 3 weeks later. In argyria the lunulae show a distinctive slate blue disoloration, and in hepatolenticular degeneration (Wilson disease) the lunulae may present an azure blue disoloration. Blue disoloration of the nails has also been described from administration of azidothymidine (AZT).<sup>549</sup> Lithium carbonate can cause brownish-black transverse bands at the margins of the lunulae, and pigmentation in the form of transverse bands has been reported in patients receiving zidovudine, bleomycin, and doxorubicin. Gray or blue-gray nails can occur in individuals with ochronosis or argyria or as a reaction to quinacrine or phenolphthalein. When a green disoloration is seen in association with onycholysis, *Pseudomonas aeruginosa* infection must be considered.

Longitudinal erythronychia is characterized by one or more linear pink-red, usually asymptomatic bands on the nail plate that originate at the proximal nailfold, cross the lunula, and extend to the free edge of the nail plate.<sup>565</sup> With time, the lesion may become brown, especially if hemorrhage is associated. One or more digits may be involved. Localized cases in children can be associated with a wart, vascular or glomus tumor, epidermal nevus, or a postsurgical scar, whereas polydactylous cases are seen in Darier disease (see Chapter 5) and lichen planus.<sup>566</sup> Nail fragility with splitting or V-shaped nicks, onycholysis, splinter hemorrhage, and/or subungual keratosis may be associated. Red lunulae can be seen in patients with AA, lupus erythematosus, dermatomyositis, congestive heart failure, reticulosarcoma, psoriasis, carbon monoxide poisoning, and lymphogranuloma venereum. When the distal 1- to 2-mm portion of the nail has a normal pink color and the rest of the nail has a white appearance, the disorder has been termed *Terry nails* (Fig. 7-67). Seen in patients with cirrhosis, chronic congestive heart failure, adult-onset diabetes, and

**Figure 7-66** Melanonychia. Nail pigmentation can progress, as occurred in this girl over 12 years. This benign nail pigmentation began as discrete longitudinal streaks (**A**) and progressively covered half (**B**) and then all (**C**) of the nail. Although no biopsy was performed, this most likely represents a benign pigmented nevus of the nail matrix.

**Figure 7-67** Terry nails. The distal 1 to 2 mm of the nail have a normal pink color, and the rest of the nail has a white appearance. This girl had hepatic cirrhosis.

**Figure 7-68** Nail discoloration from onychomycosis. Horizontal striations were colored yellow on the hallux nail but white on other nails. Note the annular scaling erythematous lesion on the top of the foot and the erythema and scaling interdigitally, both signs of tinea pedis.

polyneuropathy, organomegaly, endocrinopathy, M component, and skin changes (POEMS) syndrome, Terry nails may also be seen in normal children younger than 4 years of age, in the very elderly, and at times in normal individuals without evidence of cirrhosis or other systemic disease.

The term *leukonychia* (white nails) is used to describe a disorder in which at least a portion of the nail becomes white. The white color may be seen as punctuate, striate, or encompassing much or all the nail. Several forms of leukonychia striata have been described. Most common are variably sized white areas, sometimes multiple, that result from local manipulation. They tend to be horizontal in orientation (rather than following the shape of the nailfold or lunula), do not extend across the entire nail, are not depressed (vs. Beau lines from nail matrix arrest), and grow out with the nail. Mees bands are transverse 1- to 2-mm white bands that follow the lunula, tend to extend to the margins, and move distally as the nail grows out; they have been described in arsenic or heavy metal poisoning, septicemia, dissecting aortic aneurysm, and renal failure. The white transverse bands in Muehrcke nails affect the vascular bed under the nail plate and do not move as the nail grows out; they have been associated with hypoalbuminemia such as from nephrotic syndrome, cirrhosis, or cytostatic chemotherapy agents. The half-and-half nail results from renal disease and azotemia and shows whitening of the proximal nailbed

with red, pink, or brown coloration of the distal half. The toenail may also be white because of superficial onychomycosis or proximal subungual onychomycosis (see Chapter 17); however, these forms of onychomycosis are uncommon in children in comparison with the more typical distal lateral subungual onychomycosis, in which the nail plate is yellow with subungual debris, thickening, and onycholytic (Fig. 7-68). Leukonychia is associated with palmoplantar keratoderma, knuckle pads, and hearing loss in Bart–Pumphrey syndrome, caused by mutations in *GJB2*, encoding connexin 26, and with erythrokeratodermia variabilis from mutations in *connexin 43* (see Chapter 5). Congenital porcelain-like whitening of all (leukonychia totalis) or part (leukonychia partialis) of the 20 nails can be inherited as an autosomal recessive or autosomal dominant disorder without other manifestations as a result of mutations in *PLCD1*, encoding a phospholipase of the nail matrix that controls nail growth.<sup>567</sup>

The yellow nail syndrome is a disorder associated with severe long-term lymphedema and most commonly, respiratory disease, especially chronic bronchitis, bronchiectasis, interstitial pneumonitis, and pleural effusion. Other associations include persistent hypoalbuminemia, thyroid disease, immunologic deficiencies (IgA), lymphoreticular malignancy, rheumatoid arthritis, lupus erythematosus, Hodgkin disease, and the nephrotic syndrome. Most often a phenomenon of middle-aged individuals but also described in neonates

**Figure 7-69** Yellow nail syndrome. Yellowish discoloration of the nails is associated with slow growth, thickening, excessive curvature, and an absence of lunulae in some of the nails of this 8-year-old boy who had congenital chylothorax. The toenails were also affected.

and young children, the nails show a pale yellow or greenish-yellow to brown discoloration of the nails (Fig. 7-69) associated with slow growth; thickening; excessive curvature from side to side (on its long axis); increased hardness, onycholysis, or spontaneous shedding of the nails; absence of lunulae; and swelling of the periungual tissues,

as might be seen in patients with chronic paronychia. The nail changes are often permanent, but administration of oral and topical vitamin E has been reported to be effective in some individuals.<sup>568–570</sup>

## Disorders of the Sebaceous Glands

### ACNE VULGARIS

Acne vulgaris is the most common skin problem in the United States, affecting nearly 80% to 85% of individuals at some point between 11 and 30 years of age.<sup>1,2</sup> Although not a serious disease, acne may be the source of permanent scarring and even more importantly, psychosocial morbidity and decreased emotional well-being. Withdrawal from society, depression, and decreased self-esteem may occur in individuals with more significant disease. Girls and boys with acne have more feelings of uselessness and lower body satisfaction compared with those without acne, and these features are compounded by the fact that acne typically presents in adolescents, who tend to be psychologically vulnerable and sensitive to modification in their physical appearance.<sup>3</sup> In one study, acne severity was directly correlated with extent of embarrassment and lack of enjoyment of or participation in social activities.<sup>4</sup> Patients with even mild to moderate acne have demonstrated high scores on the Carroll Rating Scale for Depression and an increased prevalence of suicidal ideation (SI).<sup>5</sup> In addition, patients with severe acne may have poorer academic performance<sup>6</sup> and higher unemployment rates.<sup>7</sup> Issues such as these highlight that the potential benefits of acne therapy extend far beyond the simple cosmetics of the disease.

Pediatric acne is the terminology applied to acne occurring from birth through 11 years of age; adolescent acne describes patients from age 12 to adulthood.<sup>8</sup> The contemporary classification of pediatric acne based on age of onset of the disease is shown in Figure 8-1.

Acne vulgaris is seen routinely by primary care physicians, and so familiarity with the treatment of this condition is vital. The majority of acne patients with mild to moderate disease respond well to traditional therapies; patients with severe or recalcitrant disease may merit treatment with agents most appropriately prescribed by dermatologists. Although the underlying cause of acne vulgaris remains unknown, considerable data concerning its pathogenesis have accumulated in recent decades to allow a rational and therapeutically successful approach to its management. There is no single “gold standard” therapy for acne, and treatment regimens must be individualized and occasionally fine tuned in order to achieve the optimal response.

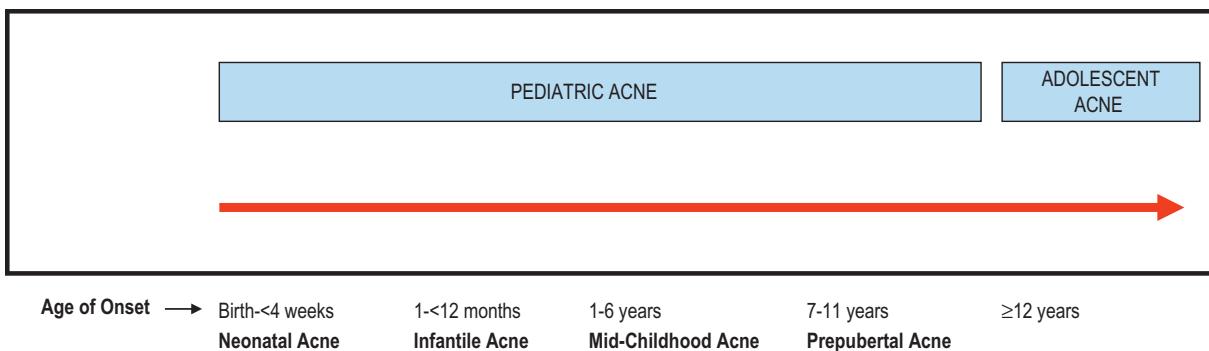

The tendency to develop acne is often familial and is felt by some to be inherited as an autosomal dominant trait. However, because of the high prevalence, the genetics of the disease remain unclear. Adolescent acne usually begins around the time of onset of puberty, occurring earlier in girls than boys. However, the onset of acne may occur significantly earlier, and it may be the first sign of pubertal maturation in girls, correlating with increasing levels of dehydroepiandrosterone (DHEA), an adrenal androgen.<sup>9</sup> Natural history studies show that in 80% of patients the incidence and severity of acne decline by the early 20s, although as many as 50% of adults older than 25 years are affected and a minority may have persistence into middle age.<sup>10,11</sup> An important consideration is the timing of onset of puberty, which has followed a downward trend for many years. Studies from the mid-twentieth century onward suggest that breast and pubic hair development in American girls is occurring at younger ages, with African-American girls disproportionately represented.<sup>12</sup> As a result the regional definitions of precocious puberty have been revised such that puberty is currently considered precocious if it occurs before 8 years of age in European girls, before 7 years of age in American white girls, and before 6 years of age in African-American girls. A similar trend has not been identified in boys, in whom the cut-off age for precocious puberty continues to be 9 years.<sup>13,14</sup>

An understanding of acne pathogenesis helps the practitioner conceptualize and formulate the therapeutic plan. Four interrelated processes, including hyperkeratinization, androgen stimulation, bacterial infection, and inflammation, are traditionally believed to be involved in this multifactorial disease. A pictorial representation of acne pathogenesis is shown in Figure 8-2.<sup>15</sup> Individual acne lesions usually begin with obstruction of the pilosebaceous unit (composed of the hair follicle and the sebaceous gland). These units are localized primarily to the face and trunk, and these “follicular plugs” (or microcomedones) are caused by excessive numbers of desquamated epithelial cells from the wall of the follicle in combination with excessive amounts of sebum, the oily, lipid-rich substance produced by the sebaceous glands. Sebum production is stimulated by adrenal and gonadal androgens and rises to maximum levels during late adolescence. These microcomedones enlarge into comedones, which may be open (blackheads) or closed (whiteheads). The reason for the black appearance of open comedones is unclear; one hypothesis suggests compaction and oxidation of the keratinous material at the follicular opening results in this finding. Melanin pigment may also play a role.<sup>16,17</sup>

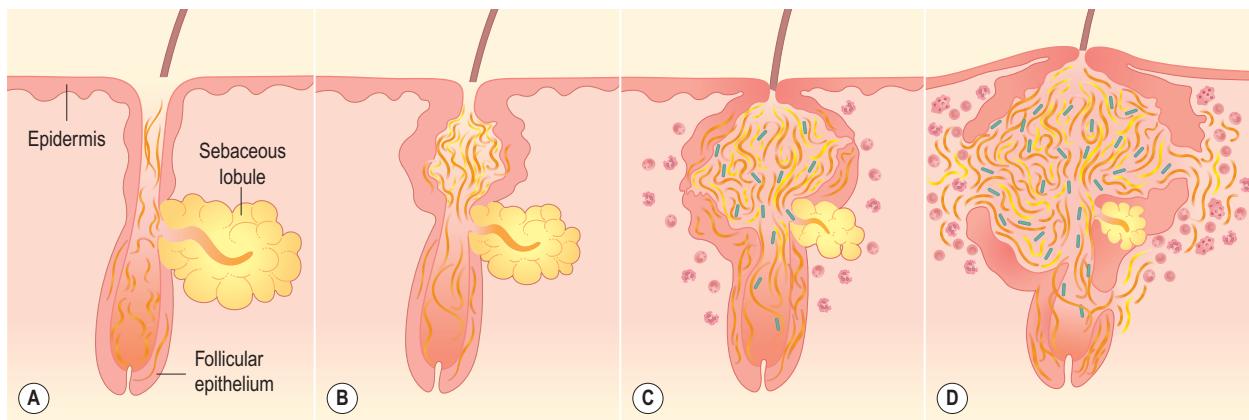

Propagation of acne lesions occurs when *Propionibacterium acnes*, a resident anaerobic organism, proliferates in this environment of sebum and follicular cells with the production of chemotactic factors and proinflammatory mediators, which contribute to inflammation.<sup>18</sup> Hypersensitivity to this organism may also play a part in the more severe forms of acne.<sup>19</sup> The clinical counterpart to these infectious and inflammatory events are papules and pustules. With continued inflammation and macrophage recruitment, larger lesions (cysts and nodules) may result. Finally, sequelae of active acne lesions include dyspigmentation (usually hyperpigmentation or, occasionally, hypopigmentation) and scarring. Box 8-1 summarizes the various types of acne lesions.

Although the pathway in Figure 8-2 has traditionally been used to explain acne pathogenesis, ongoing research continues to shed more light on these processes. Subclinical inflammation, even before the formation of the microcomedone, may be present in acne as demonstrated by upregulated levels of inflammatory cytokines and cells in uninvolved skin from acne patients.<sup>20</sup> Another study supporting this hypothesis utilized digital photographic images to follow the evolution of acne lesions and showed that nearly 30% of inflammatory lesions arose from normal-appearing skin (as opposed to comedones).<sup>21</sup> Further elucidation of the mechanisms that give rise to acne lesions will enable better targeting of acne therapies.

In addition to the established pathogenic factors discussed previously, there may be other triggers or exacerbating conditions that contribute to acne vulgaris. These other factors are less well understood and in some cases controversial. Stress appears to be a common trigger for acne, possibly via increased activation of the hypothalamic-pituitary-adrenal axis and the resultant increase in androgen production. Acute worsening of acne has been documented in college students during examination periods and correlated with an increased perceived stress score.<sup>22</sup> Mechanical factors such as skin occlusion from sports gear (i.e., helmets, chin straps, shoulder pads) may exacerbate the condition. Topically applied preparations, especially pomades and greasy ointments, to hair or skin may contribute to physical obstruction of the pilosebaceous unit and worsen the disease. Several medications may worsen acne, including anabolic steroids, progestins, lithium, isoniazid, hydantoin, and gold.<sup>23</sup> Pathologic androgen excess is often associated with acne (see below), and although endocrinologic evaluation is not indicated for the majority of patients, it should be considered in patients who have additional signs as listed in Box 8-2.<sup>24</sup>

### Box 8-1 Types of Acne Lesions

#### Active lesions (increasing severity)

- Microcomedone (may not be clinically apparent)
- Open comedone (blackhead)
- Closed comedone (whitehead)
- Papule
- Pustule
- Nodule
- Cyst-like nodule

#### Sequelae

- Dyspigmentation (usually hyperpigmentation)
- Scarring (sometimes keloidal)

### Box 8-2 Potential Signs of Androgen Excess in Acne Patients

- Young children
  - Body odor
  - Axillary hair
  - Pubic hair
  - Clitoromegaly
- Adult women
  - Recalcitrant/late-onset acne
  - Menstrual irregularity
  - Hirsutism
  - Male- or female-pattern alopecia
  - Infertility
  - Acanthosis nigricans
  - Truncal obesity

Modified from Strauss JS, Krowchuk DP, Leyden JJ, et al. Guidelines of care for acne vulgaris management. *J Am Acad Dermatol* 2007;56:651–63.

The role of diet in the pathogenesis of acne vulgaris remains controversial, and controlled studies have refuted the value of dietary restrictions. For many years the elimination of various foods such as chocolate, soft drinks, milk, ice cream, fatty foods, shellfish, and iodides was recommended. The misconception that iodine is injurious to patients with acne vulgaris originated with the concept that iodides administered orally as a medication occasionally initiate a papulopustular acneiform eruption. The concept that chocolate exerts an adverse effect on acne has been challenged, and in one controlled double-blind study, it was found that it failed to affect either the course of the disease or the production and composition of sebum.<sup>25</sup> However, the possibility that diet plays a role in the pathogenesis or exacerbation of acne remains unclear. A review of two non-Westernized populations (one in Papua New Guinea and the other in Paraguay) revealed an astonishing difference in acne prevalence in comparison to individuals in Westernized societies.<sup>26</sup> One potential explanation asserted for these differences is the diets of these populations, which are composed mainly of minimally processed plant and animal foods and are nearly devoid of the carbohydrates typical in Western diets, which may result in high insulin levels. Hyperinsulinemia, in turn, may promote the development of acne by its ability to increase androgen production.<sup>26</sup> It remains unclear whether adhering to a diet with a low glycemic load (LGL) can effect a change in acne, although several studies seem to suggest an association.<sup>27–30</sup> Studies have suggested increased sex hormone-binding globulin, reduced androgen levels, and reduced acne lesion development in young males who ate an LGL diet, although the associated weight loss in this cohort, as well as the lower saturated fat content and higher fiber level in the LGL diet, are considered by some as potential confounders.<sup>31,32</sup> The association between milk consumption and development of acne has been explored, with some studies (some of which were limited by their retrospective design) suggesting a positive association, possibly related to a combination of

**Figure 8-3** Acne vulgaris: comedonal. Open comedones present as blackheads.

**Figure 8-5** Acne vulgaris: inflammatory. Note the erythematous papules and pustules, as well as open and closed comedones.

**Figure 8-4** Acne vulgaris: comedonal. Closed comedones present as whiteheads.

**Figure 8-6** Acne vulgaris: inflammatory. This adolescent female has inflammatory papules and papulopustules, as well as hirsutism.

exogenous hormones and growth factors, and stimulation of endogenous hormones.<sup>33–35</sup> Interestingly, skim milk was consistently associated with acne in these studies, suggesting that fat content may not explain the acne-causing ability of milk in the studied cohorts.<sup>31</sup> Other dietary factors being studied with regard to acne pathogenesis include omega-3 fatty acids, antioxidants, zinc, vitamin A, and dietary fiber.<sup>32,36</sup>

Acne presents with a combination of the various lesion types previously discussed: comedones, papules, pustules, cysts, nodules, scarring, and dyspigmentation. The earliest lesion type is usually the comedone, and mild acne may be limited to these lesions (Figs. 8-3 and 8-4). With increasing severity, patients develop inflammatory lesions, including papules and pustules (Figs. 8-5 and 8-6). Nodules and cyst-like nodules may be present in patients with moderate to severe disease (Figs. 8-7 and 8-8) and may result in permanent acne scarring (Figs. 8-9 and 8-10). Dyspigmentation is a common sequela, especially in patients with darker complexions (Figs. 8-11 and 8-12). The primary sites for acne lesions correlate with the areas most concentrated with sebaceous glands: the face, chest, back, and shoulders. In patients with regressing acne lesions, macular erythema (Fig. 8-13) and hyperpigmentation are commonly seen. Although patients commonly regard these as active lesions and “scars,” they usually imply effectiveness of the therapy, and their temporary nature should be explained to the patient. The scarring that occurs in patients with the more severe papulopustular and nodulocystic forms of acne develops because of fibrous contraction after the inflammatory phase. In addition to sharply punched-out pits and craters, hypertrophic or keloidal scars may also develop. The severity of the scarring depends on the depth and degree of the inflammation and on the patient’s individual susceptibility.

Acne fulminans is a rare and severe form of acne vulgaris, occurring almost exclusively in young males. Patients present with an acute

**Figure 8-7** Acne vulgaris: nodulocystic.

onset of painful, nodular, and occasionally ulcerative acne lesions concentrated on the chest (Fig. 8-14), shoulders, back, and face. Fever, leukocytosis, and musculoskeletal pain may also be present, and the skin lesions usually result in permanent scarring. Osteolytic bone lesions may be present, especially in the clavicle, sternum, and long bones.<sup>37</sup> Systemic corticosteroids are the mainstay of therapy, with the addition of isotretinoin after the acute inflammatory stage has subsided.

### Acne Therapy

Before any attempt is made to treat acne, patient education is vital. Important considerations include explaining the nature and natural history of acne vulgaris; dispelling acne myths regarding causes and treatments; highlighting the need for adherence with therapy and

Figure 8-8 Acne vulgaris: nodulocystic.

Figure 8-9 Acne scarring. This patient has severe nodular acne vulgaris with scarring involving the trunk.

Figure 8-10 Acne scarring.

Figure 8-11 Acne-induced dyspigmentation.

Figure 8-13 Residual postacne erythema. Note erythematous macules at sites of prior lesions.

appropriate follow-up care with the physician; reviewing the correct usage of medications and the potential side-effects; and emphasizing the expected gradual improvement in symptoms with therapy. Patient-education materials are very useful to this end and will help increase adherence with treatment. Such materials can be created and personalized by the physician or purchased from national organizations such as the American Academy of Dermatology ([www.aad.org](http://www.aad.org)) or the American Academy of Pediatrics ([www.aap.org](http://www.aap.org)). Box 8-3 lists some clinical pearls for increased adherence in acne therapy.

Acne treatment in the past was hindered by mythical concepts regarding its causes, a more limited armamentarium of treatment options, and a lack of appreciation for the dire psychosocial consequences that can result for the acne patient. With the current level of understanding of acne pathogenesis, the ever-expanding array of

**Figure 8-14** Acne fulminans. This patient developed acute worsening of his acne lesions upon starting isotretinoin therapy and required systemic corticosteroids.

therapeutic approaches, and recognition of both the physical and emotional benefits of successful therapy, every patient with acne who desires treatment should be able to benefit from physician intervention. The primary care provider is optimally situated to offer therapy to patients with mild and moderate disease. For those with recalcitrant or severe involvement, referral to a dermatologist is often necessary. Although acne therapy is a combination of art and science, a solid understanding of the various classes of medication and their proper use in both monotherapy and combination therapy provides the foundation for designing treatment plans. A conceptual framework is shown in Table 8-1 for an acne treatment algorithm. Contemporary treatment algorithms are also available in the published literature.<sup>38-40</sup>

Topical therapies are first-line treatment for patients with mild acne and are very useful as part of a combination therapy regimen for patients with moderate or severe acne. Prescription-strength topical agents are summarized in Table 8-2. Benzoyl peroxide (BP) and topical retinoids (vitamin A acids), although potential irritants, appear to be

### Box 8-3 Pearls for Increasing Adherence in Acne Therapy

- Use written action plans for topical and systemic medication use.
- Keep the treatment regimen as simplified as possible; use of fixed-dose combination agents (when possible) may facilitate this goal.
- Consider the vehicles of prescribed agents and tolerability by the individual patient.
- Take time to educate the patient regarding expectations (length of time to see improvement, likelihood of mild irritation early in the course of therapy, potential side effects).
- Review appropriate application of topical medications.
- Reinforce the importance of ongoing use (maintenance therapy), once improved.
- Consider psychologic comorbidities and encourage open discussion regarding acne-associated stressors.

Modified from references 40, 101, 195.

BP, Benzoyl peroxide; ZA, zinc acetate.

\*Listed are examples; this list is not exhaustive. Many of these preparations have generic alternatives.

†Combination therapy product.

the most effective topical agents. Based on current understanding of acne pathogenesis, these two products offer a highly effective therapeutic approach that can be tailored to each patient. Although success in the management of acne vulgaris can be achieved by the use of these agents alone, the therapeutic effect can be increased substantially by their use in combination, although they are applied at separate times.

Daily facial cleansing, preferably in the morning and at bedtime, is a useful step in acne management. The goals of cleansing are to remove excess oil, dirt, and makeup. Use of a gentle, soap-free, pH-balanced cleanser or acne wash is recommended.<sup>40</sup> It is important that the acne patient be appropriately educated that harsh scrubbing and use of abrasive devices or sponges may increase inflammation and actually worsen acne or increase the risk of scarring.

BP and salicylic acid are the active ingredients in most over-the-counter (OTC) acne products. In fact most BP acne products are now limited to OTC status, excepting some prescription combination

products. Salicylic acid helps reduce sebum and decrease comedones and is found in various concentrations as a gel, lotion, wash, or cream. It may be an alternative comedonal therapy for those who cannot tolerate topical retinoids (now considered the mainstay of comedonal acne therapy). Glycolic acid, one of the  $\alpha$ -hydroxy acids, is found naturally in fruits and yogurt and may be useful in decreasing hyperkeratosis associated with acne.

BP is traditionally the most commonly used topical preparation for acne vulgaris and as noted above is available as an OTC product and in some select prescription (primarily fixed-dose combination) products. It is a powerful antimicrobial, useful for reducing colonization of *P. acnes*, and also has some comedolytic and anti-inflammatory effects. BP is available in a variety of strengths and comes as a gel, wash, cream, lotion, and even shaving cream. It is usually used once to twice daily. BP products may bleach colored clothing or linens, and patients should be warned of this possibility. Combination products of BP with topical antibiotics (erythromycin or clindamycin) are readily available, and these agents appear to be more effective than either ingredient used alone.<sup>41-43</sup> A combination BP/topical retinoid product is also available. These agents are discussed in more detail in the paragraphs that follow.

Potential side effects of BP include an irritant contact dermatitis and rarely an allergic contact dermatitis.<sup>23,44</sup> Irritant dermatitis is particularly problematic when the product is used excessively or in association with abrasive soaps or astringents or both. Therapy must be individualized and initiated gradually, particularly in fair-skinned or atopic individuals. BP should be applied as a thin film and rubbed in gently, gradually increasing the frequency and strength of the preparation as tolerance is developed (generally over several weeks). As with most topical agents, a small portion of the product is generally sufficient for application to the entire face. If irritation or excessive dryness develops, the preparation may be discontinued for several days and then restarted more sparingly, and/or noncomedogenic facial emollients may be used (in small amounts).

Topical retinoids (see Table 8-2) are a very effective class of medication used in the treatment of acne. These drugs normalize the keratinization process within the follicles, which reduces obstruction and therefore the formation of microcomedones and comedones. Some topical retinoids may also have anti-inflammatory activity. These agents are thus both comedolytic and anticomедogenic, and as such, function to help prevent new acne as well as treat existing lesions. The prototype drug in this class is tretinoin, an acid of vitamin A. Newer-generation agents include adapalene and tazarotene. Tazarotene was used initially in the treatment of psoriasis and subsequently received approval for the treatment of acne vulgaris. Although success in the management of acne can often be achieved by the use of topical retinoids alone, the therapeutic effect can be substantially increased by their use in combination with BP or a topical antibiotic. A tretinoin/clindamycin combination (see Table 8-2) has been found to improve both comedonal and inflammatory acne. More recently, an adapalene/BP combination product has become available and was found to be more effective than either agent alone and placebo.<sup>45</sup>

Topical retinoids are generally applied once nightly and should be applied sparingly. A useful analogy for the patient is to use a “pea-sized” or “chocolate chip-sized” amount of product for a full-face application. The traditional recommendation was for retinoids to be applied to a dry face, with 30 to 45 minutes of “air drying” allowed after washing and before applying the product. However, this appears to be unnecessary with the newer formulations of tretinoin, adapalene, and tazarotene. The primary side effect of topical retinoids is irritation, which can be minimized by appropriate application and use. In general, the cream forms are less drying than the gels, solutions, or pledgets, although again, newer formulations have minimized this effect, even with the gel vehicle. In patients with sensitive skin, good initial choices for retinoid therapy would be tretinoin cream (in a lower strength), adapalene cream, or one of the micro preparations. If the product is tolerated well and more effect is desired, the patient can then be advanced to higher strengths, a gel or paged formulation, or tazarotene. Another useful strategy to decrease the incidence of irritation is to have the patient begin therapy 3 nights weekly, increasing as tolerated over a few weeks to nightly application.<sup>46</sup> Since retinoids may degrade significantly when mixed with BP, such combination

therapy should be used only in the form of preformulated combination products (see Table 8-2).<sup>47</sup>

Increased sun sensitivity is another potential side effect of topical retinoids, and patients should be counseled regarding the appropriate use of a sunscreen with a sun protection factor of 30 or higher, especially if they are also using a photosensitizing oral agent. The risk of teratogenicity with use of the topical retinoids is controversial but remains a concern given the well-established teratogenic potential of the oral retinoid, isotretinoin. There are sporadic reports of congenital malformations in infants born to women who used topical tretinoin during pregnancy, but controlled human studies are lacking for this drug, which is classified as a pregnancy category C (studies in animals have revealed adverse effects on the fetus and there are no controlled studies in women or studies in women and animals are not available). The limited transdermal uptake, lack of alteration of plasma retinoid levels, epidemiologic data, and margin of safety when compared with known teratogens all suggest the unlikelihood of tretinoin being a human developmental toxicant.<sup>48-51</sup> However, until a formal consensus exists, the potential risks of topical retinoids should be discussed in detail with women of childbearing potential, and their use should probably be avoided during pregnancy.

Topical antibiotics (see Table 8-2) exert their effect primarily by decreasing the population of *P. acnes*, and they may also have anti-inflammatory effects. The most commonly utilized topical antibiotics for acne are clindamycin, erythromycin, and sulfacetamide. These agents are most useful for inflammatory acne, and in patients with mixed inflammatory and comedonal disease they should be used in combination with another agent that has comedolytic properties (i.e., BP or retinoid). These agents are usually well tolerated and are applied once to twice daily. As with other topical agents, lotions and creams are less drying than solutions, pledgets, and gels. Monotherapy with topical antibiotics should be discouraged, given the greater development of bacterial resistance, which can be lessened by the concomitant use of a preparation containing BP (see below).

Topical erythromycin has been used for decades in the treatment of acne and is usually well tolerated. The addition of zinc to erythromycin may increase its therapeutic efficacy.<sup>52</sup> For patients with extremely dry skin, an ointment-based topical erythromycin product (Akne-Mycin) is available. Topical clindamycin is another well tolerated antibiotic preparation for acne. Although pseudomembranous colitis is usually associated with oral clindamycin, there are only rare reports of this complication with topical application of this agent.<sup>53,54</sup> Therefore if a patient using topical clindamycin develops persistent diarrhea, this rare complication should be considered. Topical sulfonamide preparations (mainly sulfacetamide) are also available by prescription and may be particularly useful in patients who also show evidence of rosacea. These medications are often well accepted, although some patients may find their odor offensive. Patients with allergies to oral sulfa drugs should not use topical sulfonamides. Topical dapsone, a newer arrival in the acne antibiotic market, appears to be most effective against inflammatory lesions, although its mechanism may not be related to *P. acnes* reduction. Topical dapsone may result in clinically insignificant mild hemolysis in patients with glucose 6-phosphate dehydrogenase deficiency.<sup>55</sup>

The landscape of topical acne therapy has evolved significantly in recent decades, with the increasing availability of fixed-dose combination therapies. These agents are approved for mild to moderate acne vulgaris, and they offer the advantages of improved adherence and complementary mechanisms of action of the individual active ingredients.<sup>56</sup> Available fixed-dose combination products include those combining BP and clindamycin, BP and adapalene, clindamycin and tretinoin, and BP and erythromycin. Each of these products, in order to receive US Food and Drug Administration (FDA) approval, was demonstrated to have superior efficacy over placebo as well as the individual active ingredients ("monads") in large, multicenter clinical trials.

With increasing use of topical antibiotics for the treatment of acne vulgaris, the development of resistant strains of *P. acnes* is being observed. Cross-resistance of *P. acnes* to erythromycin and clindamycin is now widespread.<sup>57</sup> In one study, erythromycin-resistant organisms were isolated from 51% of patients treated with oral erythromycin but also from 42% of patients treated with topical clindamycin.<sup>58</sup>

Antibiotic-resistant propionibacteria may be transmissible between acne-prone individuals as well as between patients and their physicians.<sup>59</sup> Data suggest that the concomitant use of BP with topical (as well as oral) erythromycin or clindamycin diminishes the emergence of resistant bacterial strains.<sup>24,38,60</sup>

Azelaic acid is a naturally occurring dicarboxylic acid produced by the fungal organism *Pityrosporum ovale*. It has antibacterial and antimicrobial properties and is felt by some to be equal in efficacy to BP or tretinoin. The effectiveness of azelaic acid may be increased by using it in combination with other topical medications such as retinoids, antibiotics, or BP.<sup>61</sup> Another benefit of this agent is its ability to decrease hyperpigmentation caused by acne. Azelaic acid is marketed as a 20% cream and is applied twice daily. Side effects are rare but include burning, tingling, mild erythema, and pruritus.

Physicians are commonly consulted regarding the safety of acne treatment in women who are pregnant, may become pregnant, or are breastfeeding an infant. Although there are no long-term studies on the use of topical antibiotics during pregnancy, erythromycin seems to be safe. Since it is estimated that approximately 8% of topically applied clindamycin can be absorbed,<sup>48</sup> this drug is probably best avoided for women who are breastfeeding, are pregnant, or are contemplating pregnancy. Although approximately 5% of topically applied BP is absorbed through the skin, it is rapidly metabolized to benzoic acid, enters the dermal blood vessels as benzoate, and is then transported to the kidneys and excreted in the urine. Thus BP appears to be safe during pregnancy, although controlled studies are lacking. The use of tretinoin is discussed earlier in this section.

Oral antibiotics (Table 8-3) are the most common form of systemic therapy utilized in the treatment of acne vulgaris, despite the fact that the only agent with FDA-approval for this indication is extended-release minocycline. These agents are quite effective and are best reserved for patients with moderate or severe inflammatory acne. They are useful in decreasing *P. acnes*, free fatty acids found in sebum, and inflammation (via their inhibitory effect on neutrophil chemotaxis). Oral antibiotics generally require 4 to 8 weeks to achieve their maximum effect, and it is usually necessary to continue therapy for several months, with gradual tapering as tolerated once the disease activity has diminished. The most commonly utilized antibiotics for treating acne are the tetracycline-class drugs (tetracycline, minocycline, doxycycline) and erythromycin. Less commonly, clindamycin, trimethoprim-sulfamethoxazole, azithromycin, and cephalexin are used. These medications are usually given on a twice-daily basis.

The safety of long-term antibiotic therapy for acne has been a concern of patients, parents, and physicians. Although the risk-to-benefit ratio of the most commonly used medications is favorable, each agent carries its own inherent potential toxicities, some of greater concern than others. The development of *P. acnes* resistance has been demonstrated for most of the agents utilized in this setting, especially erythromycin and clindamycin, in which case cross-resistance patterns may emerge.<sup>62,63</sup> General guidelines for oral antibiotic use in acne include avoiding the oral agent if topical agents will suffice, continuing treatment for no longer than is necessary, reusing the same drug when possible (if restarting oral therapy is required), and avoidance of concomitant oral and topical treatment with dissimilar antibiotics.<sup>63</sup> In patients who do not respond to oral antibiotics, the possibility of resistant strains should be considered. Overall, the commonly used oral antibiotics for acne are well tolerated, side-effects are uncommon, and routine laboratory testing is unnecessary. Concomitant use of antibiotics and oral contraceptive agents may result in decreased efficacy of the latter, and this possibility should be discussed with female patients.

Tetracyclines are the gold standard of oral antibiotic therapy for acne. These agents have a long track record of safety and efficacy, although side effects are possible. The possibility of dental staining (Fig. 8-15) in children under 9 years of age precludes their use in this population, who only occasionally have moderate to severe acne. Tetracycline-class antibiotics should also not be used in pregnant females, given the deposition of the drug in developing teeth as a result of its chelating properties and the formation of a tetracycline–calcium orthophosphate complex.

The most common side effects of the tetracyclines are photosensitivity and gastrointestinal upset. The risk of phototoxicity is greatest with

**Table 8-3** Oral Antibiotics for Acne Vulgaris

Drug	Usual Dosage*	Comments/Side-Effects
<b>COMMONLY USED</b>		
Tetracycline	250–500 mg	Dental staining <9 years Dairy products decrease absorption GI upset, photosensitivity, teratogenic, PTC, VVC, IBD
Minocycline	50–100 mg 55, 65, 80, 105, 115 mg ER (1 mg/kg once daily)	Dental staining <9 years Dairy products decrease absorption  Vertigo (lower incidence with ER preparation), GI upset, blue-gray skin pigmentation, severe drug reactions with hepatitis/pneumonitis, lupus-like reactions, SJS, teratogenic, hepatitis, PTC, VVC, IBD
Doxycycline	50–100 mg 75, 100, 150 mg ER, once daily 20 mg ("subantimicrobial dose")	Dental staining <9 years Dairy products decrease absorption  Photosensitivity, photoonycholysis, GI upset (rare), teratogenic, PTC, VVC, IBD
Erythromycin	250–500 mg	GI upset (common), VVC, drug-drug interactions, prolongation of the QT interval; no longer recommended by most experts given increased resistance
<b>LESS COMMONLY USED</b>		
Trimethoprim-sulfamethoxazole	80/400 mg, 160/800 mg	Severe drug reactions, SJS, bone marrow suppression, hepatitis, GI upset, VVC, fixed drug eruption; routine use for acne strongly discouraged
Clindamycin	75–150 mg	Pseudomembranous colitis, GI upset, drug reactions, VVC
Cephalexin	250–500 mg	GI upset, drug reactions, VVC

ER, Extended release formulation; GI, gastrointestinal; IBD, inflammatory bowel disease; PTC, pseudotumor cerebri; SJS, Stevens-Johnson syndrome; VVC, vulvovaginal candidiasis.

\*Usually given twice daily for acne unless otherwise noted in table.

**Figure 8-15** Dental staining from tetracycline. (Courtesy of Maria Simon, DDS.)

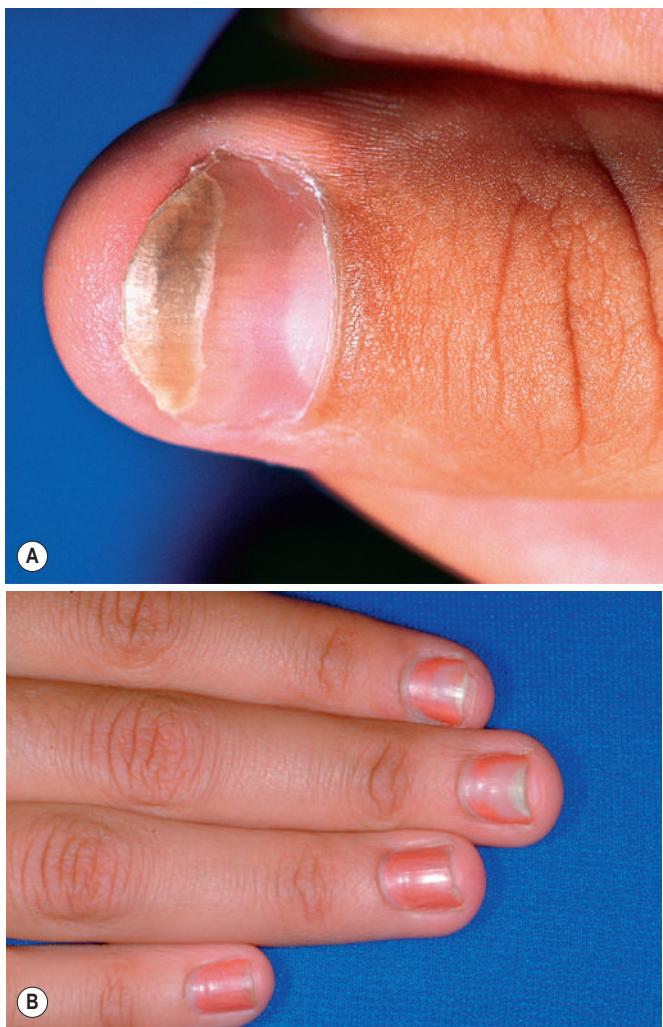

tetracycline and doxycycline and extremely rare with minocycline. Pseudotumor cerebri is a rare side effect, the risk being greatest when isotretinoin and a tetracycline are taken concomitantly. Tetracyclines cannot be taken with dairy products or antacids, which impair absorption. In addition, tetracycline (but not doxycycline or minocycline) absorption is impaired in the presence of food, and thus the medication must be taken 1 hour before or 2 hours after a meal. This feature may result in decreased compliance among active teenagers. Tetracyclines should be used with caution in patients with renal disease.

Doxycycline has the benefit of sustained absorption in the presence of food but may result in severe photosensitivity reactions. One such type of reaction is "photoonycholysis," which presents with erythema and separation of the nail plate from the nailbed (Fig. 8-16). These patients usually also have an associated photosensitivity rash on exposed areas of skin. Pill esophagitis is another potential side effect of oral doxycycline and can usually be prevented by taking the medication with a full glass of water and avoiding recumbency for at least

1 hour after dosing. In a retrospective cohort study of patients with acne who were treated with oral tetracycline-class antibiotics, the hazard ratio (HR) for developing inflammatory bowel disease (IBD) was increased for all agents in this class but most notably for doxycycline (HR of 1.63).<sup>64</sup> However, a definitive causal link between tetracycline-class antibiotics and development of IBD remains to be proven. Off-label use of subantimicrobial-dose doxycycline hydiate (20-mg tablets taken twice daily) has been reported in acne vulgaris and has been shown to significantly reduce the number of lesions without any detectable antimicrobial effect on skin flora or alteration of resistance patterns.<sup>65</sup> An extended-release formulation of doxycycline is available and can be administered once daily.

Minocycline is the most widely prescribed systemic antibiotic for the management of acne in the United States, Canada, and the United Kingdom, and it is estimated that 65% of prescriptions for this drug are for acne.<sup>66</sup> It is particularly effective against *P. acnes* and also has anti-inflammatory properties. Similar to doxycycline, an extended-release formulation of minocycline is available and may improve adherence as well as decrease the incidence of vestibular side effects. Although the side-effect profile is somewhat similar to that of other tetracyclines, minocycline rarely causes photosensitivity. Other side effects more specific to minocycline are headache, dizziness, vertigo, and a blue-gray pigmentation of mucosae (see Fig. 11-57) or at sites of previous inflammation such as acne scars.

Occasional yet potentially serious toxicities may be associated with minocycline, including autoimmune hepatitis, drug-induced lupus (DIL), serum sickness-like reaction (SSLR), and a drug hypersensitivity reaction (HSR).<sup>66,67</sup> This HSR is characterized by a diffuse erythematous rash, facial (especially periorbital) edema, lymphadenopathy, fever, and internal organ involvement (most commonly the liver). It tends to occur within 6 to 8 weeks of starting the drug and is similar to the hypersensitivity reaction occasionally seen with the aromatic anticonvulsants (phenytoin, carbamazepine, phenobarbital, lamotrigine). SSLR presents with fever, urticarial rash, periarticular swelling with arthralgia, and occasional nephritis and lymphadenopathy. A comparative study reviewing adverse events of tetracycline, minocycline, and doxycycline revealed that these reaction patterns (DIL, SSLR, and HSR) are all more commonly seen with minocycline than with the other two medications.<sup>68</sup> Also of note is the fact that

**Figure 8-16** Doxycycline-induced photoonycholysis in two patients. Note distal nail plate separation with new nail growing in proximally (A) and separation of nail plate from underlying nailbed in the index and middle fingers (B).

SSLR and HSR usually occur within 2 months of beginning treatment, whereas DIL may be delayed for up to 2 years.<sup>68</sup> Like doxycycline, minocycline use has been linked to a possible increased risk of IBD, but this link remains definitively unproven.

Autoimmune hepatitis, DIL, arthritis, vasculitis, and development of autoantibodies have been unified under the moniker of minocycline-induced autoimmunity (MIA). A study of 27 children with MIA revealed a mean duration of treatment of 13 months before the diagnosis. The majority of patients had polyarthralgia or polyarthritis, mostly of the hands and feet. Other features included constitutional symptoms, livedo reticularis, Raynaud phenomenon, elevation of liver enzymes, and elevated antinuclear antibody titers. Importantly, 26% of patients had chronic autoimmunity, manifested mostly as persistent arthritis.<sup>69</sup> Many patients with minocycline-associated DIL have no skin eruption. Polyarteritis nodosa has been reported in some patients, and positivity for perinuclear antineutrophil cytoplasmic antibody (p-ANCA) is believed to strongly support the diagnosis.<sup>40</sup> Antihistone antibodies, traditionally considered pathognomonic for DIL, are often negative in patients with minocycline-associated disease.

Although these major types of tetracycline class drug reactions are rare overall, their possibility should be discussed with the patient, especially when minocycline is being considered. Many experts consider doxycycline to be a safe alternative, even in patients who have a history of MIA.

Erythromycin is a useful antibiotic for acne vulgaris, but its use is often limited by the fairly high incidence of gastrointestinal disturbance, even with the enteric-coated preparations. Otherwise it has few side effects and carries the distinct benefit of no phototoxicity. However, the high prevalence of erythromycin-resistant *P. acnes* organisms may further limit its clinical utility. Other antibiotics occasionally used for acne include clindamycin, trimethoprim-sulfamethoxazole, and cephalaxin. Prolonged use of oral clindamycin is not desirable because of the risk of pseudomembranous colitis caused by the toxin liberated by *Clostridium difficile*, which is able to grow in large numbers in the intestinal tract of some patients who receive this drug. Trimethoprim-sulfamethoxazole can be very effective for acne, but it is not recommended as a first-line agent given the severe and potentially life-threatening reactions (i.e., HSR, Stevens-Johnson syndrome, and toxic epidermal necrolysis) as well as bone marrow suppression that may occur.

The most common complication of antibiotic therapy in adult female patients is vaginal candidiasis, but it rarely occurs in teenagers. This complication is proportionately more common in women who take combined oral contraceptives (COCs) concomitantly with their systemic antibiotics. Another concern in patients who are also taking COCs is the possibility of the oral antibiotic diminishing the effectiveness of the contraceptive. Although this possibility remains controversial, it should be discussed with patients and alternative forms of birth control considered during the period of treatment. Patients on long-term antibiotic therapy may rarely develop a condition termed *Gram-negative folliculitis*, caused by superinfection of the pilosebaceous units with Gram-negative organisms. This complication is manifested by a pustular folliculitis or deep nodulocystic lesions recalcitrant to the acne regimen. It may respond to a change in antibiotics to reduce Gram-negative organisms, but it responds more consistently to isotretinoin.<sup>70</sup>

Hormonal therapies are another option for the treatment of acne in female patients. The primary goal of these therapies is to oppose the effects of androgens on the sebaceous glands.<sup>71</sup> Hormonally driven acne may have some distinguishing clinical features, including larger and deep-seated inflammatory nodules in the mandibular and antero-lateral neck regions, menses-associated flares, and associated signs of hyperandrogenism such as hirsutism and menstrual irregularities. If polycystic ovary syndrome (PCOS) is suspected, initial laboratory testing should include serum total and free testosterone, DHEA, and luteinizing hormone (LH)/follicle stimulating hormone (FSH) levels, as well as the 17-hydroxyprogesterone level if late-onset congenital adrenal hyperplasia is suspected. Abnormal findings should prompt referral to an endocrinologist.

Hormonal acne therapies include androgen receptor blockers, adrenal androgen production blockers, ovarian androgen blockers, and enzyme inhibitors, and they may be prescribed in consultation with a gynecologist or endocrinologist. This group of medications may have other beneficial effects on the hirsutism, androgenetic alopecia, and menstrual irregularities in some females.<sup>23</sup> COCs contain both an estrogen and a progestin, and those with a lower intrinsic androgenic activity type of progestin (desogestrel, norgestimate, and drospirenone) are most desirable for acne therapy. Drospirenone, a novel progestin, has both antiandrogenic and antimineralcorticoid activity and is reportedly better tolerated in terms of weight gain and mood changes.<sup>72</sup> Norgestimate and ethynodiol (Ortho Tri-Cyclen); norethindrone and ethynodiol (Estrostep); and drospirenone and ethynodiol (Yaz) are FDA-approved for use in the treatment of acne vulgaris. COCs may be the first-line treatment in females with skin manifestations of hyperandrogenemia.<sup>73</sup> Risks of COCs include venous thromboembolism, myocardial infarction, and ischemic or hemorrhagic stroke, although these risks seem to be more clinically significant in patients with other risk factors such as tobacco use, diabetes mellitus, and hypertension.<sup>74</sup>

Antiandrogenic agents include spironolactone, flutamide, cyproterone, gonadotropin-releasing hormone antagonists, and 5- $\alpha$ -reductase inhibitors. Spironolactone, which is used primarily as a diuretic in the treatment of hypertension, competes for androgen receptors on target cells. It is usually started at 25 to 50 mg/day, and maintenance doses, which vary by the individual, are in the range of 25 to 200 mg/day.<sup>75</sup> Potential side effects of spironolactone therapy include menstrual

irregularities, breast tenderness, hyperkalemia, and fatigue. In a study of 27 women with severe acne who were treated with spironolactone and a combined contraceptive (drospirenone and ethinylestradiol), this combination was demonstrated effective and safe, without hyperkalemia or other serious side effects.<sup>75</sup>

Isotretinoin (13-cis retinoic acid, Amnesteem, Claravis, Sotret, Absorica, Zenatane) is a derivative of vitamin A that is highly effective for recalcitrant nodulocystic acne, and the availability of this agent revolutionized the treatment of severe disease. Although the precise mechanism of action is unknown, its effects appear to be related to marked inhibition of sebum synthesis; lowering of *P. acnes* concentration; inhibition of neutrophil chemotaxis; and comedolytic and anti-inflammatory effects. Isotretinoin therapy often results in complete and often, but not always, permanent remission of acne vulgaris.<sup>76</sup> Preteens and young teenagers seem to have the highest rate of relapse. In patients who experience a recurrence of disease, however, the flares may be milder and more responsive to therapies utilized before isotretinoin therapy. Repeat courses may occasionally be necessary.

Patients usually start by taking 0.5 mg/kg per day of isotretinoin and increase the dosage to 1 mg/kg per day, usually for 16 to 24 weeks. Cumulative dosing goals, ranging from 100 to 150 mg/kg for the entire course of treatment, have been advocated, because they may decrease the rate of relapse.<sup>77,78</sup> Early in the course of isotretinoin therapy, there may be a temporary flare of lesions, and patient education regarding this possibility is vital. Although isotretinoin is truly a "miracle" drug for severe forms of acne, it has many potential side effects and prescribing should be done only by physicians experienced in its use.

Potential adverse effects of isotretinoin are numerous and are summarized in Table 8-4. A newer risk management program, iPLEDGE ([www.ipledgeprogram.com](http://www.ipledgeprogram.com)), was approved by the FDA and drug manufacturers and implemented in March of 2006. This program requires prescribers, patients, pharmacies, drug wholesalers, and manufacturers in the United States to register and comply. This mandatory distribution program was created in an effort to prevent the use of isotretinoin during pregnancy because its teratogenic effects (see

below). Under this system, prescribers must record two negative pregnancy tests before a female patient can commence therapy with isotretinoin. The iPLEDGE program represents the most rigorous risk-management program in history for such a widely prescribed drug.<sup>79</sup> Overall the risk of major side effects from isotretinoin (assuming pregnancy is avoided) is quite low. Unfortunately, a recent retrospective cohort study found no significant decrease in fetal exposure in females of childbearing age when compared to the prior risk management program (System to Manage Accutane-Related Teratogenicity [SMART]).<sup>80</sup>

Isotretinoin is a known human teratogen and is a pregnancy category X drug. Major fetal malformations have been observed in exposed infants, including abnormalities of the skull, ear, eye, central nervous system, and heart. As little as one pill can have devastating consequences on the developing fetus.<sup>23</sup> To qualify for therapy, females of childbearing potential must have two negative serum or urine pregnancy tests, and commitment to two forms of contraception, one of which must be a primary form (COC, intrauterine device, injectable or implantable hormonal birth control product, partner's vasectomy, or tubal ligation), for at least 1 month before initiation of therapy and for 1 month after discontinuing therapy. Abstinence is most desirable for females on isotretinoin therapy. A signed patient consent form is required. Unfortunately, even with dedicated pregnancy prevention programs and education regarding isotretinoin-associated teratogenicity, inadequate birth control efforts continue to be practiced by some females being treated with isotretinoin. Ongoing fetal exposure to isotretinoin has been demonstrated to be an international problem, highlighting the need for more effective strategies that incorporate considerations for cultural differences.<sup>81</sup>

The risks of isotretinoin-related depression and SI have come to the forefront in recent years. The exact association, if any, remains controversial, and arguments both supporting and refuting the potential for mood disturbance have been made. Epidemiologic data have demonstrated a lower suicide rate of 12- to 18-year-old isotretinoin users when compared with the annual rate of suicide for that population in the United States. Critical literature reviews have failed to confirm an association, and although retinoid receptors are widely distributed in the brain, there is no known pharmacological mechanism to account for isotretinoin-induced psychiatric symptoms.<sup>82-84</sup> In one systematic literature review, it was noted that studies comparing depression before and after treatment did not show a significant increase and that, surprisingly, some revealed a trend toward fewer or less severe depressive symptoms after isotretinoin therapy.<sup>84</sup> In a cross-sectional questionnaire-based study exploring the relationship of SI, mental health problems, and social functioning to acne severity among adolescents, SI was reported two to three times more often in those with increasingly severe acne when compared to those with little to no acne. Mental health problems and poorer school functioning were also associated with substantial acne, and the authors concluded that adverse events such as depression and SI that have been ascribed to acne therapies may actually reflect the burden of the disease rather than a medication effect.<sup>85</sup> Nonetheless, until more conclusive data are available, patients and parents must be thoroughly informed of the potential risks of depression and SI, and patients on isotretinoin therapy should be monitored closely and referred for psychiatric evaluation if indicated.

The potential association between isotretinoin use and IBD, which was first suggested in the mid-1980s, continues to be debated, with conflicting findings. A case-control study of over 8000 cases of IBD compared with nearly 22,000 controls revealed a strong association between previous isotretinoin exposure and ulcerative colitis, but not Crohn disease, with the risk increasing in a dose-dependent manner.<sup>86</sup> In another case-control study and meta-analysis, there was no increased risk ratio for IBD in patients who had been treated with isotretinoin.<sup>87</sup> In a retrospective population-based cohort study in Canada, no significant association between isotretinoin use and IBD was found, although in a secondary analysis of individuals limited to the ages of 12 through 19 years, a weak IBD association was noted for both isotretinoin and topical acne medications.<sup>88</sup> The significance of confounding variables (such as preceding antibiotic therapy for acne; see earlier in this chapter) and the possibility that another factor (i.e., inherently increased risk of IBD in patients with inflammatory

**Table 8-4** Potential Isotretinoin-Associated Adverse Effects

Side Effect	Comment
Dry skin and nasal membranes	Occasional epistaxis
Dry eyes	Most problematic for contact-lens wearers; may develop conjunctivitis, chalazion, hordeolum
Cheilitis	May be quite severe
Photosensitivity	
Decreased night vision	
Corneal opacities	
Alopecia	Diffuse thinning; generally reversible but can be the start of androgenetic alopecia
Headache	
Pseudotumor cerebri	Most common with concomitant use of tetracycline-class antibiotic
Musculoskeletal pain	
Hyperostosis	Mainly seen with prolonged use
Elevated triglycerides, cholesterol	Rare pancreatitis
Hepatitis	
Inflammatory bowel disease	Controversial
Rhabdomyolysis	
Teratogenicity	See text for discussion
Depression, suicidal ideation	See text for discussion

**Table 8-5** Alternative Treatments for Acne Vulgaris

Treatment	Comment
Comedone extraction	Performed with comedone extractor
Injections	Intralesional triamcinolone injected into large cysts or nodules
Light therapy	Blue light (may photoinactivate <i>P. acnes</i> ) Red light (may have anti-inflammatory effect) Combination blue-red light Intensed pulse light (IPL) Photodynamic therapy (PDT)
Laser therapy	KTP, pulsed dye laser (rarely used) Resurfacing laser (including both nonablative and ablative resurfacing lasers); useful for acne scarring
Dermabrasion/dermasanding	Useful for acne scarring
Collagen injection	Useful for acne scarring
Chemical peels	Useful for acne scarring and hyperpigmentation
Punch grafts/tissue augmentation	Useful for acne scarring
Trichloroacetic acid	Useful for atrophic acne scars
Radiation therapy	Outdated modality

#### Box 8-4 Acne Treatment Vignettes\*

##### Mild comedonal acne

Topical retinoid once daily, or  
Topical retinoid/BP combination product once daily, or  
BP wash once daily

##### Mild-moderate combined acne (inflammatory and comedonal lesions)

BP cleanser daily and topical retinoid once daily, or  
BP/topical antibiotic combination product in AM and topical retinoid in PM, or  
BP cleanser daily and topical retinoid/topical antibiotic combination product once daily

##### Moderate-severe combined acne (inflammatory and comedonal lesions)

Oral antibiotic and topical retinoid once daily, or  
Oral antibiotic and topical retinoid/BP combination product once daily, or  
Oral antibiotic and spironolactone (female patient), or  
COC and oral antibiotic and topical retinoid once daily

##### Severe or scarring acne

Isotretinoin

BP, Benzoyl peroxide; COC, combined oral contraceptive.

\*The above vignettes are therapeutic examples only and not intended to be specific recommendations; acne therapy should always be tailored to the specific patient and severity of involvement.

acne vulgaris) may explain these observations precludes confirmation of causality. Until more is known, however, it is prudent to mention this possible association to patients and parents and to monitor patients appropriately during therapy.

There are a variety of miscellaneous treatments for acne vulgaris, and these are listed in Table 8-5.<sup>23,89-91</sup> Box 8-4 lists examples of therapeutic approaches based on acne type and severity.

#### NEONATAL ACNE

Although acne is usually a disorder of adolescents and young adults, neonates and infants are occasionally affected. Neonatal acne has its onset within the first weeks of life and may be congenital in up to 20% of newborns.<sup>92</sup> Infantile acne (see *Infantile Acne* section), on the other hand, usually presents between 1 and 12 months of life and tends to

**Figure 8-17** Neonatal acne. This newborn had typical papules and pustules with rapid resolution over 1 month.

be more severe and more persistent.<sup>93</sup> Both types occur more often in boys than in girls.

Neonatal acne typically presents with mildly erythematous papules involving the face and scalp and less commonly the chest and back (Fig. 8-17). Comedones may occasionally be present, although these tend to be more characteristic of infantile acne. Neonates presenting with more pustular lesions may have a variant referred to as *neonatal cephalic pustulosis* (see below). Neonatal acne should be distinguished from other potentially papulopustular disorders of the neonate, including infection (bacterial, candidal, or viral), erythema toxicum neonatorum, miliaria (prickly heat), eosinophilic folliculitis and milia (typically noninflamed white papules rather than pustules).

The etiology of neonatal acne is believed to relate to increased production of DHEA by the fetal adrenal glands. Another factor may be androgens, both transplacentally delivered as well as those manufactured by the neonatal testicles. Testicular androgen production serves as a stimulus to primed adrenal glands, which may partially explain the increased incidence of neonatal acne in males.<sup>76</sup> In babies with neonatal acne, a family history of acne may or may not be present.<sup>94</sup>

In recent years, a neonatal pustular eruption that presents in a similar fashion to neonatal acne has been described and has been termed *neonatal cephalic pustulosis*. This disorder presents with multiple facial papules and pustules (see Fig. 2-12), and direct examination of pustule smears may reveal yeasts of *Malassezia furfur* or *Malassezia sympodialis*.<sup>95,96</sup> In a 1996 series of 13 neonates with such a pustular eruption, smears were notable for *M. furfur* in 8 of the patients, all of whose conditions cleared rapidly after application of ketoconazole cream.<sup>95</sup> Colonization of neonates with *Malassezia* begins at birth and increases over the first few weeks of life.<sup>97</sup> However, the exact role of *Malassezia* in this setting is poorly understood with inconsistent findings in subsequent reports.<sup>98</sup> The association between neonatal cephalic pustulosis and neonatal acne remains unclear.<sup>99</sup>

Neonatal acne usually regresses spontaneously over 3 to 6 months, only occasionally persisting longer. In mild cases, therapy is generally unnecessary; daily cleansing with a gentle soap and water may be all that is required. Exogenous oil such as baby oils, creams, ointments, and lotions may aggravate the condition and should be avoided. For infants with more inflammatory or persistent disease, a low-strength (2.5% to 5%) BP gel or a topical antibiotic (i.e., erythromycin gel) are reasonable treatment options. In the otherwise-well neonate with a significantly pustular facial eruption (i.e., more suggestive of neonatal cephalic pustulosis), topical antifungal therapy can be considered. If there is a significant comedonal component or nodules are present, the infant more likely has infantile acne (see *Infantile Acne* section),

and other therapeutic options may be necessary, including oral antibiotics.

### INFANTILE ACNE

Infantile acne presents between 1 and 12 months of life. Clinically, the infant most often has open and closed comedones, but inflammatory papules and pustules occasionally occur. They may also develop larger papules and nodules (Fig. 8-18) with the potential for scarring, even without comedonal lesions. Lesions occur most commonly on the face, but the neck, back, and chest may also be involved. Most experts consider treatment of infantile acne vital in order to prevent scarring and permanent facial disfigurement.

The patient with infantile acne should have a concomitant growth assessment (with charting of height and weight) and examination for any features of precocious puberty or androgen excess, including axillary odor, clitoromegaly, presence of axillary or genital hair, breast development, and increased muscle mass. If any concerns are noted, an evaluation for hyperandrogenism should be performed (Box 8-5).

Treatment for infantile acne depends on the severity of the clinical lesions. Mild to moderate disease is usually treated with a combination of BP, topical antibiotics, and/or topical retinoids. The latter should always be included in patients with more comedonal disease. For disease that does not respond to topical measures, oral erythromycin is an excellent first-line antibiotic therapy, and the ethylsuccinate form is generally well tolerated. Refractory involvement or the presence of nodules or scarring suggest the need to consider oral isotretinoin therapy.<sup>100</sup> Intralesional steroids have also been used to treat larger nodules.

### MID-CHILDHOOD ACNE

*Mid-childhood acne* is defined as acne that has its onset between 1 and 7 years of age. This is an important diagnosis to render, because acne that begins during this age range is generally considered abnormal. This is related to the fact that children of these ages do not produce

**Figure 8-18** Infantile acne. This infant had more persistent involvement with larger lesions such as the deep papulopustule on the left cheek.

#### Box 8-5 Recommended Laboratory Evaluation for the Child with Acne and Suspected Hyperandrogenism

- Prolactin
- Radiographic bone age

significant levels of either adrenal or gonadal androgens. Mid-childhood acne is the most likely type to be associated with an underlying endocrinologic disorder. Diagnoses such as late-onset congenital adrenal hyperplasia, androgen-secreting tumors of the adrenal glands or gonads (benign or malignant), and true precocious puberty can all present with early acne.<sup>56,101</sup> A hyperandrogenism evaluation (see Box 8-5) or referral to a pediatric endocrinologist is strongly recommended in this setting. Treatment for mid-childhood acne is similar to that outlined in the previous section for infantile acne.

An important consideration for any infant or young child with acne is the possibility of virilization related to exogenous androgen exposure. Topical androgens (primarily in the form of testosterone gel or cream) are being increasingly utilized by males with hypogonadism as well as for an off-label therapy for increased libido and enhanced manhood.<sup>102,103</sup> Inadvertent exposure of young children through contact with the treated individual has been increasingly reported and may result in clitoromegaly, appearance of secondary sexual hair, penile/testicular enlargement, frequent erections, growth acceleration, increased muscle mass, greasy hair, and acne.<sup>103,104</sup> This resultant pseudo-precocious puberty (PPP) highlights the need to obtain a thorough family history and inventory of medications being used by close contacts.

### ANDROGEN EXCESS AND ACNE

It is well recognized that androgens precipitate acne in both men and women, in addition to the potential effects of hyperandrogenemia in younger children as discussed in the previous sections. Acne may be produced or aggravated by increased adrenal gland production in response to stress, adrenal tumors, gonadal dysgenesis, Cushing syndrome, and ovarian androgen excess, such as that occurring in patients with PCOS (see Chapter 23). This condition seems to be quite common. In one study of women with acne (but lacking menstrual disorders, obesity, or hirsutism), polycystic ovaries were found in 45%, compared with 17% of age-matched controls.<sup>105</sup> Adolescent females with severe, persistent, or recalcitrant forms of acne, especially in the setting of other signs of androgen excess (i.e., menstrual irregularity and hirsutism) should be screened for this disorder with laboratory examinations (as discussed earlier) and transabdominal ovarian ultrasound. In patients with acne who show rapid development of virilizing signs such as voice deepening, increased muscle mass, or androgenetic alopecia, the evaluation should focus more on a search for a tumor rather than polycystic ovaries.<sup>106</sup> *Metabolic syndrome* (previously referred to as *syndrome X*) describes the clinical presentation of severe insulin resistance, obesity, hypertension, dyslipidemias, and microvascular angina. Occasionally, ovarian hyperandrogenism and polycystic ovaries may occur in this setting.<sup>107</sup> Treatment for PCOS typically consists of hormonal agents and antiandrogens such as spironolactone.

### ACNE ROSACEA

Acne rosacea (also known simply as *rosacea*) is a chronic vascular inflammatory disorder usually limited to the face and characterized by erythema, telangiectasia, papules and pustules, and occasionally, hyperplasia of the sebaceous glands and the soft tissues of the nose (rhinophyma). Rosacea is primarily a disease of adults between the ages of 30 and 50 but may also appear as early as the second decade of life, at times coexisting with acne vulgaris. Rosacea most often manifests as erythema and telangiectasia of the cheeks. A variety of ocular lesions may occur in the setting of rosacea. This association is termed *ocular rosacea* and is characterized by blepharitis, conjunctivitis, episcleritis, iritis, keratitis, and occasionally corneal ulceration and subsequent opacity. Several aberrant responses have been identified in rosacea, including altered toll-like receptor 2 (*TLR2*) expression, enhanced vasodilation triggered by cathelicidin, and greater lesional skin activity of reactive oxygen species.<sup>108</sup>

There are several potential exacerbating factors in rosacea, including sun exposure, stress, cold weather, hot beverages, alcohol consumption, and certain foods.<sup>109</sup> Avoidance of these factors may help prevent flares in certain individuals. Although the etiologies of rosacea and ocular rosacea are not well understood, a primary genetic predisposition is suggested, because single genes may control mediators

involved in rosacea pathways, namely enzymes, neuroendocrine transmitters, and cytokines.<sup>110</sup> Complete clearing of rosacea is rarely achieved, but satisfactory control can usually be accomplished by the use of topical or oral agents. Systemic therapy options include metronidazole, doxycycline, minocycline, tetracycline, or clarithromycin, and the most useful topical therapy appears to be metronidazole.<sup>111</sup> Topical sulfonamide preparations, azelaic acid, and sulfa-based washes may also be useful. Patients with rosacea tend to tolerate topical retinoids and BP poorly. Oral isotretinoin has been effective in patients with severe rosacea, predominantly of the granulomatous type. The telangiectasias may improve after pulsed-dye laser therapy or photodynamic therapy with red light, and recently a topical vasoconstrictor (brimonidine gel) was approved for the facial erythema of rosacea. Rhinophyma, if it develops, is a difficult finding to treat and usually requires aggressive dermatologic surgical procedures with or without laser surgery.

Although clinically classic acne rosacea does not typically occur in young children, two entities that do classically occur in childhood may be related: periorificial dermatitis and idiopathic facial aseptic granuloma (IFAG). These are discussed in more detail below.

### POMADE ACNE

A variety of external agents can induce acne-like eruptions upon repeated exposure to the skin of susceptible persons. These include greasy or oily sunscreen preparations, heavy make-up bases, and grooming agents. An acneiform eruption induced by various grooming substances used on the scalp has been termed *pomade acne*. It is usually seen on the forehead and temples and consists of numerous, closely set, closed comedones. The cheek and chin may also be involved if the agent has been applied over the entire face. Pomade acne may in fact represent true acne vulgaris potentiated by the use of occlusive products. It usually responds to standard acne therapy along with discontinuation of the offending comedogenic preparation.

### ACNE COSMETICA

Acne cosmetica is a variant of acne described in women, usually women who are older than 20 years of age, that is attributed to the frequent or heavy use of cosmetics,<sup>112</sup> particularly those containing lanolin, petrolatum, certain vegetable oils, butyl stearate, isopropyl myristate, sodium lauryl sulfate, lauryl alcohol, or oleic acid. The lesions are predominantly small, scattered, closed comedones on the face. Although common in women without a history of acne, those with a history of adolescent acne seem to be the most susceptible. A prominent feature is a coarse facial appearance associated with prominent dark follicles that is often more distressing to the patient than the actual acne lesions themselves. The most extensive eruptions are seen in women who attempt to mask the lesions under a heavy coating of cosmetics. Fortunately, most cosmetic companies today are aware of the problem of comedogenicity and many cosmetics are now marketed as "noncomedogenic." A variant of acne cosmetica, consisting of deep-seated nodules and closed comedones that heal very slowly with hyperpigmentation, may occur after facial beauty treatments.<sup>113</sup>

### ACNE EXCORIÉE

Acne excoriée is a form of acne most commonly seen in adolescent girls. It is a self-inflicted skin condition in which the patient feels compelled to pick real or imagined acneiform lesions, which then propagates the disorder.<sup>114</sup> Associated comorbidities may include obsessive-compulsive disorder, anxiety, body dysmorphic disorder, substance use disorders, eating disorders, trichotillomania, kleptomania, compulsive buying, and borderline personality disorder.<sup>115</sup> Patients usually spontaneously admit the self-inflicted nature of the condition, unlike most artifactual dermatoses<sup>114,116</sup> (see Chapter 26). Acne excoriée is often precipitated by emotional stress. Excoriation or squeezing of acne lesions may vary from mild to moderate irritation (Fig. 8-19) to severe scarring and occasional gross mutilation. Therapeutic options include behavioral modification or pharmacologic therapies, including selective serotonin reuptake inhibitors, doxepin, clomipramine, pimozide, and olanzapine.<sup>115,117</sup>

**Figure 8-19** Acne excoriée. Note the numerous excoriated and crusted papules of the forehead.

### PYODERMA FACIALE

Pyoderma faciale is a relatively rare condition that presents with the sudden onset of coalescent fluctuant cysts, nodules, and papulonodules with draining sinuses. It is usually confined to the face and occurs exclusively in postadolescent females. Pyoderma faciale seems to represent a severe form of rosacea, and isotretinoin is the most effective therapy, especially when used in combination with corticosteroids.<sup>118,119</sup> Most patients develop scarring as a sequela.<sup>120</sup> Although it is usually sporadic, a patient with concomitant erythema nodosum has been reported.<sup>121</sup>

### ACNE CONGLOBATA

Acne conglobata is a severe suppurative form of acne vulgaris that is usually chronic and seen in men (especially African-Americans) between 18 and 30 years of age. It is characterized by cysts, abscesses, and sinus tracts and often heals with cosmetically disfiguring keloidal scars. Axial and/or peripheral arthritis may be associated, and the latter tends to involve large joints in an oligoarticular pattern.<sup>122</sup> Treatment is challenging, and may include nonsteroidal anti-inflammatory drugs (NSAIDs), prednisone, methotrexate, penicillamine, and isotretinoin.

Synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO) syndrome is an association of musculoskeletal disorders (synovitis, arthritis, hyperostosis, osteitis) with skin conditions, including palmoplantar pustulosis and acne conglobata.<sup>123,124</sup> Sacroiliitis may also occur, with or without hidradenitis suppurativa (HS) (see below) or a peripheral arthropathy.<sup>125,126</sup> Skin involvement is very common in SAPHO syndrome and may occur before or after the onset of bone and joint symptoms. Palmoplantar pustulosis appears to be the most common associated skin finding,<sup>127</sup> but the diagnosis is based on the typical oligoarticular findings (including erosions and joint space narrowing) in the absence of infectious or other etiologies, and skin findings are not required.<sup>127</sup> Acne occurs in around 25% of patients. The most common skeletal site of involvement in adults is the anterior chest wall. Treatment options for SAPHO syndrome may include NSAIDs, steroids, joint injections, antibiotics, methotrexate, colchicine, bisphosphonates, infliximab, and surgical interventions.<sup>122,128</sup>

### ACNE WITH FACIAL EDEMA

Acne may at times be associated with an inflammatory edema of the middle face (cheeks, forehead, periorbital areas, base of the nose, and glabella). Although its pathogenesis is unknown, it is believed to be a manifestation of chronic cutaneous inflammation and edema, analogous to that occurring in the legs of patients with recurrent cellulitis and venous insufficiency. This complication, which tends to be unresponsive to oral antibiotics or topical therapy, may respond to oral corticosteroids and isotretinoin.<sup>129</sup>

**Figure 8-20** Periorificial dermatitis. Numerous erythematous papules in a perioral distribution.

**Figure 8-21** Periorificial dermatitis. Erythematous papules and papulopustules and hyperpigmented macules of the inferior eyelid and periorbital region.

## PERIORIFICAL DERMATITIS

Periorificial dermatitis (known traditionally as *perioral dermatitis*) is a fairly common acneiform condition in children as well as young women, in whom it was originally described. Patients exhibit erythematous discrete papules and papulopustules distributed in the perioral (Fig. 8-20), nasolabial, and periocular (Fig. 8-21) locations. Occasionally, flesh-colored papules or nodules may be present.<sup>130</sup> As the papules resolve, they may be replaced by a diffuse redness or erythematous scale.

Some consider periorificial dermatitis to be a juvenile form of acne rosacea and in particular the subtype of ocular rosacea, in part related to the overlapping histologic features in these conditions. The etiology of periorificial dermatitis is unknown, but in many patients, use of mid- to high-potency topical corticosteroids seems to be related to the pathogenesis.<sup>131,132</sup> In one retrospective study of 79 children with the disorder, 72% had a history of previous topical, inhaled, or systemic steroid exposure.<sup>133</sup> However, periorificial dermatitis also occurs in children who have no preceding history of corticosteroid therapy. Blepharitis, conjunctivitis, chalazion and hordeolum (stye) (Fig. 8-22) may occur in children with periorificial dermatitis and account for the significant clinical overlap with ocular rosacea.<sup>134</sup>

Granulomatous periorificial dermatitis is a less common variant of periorificial dermatitis and is characterized by discrete yellow-brown papules (Fig. 8-23), less prominent erythema, and a granulomatous

**Figure 8-22** Hordeolum (stye) in a patient with periorificial dermatitis. This toddler male had a history of recurrent perioral and periorbital papules and pustules, as well as recurrent styes.

**Figure 8-23** Granulomatous periorificial dermatitis. Note the translucent quality of the erythematous papules and the nasolabial fold involvement.

infiltrate on histologic examination. In addition to facial involvement, patients with this disorder may have extrafacial lesions clinically and histologically identical to the facial ones.<sup>135</sup> Ocular features such as those as previously listed may also be present. Most reported cases of granulomatous periorificial dermatitis have been in prepubertal children, especially in those with a preceding history of topical corticosteroid application to the affected areas. Some patients have been initially misdiagnosed as having sarcoidosis, based primarily on histopathological findings. Nonetheless, sarcoidosis and Blau syndrome (see Chapter 25), an entity that may be difficult to distinguish from sarcoidosis, may be in the differential diagnosis in patients with more extensive periorificial dermatitis (and with more generalized involvement).

Periorificial dermatitis is generally self-limited, although resolution may take months to years, and the lesions may occasionally heal with scarring. Treatment options include topical antibiotics (the most effective being metronidazole, erythromycin, or sulfur-based products) and in more severe cases, oral erythromycin or tetracyclines (in patients >8 years of age). In patients treated with oral antibiotics, treatment should be continued for a minimum of 6 to 8 weeks, with gradual tapering, in an effort to avoid the rapid rebounding that is commonly seen with shorter courses of therapy. If erythromycin is used (i.e., in younger children), enteric-coated preparations are recommended and generally well tolerated.

### IDIOPATHIC FACIAL ASEPTIC GRANULOMA

Idiopathic facial aseptic granuloma (IFAG) was initially described in the French literature as *pyodermitre froide du visage* and believed to be a pyoderma.<sup>136</sup> More recently it has been viewed as a possible manifestation of granulomatous rosacea in childhood.<sup>136–138</sup> The possible link of IFAG to rosacea is based on its association with relapsing chalazions, facial telangiectasias, erythema and flushing, conjunctivitis and conjunctival hyperemia, as well as its response to therapies traditionally used in rosacea.<sup>138–140</sup> IFAG presents as a large inflammatory nodule, often solitary, on the face (usually the cheek) of a child. Histologic evaluation reveals follicular and perifollicular inflammation with granulomas, a similar picture to that of granulomatous rosacea. Lesions of IFAG resolve spontaneously in some patients, but others may require treatment. Reported therapies for the condition have included oral antibiotics (erythromycin or tetracycline-class antibiotics), oral metronidazole, and topical azelaic acid or metronidazole. Fortunately, most lesions resolve without scarring.

### FORDYCE SPOTS

Fordyce spots are a relatively common benign condition characterized by minute yellow to yellow-white macules and globoid papules distributed on the vermillion region of the lips and the buccal mucosa. Other less common locations include the glans penis or labia minora. Fordyce spots are composed of “free” (i.e., not associated with hair follicles) sebaceous glands, and they probably represent a normal anatomic variant. They may present or become more prominent during puberty. Fordyce spots are asymptomatic, and treatment is unnecessary.

## Disorders of the Apocrine Glands

Apocrine sweat glands are found in only a few areas: the axillae, anogenital region, and areolae of the breasts. They are poorly developed in childhood but begin to enlarge with the approach of puberty, triggered by androgen production. Apocrine secretion is sterile and odorless when it initially appears on the cutaneous surface. Associated odor develops as a result of bacterial decomposition of the secreted substances.

### FOX–FORDYCE DISEASE

Fox–Fordyce disease (also known as *apocrine miliaria*) is a chronic papular eruption of apocrine gland-bearing areas, principally the axillae, the breast areolae, and the pubic and perineal regions. It is seen primarily in young women and is a disorder of unknown etiology. It appears to be related to apocrine sweat retention associated with obstruction and rupture of the intraepidermal portions of the affected apocrine glands. Fox–Fordyce disease is usually seen in postpubescent females and is quite rare in prepubertal children owing to quiescence of the apocrine glands.

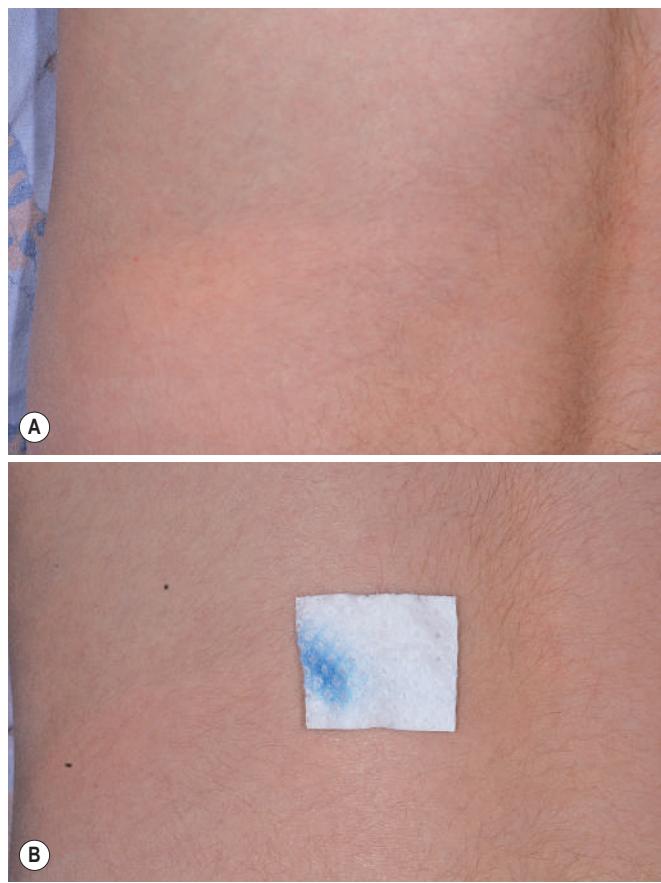

This disorder presents with dome-shaped, flesh-colored to erythematous follicular papules (Fig. 8-24) in the affected areas. Pruritus may be severe, is often paroxysmal, and is aggravated by emotional stress. Treatment is notoriously difficult and may include topical or intralesional corticosteroids, topical antibiotics, or topical retinoids. Topical pimecrolimus was helpful in one reported patient.<sup>141</sup> Surgical excision of the affected areas is occasionally necessary in severely afflicted patients.

### CHROMHIDROSIS

Chromhidrosis is a rare disorder in which the sweat appears colored. It typically involves the apocrine glands (apocrine chromhidrosis), although eccrine chromhidrosis may also occur, albeit less often. The etiology of chromhidrosis is unclear, although it may be associated with drug ingestion in some patients. The reported colors include yellow, blue (Fig. 8-25), green, red, and black. *Pseudochromhidrosis* refers to chromhidrosis occurring as the result of an extrinsic factor, such as skin surface chemicals found in dyes (e.g., from clothing) and other colored chemicals or from chromogenic organisms, including

**Figure 8-24** Fox–Fordyce disease (apocrine miliaria). Small, round, follicular papules in the axilla of an adolescent girl.

**Figure 8-25** Chromhidrosis. This 9-year-old boy had diffuse cutaneous pigmentation that improved after showering but rapidly reaccumulated. Note the blue hue to the skin, highlighted by the normal-colored stripe seen after rubbing (**A**) and the accumulation of blue pigment on the alcohol pad used to rub (**B**). Surface cultures for bacteria and fungi were negative, but some improvement was noted after antifungal therapy.

**Figure 8-26** Hidradenitis suppurativa. Erythematous papules, cysts, nodules, and sinus tracts are seen in the axilla of this adolescent male.

*Corynebacteriae* (which may result in red pseudochromhidrosis), *Bacillus* spp., and *M. furfur* (the latter two associated with blue pseudochromhidrosis).<sup>142,143</sup> Treatment for chromhidrosis is difficult and may include topical antiperspirants, capsaicin, and botulinum toxin type A.<sup>144–148</sup>

### HIDRADENITIS SUPPURATIVA

Hidradenitis suppurativa (HS) is a chronic suppurative and scarring disease that primarily involves apocrine gland-bearing skin in the axillary, inguinal, and anogenital regions. The breasts and scalp are less commonly involved. HS affects African-Americans and females more often than Caucasians or males, usually develops after puberty, and has traditionally been ascribed to plugging of the apocrine duct and associated bacterial infection. Prepubertal individuals may occasionally be affected.<sup>149</sup> Studies have more recently suggested that the primary event may be a folliculitis with secondary involvement of the apocrine glands.<sup>150,151</sup> Some authors have thus suggested the alternative name, *acne inversa*. The etiology of HS is poorly understood. Genetic factors, hormonal influences, obesity, smoking, and tight-fitting clothing have each been hypothesized to play a role.<sup>151,152</sup> Dysregulation of the immune response may be implicated and is supported by the beneficial effect of biologic agents in some patients, studies demonstrating upregulation of some immune components such as *TLR2*, and the observed potential association with other inflammatory conditions such as Crohn disease.<sup>153</sup> Familial HS has been shown to segregate in an autosomal dominant manner and may be associated with mutations in the  $\gamma$ -secretase genes, which include *NCSTN*, *PSENEN*, and *PSEN1*.<sup>154–157</sup> These observations offer insight that may facilitate the development of new therapies.

The earliest clinical finding in HS is a painful, inflammatory abscess-like swelling, usually 0.5 to 1.5 cm in diameter, in the affected apocrine area(s). Within hours to days, the abscess enlarges and may open onto the overlying skin, resulting in purulent drainage. With further development and enlargement of abscesses, sinus tracts form (Fig. 8-26) and eventual scarring ensues with the development of deep fibrosis. Hypertrophic scarring may be seen, as may open comedones (Fig. 8-27). HS may be extremely debilitating in severely afflicted patients, with chronic pain, drainage, and secondary infection. Bacteriologic study of early lesions often reveals coagulase-positive staphylococci or streptococci, probably representing secondary infection. Occasionally *Escherichia coli*, *Pseudomonas aeruginosa*, or other Gram-negative organisms contaminate lesions. HS has a significant impact on quality of life and has been shown to result in more impairment than found with several other dermatologic conditions including chronic urticaria, psoriasis, and atopic dermatitis.<sup>158</sup>

Therapy for HS may be challenging. Management must be individualized based on the severity of disease and symptomatology. Initial

**Figure 8-27** Hidradenitis suppurativa. Sinus tracts with chronic scarring and cyst-like papules in the inguinal region of a young boy with chronic disease. Note the associated open comedones.

measures include antibiotics (especially tetracyclines) and local wound care. Topical clindamycin, intralesional steroid injections, oral cyclosporine, and combination oral clindamycin-rifampin therapy have been reported as useful.<sup>153,159,160</sup> Incision and drainage may be useful in certain instances, but for more severe cases surgical modalities are generally necessary. These include local excision, unroofing of lesions with marsupialization, and wide excision with primary or secondary closure, skin grafting, or flaps.<sup>161,162</sup> Carbon dioxide or neodymium:yttrium-aluminum-garnet (Nd:YAG) laser therapy are other options that seem to be quite effective.<sup>160,163</sup> Low efficacy or a high risk-to-benefit ratio have been suggested as possible limitations for isotretinoin and the tumor necrosis factor (TNF)- $\alpha$  inhibitors etanercept and infliximab in this setting,<sup>164–166</sup> although these agents, as well as adalimumab, have been demonstrated helpful in some studies.<sup>160,167–169</sup>

Several disorders have been described in which HS is present in conjunction with other inflammatory processes. These presentations seem to fall under the umbrella of auto-inflammatory disorders (see Chapter 25). The association of pyoderma gangrenosum, acne and HS (PASH) was described as a syndrome sharing some clinical overlap with pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome (see Chapter 25) but lacking the joint inflammation and with the added feature of suppurative hidradenitis in skin folds.<sup>170</sup> Whereas PAPA syndrome is related to mutations in the *PSTPIP1* gene, no mutations (aside from some microsatellite repeats of unclear significance in the promoter region) were found in this original cohort with PASH syndrome, nor were there mutations found in other genes linked to several other auto-inflammatory disorders. The association of pyogenic arthritis with pyoderma gangrenosum, acne, and hidradenitis suppurativa (PAPASH) has significant clinical overlap with PASH, and in the originally reported patient a missense mutation in the *PSTPIP1* gene was noted and felt to be related to the clinical presentation.<sup>171</sup> A patient has also been reported with the findings of pyoderma gangrenosum, acne, suppurative hidradenitis, and axial spondylarthritis, for which the author proposed the term PASS.<sup>172</sup> The clinical overlap in these described associations highlights the need for continued study of the clinical presentations and molecular bases.

## Disorders of the Eccrine Glands

The eccrine sweat glands are distributed over the entire skin surface and are found in greatest abundance on the palms and soles and in the axillae. They represent the principal means of maintaining homeostatic balance by evaporation of water. Their secretion depends on their sympathetic nerve supply, which is controlled by various stimuli, including thermal and emotional types. By these mechanisms the quantity and quality of sweat may be varied. Disorders associated with decreased eccrine sweating (i.e., ectodermal dysplasia) are discussed in Chapter 7.

### HYPERHIDROSIS

Hyperhidrosis (idiopathic hyperhidrosis or primary pediatric hyperhidrosis) is a disorder characterized by the excessive production of sweat in response to heat or emotional stimuli and not related to an underlying disease or drug toxicity. It is a poorly understood disorder, and the clinical spectrum ranges from a mild increase over the normal level of physiologic sweating to an extreme, debilitating expression of the disease. Such extreme sweating may be socially embarrassing and occupationally disabling and may negatively affect the patient's psychological well-being.<sup>173,174</sup> Hyperhidrosis may be palmoplantar and/or axillary and in rare instances, generalized. In patients with these forms of idiopathic hyperhidrosis, neurovascular or metabolic abnormalities are absent. Idiopathic localized unilateral hyperhidrosis is a rare form of hyperhidrosis localized to a sharply demarcated area on the face or upper extremities of an otherwise healthy individual.<sup>175,176</sup> Auriculotemporal nerve (Frey) syndrome is the constellation of facial flushing and hyperhidrosis in response to gustatory stimuli and is discussed in Chapter 12.

There are a variety of treatment options for idiopathic hyperhidrosis (Table 8-6). The first-line therapies are topical, and consist of both OTC and prescription-strength antiperspirant preparations. The active

ingredient in many of these is either aluminum chloride or formaldehyde. These products are best applied to dry skin at bedtime, and their effect may be potentiated when they are used along with plastic wrap occlusion overnight (when practical). However, for some patients occlusion results in more irritation. Systemic anticholinergic agents such as glycopyrrolate or propantheline bromide are often useful but may occasionally be limited by their side-effect profiles, which include dry eyes, dry mouth, and bowel and bladder dysfunction. Oral glycopyrrolate appears to be very effective and well tolerated in children with hyperhidrosis. It is usually started at a dose of 1 mg taken once to twice daily and may be titrated to a maximal dose of 6 mg daily (usually divided into twice or three times daily dosing). In a series of 31 pediatric patients (between 9 and 18 years of age) treated with oral glycopyrrolate, 90% reported improvement, and nearly three-quarters reported no side effects, with dry mouth and dry eyes reported by 26% and 10% of patients.<sup>177</sup> The  $\alpha$ -adrenergic receptor agonist clonidine has also been used for hyperhidrosis, and in one series of 13 patients receiving this therapy, the response rate was 46%.<sup>178</sup> Sedative agents such as diazepam may be useful before an anxiety-provoking event, but their continual use is not recommended.

Iontophoresis is a successful therapy for some patients. This therapy utilizes a small device that delivers a direct current utilizing tap water (with or without anticholinergic agents) as the conductive medium. Its proposed mechanism of action is the development of keratotic plugs in the eccrine sweat ducts, and its effect may last up to 6 weeks between treatments. This treatment appears to be quite safe, with side effects limited to dryness and fissuring of treated sites. Iontophoresis units (Drionic, General Medical Co., Los Angeles, CA) are available without a prescription via mail or internet ([www.drionic.com](http://www.drionic.com)).

Botulinum toxin type A, injected either intradermally or "intracutaneously" (more superficial injections), has been demonstrated to be quite effective in the treatment of axillary or palmoplantar hyperhidrosis.<sup>176,179,180</sup> Studies have revealed improved quality of life and an excellent safety profile of this modality.<sup>180-182</sup> Botulinum toxin type B has also been efficacious for this condition but may be more limited by injection site pain and autonomic side effects. In patients with severe and recalcitrant idiopathic hyperhidrosis, surgical therapy may be indicated. Thoracoscopic sympathectomy (or endoscopic thoracic sympathectomy) is the traditionally utilized procedure, although postoperative compensatory and gustatory sweating may be a problem.<sup>183-186</sup> Up to 20% of patients may have such severe disabling compensatory sweating that they regret having had the procedure.<sup>187</sup>

### DYSHIDROSIS

*Dyshidrosis* (dyshidrotic eczema or pompholyx) is the term applied to a condition of recurring vesiculation of the palms, soles, and lateral aspects of the fingers in which hyperhidrosis is often associated. It is not a primary disorder of eccrine glands but rather a type of eczematous eruption. It is discussed in more detail in Chapter 3.

### ANHYDROSIS

Anhidrosis is the abnormal absence of (or in the case of hypohidrosis, decrease in) perspiration from the surface of the skin in the presence of appropriate stimuli, which may result in hyperthermia. This condition may be caused by a deficiency or abnormality of the sweat glands (as in hypohidrotic ectodermal dysplasia; see Chapter 7) or of the nervous pathways from the peripheral or central nervous system leading to the sweat glands (as in syringomyelia, leprosy, anticholinergic drug therapy, or sympathectomy). Cool baths, air conditioning, light clothing, and reduction of the causes of normal perspiration help to relieve symptoms.

In congenital insensitivity to pain with anhidrosis (CIPA), also known as *hereditary sensory and autonomic neuropathy type IV*, patients have recurrent episodes of fever, anhidrosis, absence of reaction to noxious stimuli, self-mutilating behavior, and mental retardation. These patients commonly show evidence of oral self-mutilation, including biting injuries and scarring of soft tissues of the mouth and oral mucosa.<sup>188</sup> They are prone to infections of the skin and skeleton, most often caused by *S. aureus*.<sup>189</sup> This autosomal recessive condition

**Table 8-6 Therapeutic Options for Primary Hyperhidrosis**

Treatment	Comment
Topical antiperspirants	Aluminum chloride, formaldehyde, others Both OTC and prescription strengths Usually applied at bedtime
Oral anticholinergic agents	Glycopyrrolate, propantheline bromide, oxybutynin May be limited by side effects (dry eyes, dry mouth, bowel/bladder dysfunction) Clinical experience greatest with glycopyrrolate
Other systemic agents	Clonidine, calcium channel blockers, benzodiazepines
Iontophoresis	Safe and well tolerated Tap water utilized, with or without anticholinergic agents Efficacy variable
Botulinum toxin types A or B	Injected intradermally or intracutaneously Effective, but painful Often requires repeat injections at 3–6 month intervals
Thoracic sympathectomy	Reserved for patients with severe or recalcitrant disease Postoperative compensatory sweating may occur Video-assisted surgery: quicker and fewer complications

Modified from Stolman LP. Treatment of hyperhidrosis. Dermatol Clin 1998;16(4):863-9; and Gelbard CM, Epstein H, Hebert A. Primary pediatric hyperhidrosis: a review of current treatment options. Pediatr Dermatol 2008;25(6):591-8. © 2008 by John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.  
OTC, Over the counter.

has been ascribed to mutations in the *NTRK1* (*TRKA*) gene as well as the *SCN9A* gene. Defects in the *NTRK1* gene, which encodes the receptor tyrosine kinase for nerve growth factor, impair intracellular signal transduction in response to nerve growth factor.<sup>190</sup> The *SCN9A* gene is one of the nine genes encoding voltage-gated sodium channels, which play a crucial role in converting mechanical or chemical stimuli into electrical signals within excited cells. Nav1.7 is the sodium channel encoded by the *SCN9A* gene, and mutations have also been linked to primary erythromelalgia (PE) (see Chapter 12) and paroxysmal extreme pain disorder (PEPD).<sup>191</sup>

## BROMHIDROSIS

Bromhidrosis is an embarrassing malodorous condition in which an excessive and usually offensive odor emanates from the skin. It may be of two types: (1) apocrine, resulting from bacterial degradation of apocrine sweat; or (2) eccrine, from the microbiologic degradation of stratum corneum softened by excessive eccrine sweat.

The term *apocrine bromhidrosis* refers to an exaggeration of the axillary odor normally noted by all postpubertal individuals. *Eccrine bromhidrosis* refers to the excessive odor produced by bacterial action on the stratum corneum when it becomes macerated by eccrine sweat. This disorder occurs primarily on the plantar surfaces of the feet and intertriginous areas, particularly the inguinal region. Eccrine bromhidrosis may also occur in association with metabolic disorders including phenylketonuria, maple syrup urine disease, and isovaleric academia.

Bromhidrosis is best managed by regular thorough cleansing (preferably with an antibacterial soap), the use of commercial deodorants and antiperspirants, the application of topical antibiotics as necessary, and frequent changes of clothing. Plantar bromhidrosis may be associated with pitted keratolysis (see Chapter 14).

## MILIARIA

Miliaria (see Chapter 2) is a common dermatosis caused by sweat retention and is characterized by a papulovesicular eruption secondary to prolonged sweating with obstruction of the eccrine ducts. The pathophysiologic events that lead to this disorder are keratinous plugging of eccrine ducts followed by disruption of the normal escape of eccrine sweat into the skin. The clinical findings vary depending on the depth of obstruction of the eccrine duct within the skin. The three forms of miliaria are miliaria crystallina (sudamina), miliaria rubra (prickly heat), and miliaria profunda. The incidence of miliaria is greatest in the first few weeks of life, owing to a relative immaturity of the eccrine ducts that favors poral closure and sweat retention. In addition, older infants and children may develop miliaria in any situation predisposing them to increased sweating and/or skin obstruction (i.e., warm summer climates, swaddling with several layers of clothing during winter months, febrile illnesses).

Miliaria crystallina is characterized by clear, thin-walled, noninflammatory vesicles, 1 to 2 mm in diameter, occurring in crops on otherwise normal-appearing skin. The vesicles are asymptomatic and occur most often in intertriginous areas, particularly on the neck and axillae, or on parts of the trunk covered by clothing. Lesions of miliaria crystallina are highly characteristic and easily differentiated from other vesicular diseases. When the diagnosis is in doubt, rupture of vesicles with a fine needle results in release of the clear, entrapped

sweat. The obstruction in miliaria crystallina is quite superficial, either within or just beneath the stratum corneum.

Miliaria rubra (prickly heat) is the most common form of miliaria. These lesions have a predilection for occluded areas of skin, especially the upper trunk, back, volar aspects of the arms, and body folds. The face may also be involved. Clinically there are discrete but closely aggregated, small erythematous papules or papulovesicles (see Chapter 2, Fig. 2-8). The lesions of miliaria rubra are always nonfollicular, which helps to differentiate this disorder from folliculitis. Viral exanthems and drug reactions may sometimes be in the clinical differential diagnosis, but the distribution of lesions combined with the history and physical examination usually allow for distinction. Miliaria pustulosa is a variant of miliaria rubra consisting of distinct superficial pustules that are also not associated with hair follicles. Lesions tend to occur in areas of skin that have had previous inflammation and often appear coexistent with lesions of miliaria rubra.

Miliaria profunda is a more pronounced form of miliaria quite uncommon outside of the tropics. This disorder usually follows repeated episodes of miliaria rubra and is characterized by firm, white, 1- to 3-mm papules. This papular presentation is related to the deep level of obstruction. Lesions are most prominent on the trunk and proximal extremities, and this form of miliaria is extremely rare in infants and children.

The key to the management of miliaria is prevention by avoidance of excessive heat and humidity. In infants, all that is generally required is parental reassurance and advice on proper clothing and temperature regulation. The lesions of miliaria are self-limited, but simple strategies such as cool baths, light clothing, and use of air conditioning can make the patient more comfortable while awaiting resolution. Topical preparations are of little value and in fact may further propagate the condition by compounding eccrine duct obstruction.

Because of the increasing public awareness and incidence of skin cancer, physicians are often consulted regarding tumors of the skin. In children, the vast majority of cutaneous tumors are benign, and their importance lies predominantly in the cosmetic defect they may create or in their occasional association with systemic disease. Malignant skin lesions, however, despite their relative rarity in children, cannot be completely disregarded or ignored. Each lesion in children, as in adults, must be assessed individually with a consideration of its cosmetic effect, its possible association with systemic manifestations, and its capacity for malignant degeneration.

Cutaneous tumors can be differentiated into those arising from epidermal (or mucosal) cells, from melanocytes, from the epidermal appendages, or from dermal or subcutaneous cells or tissues. The latter category includes tumors of fibrous, neural, vascular, fatty, muscular, and osseous tissues. Skin tumors can also be divided into benign (the vast majority of lesions in children) and malignant. The term *nevus* (plural *nevi*) has a broad meaning in dermatology. Strictly defined, this term refers to a circumscribed congenital abnormality of the skin. When this term is used, therefore, it is appropriate to include a qualifying adjective (i.e., epidermal nevus, melanocytic nevus, or vascular nevus), thus specifying the cell of origin. In commonplace practice, however, the term *nevus* is usually used to imply a benign tumor of pigment cells (melanocytes). Hence to many practitioners, a nevus is the same as a "mole."

In this chapter, we will discuss several cutaneous tumors (and corresponding tumor syndromes where applicable). Pigmented lesions are discussed as a separate entity apart from the above classification, given their high incidence.

## Pigmented Lesions

Pigmented lesions, especially melanocytic nevi (moles), are the most common neoplasms found in humans. In this section, we will discuss melanocytic nevi (both congenital and acquired) and several variants, including dysplastic, Spitz, and halo types. Nevus spilus and Becker nevus, two distinct pigmented lesions, will also be discussed, as will malignant melanoma (MM), which although rare in childhood, does occasionally occur.

### MELANOCYTIC NEVI

Melanocytic nevi are extremely common skin neoplasms composed of "nevocytes" or nevus cells that are believed to be slightly altered melanocytes. The melanocyte is a dendritic cell that produces melanin and transfers it to keratinocytes (epidermal cells) and hair cells, thus supplying the normal brown pigment to skin and hair. Both melanocytes and nevus cells are of neural origin. Melanocytes originate in the neural crest and early in fetal life migrate from there to the skin. After birth some melanocytes occasionally remain in the dermis of certain races (Asians, Native Americans, African-Americans, and individuals from the Mediterranean region), where they may appear as Mongolian spots (see Chapter 11). Blue nevi and the nevi of Ota and Ito (see Chapter 11) also represent examples of arrested melanocytic migration in which the melanoblasts remain in the dermis.

Melanocytic nevi can be either congenital (described in more detail below) or acquired. Acquired nevi usually appear after infancy, increase in size and number during early childhood, and peak during the third or fourth decade, with slow involution as aging progresses. The predisposition of an individual to the development of acquired

melanocytic nevi seems to be related to several factors, including skin type, race, genetic predisposition, and ultraviolet light exposure. These lesions tend to be few in childhood, increasing in number with age to a peak in the third decade. Sun exposure, sunburns, and fair skin pigmentation seem to be associated with their development in childhood.<sup>1</sup> In one large cross-sectional study, nevus counts were found to steadily increase with age from a median of three at age 2 years to 19 at age 7 years.<sup>1</sup> High numbers of nevi were associated with moderate sun exposure and outdoor activities. In another study, 5- and 6-year-old children with a history of sunburns or an increased number of holidays in foreign countries with a sunny climate had significantly higher nevus counts than controls without these characteristics.<sup>2</sup> Higher numbers of childhood nevi have been demonstrated in areas of skin chronically exposed to the sun and in children with lighter skin, blond hair, and blue eyes.<sup>3</sup> Higher nevus counts are noted in children who reside in sunny climates (i.e., Australia) when compared with age- and race-matched control children. Melanocytic nevi may also occur in higher numbers in children with a history of leukemia and/or a history of chemotherapy, and in these settings the lesions may occur with greater incidence on acral areas such as the palms and soles.<sup>4-6</sup>

The primary importance of melanocytic nevi lies in their possible transformation into MM. These lesions are felt to be both markers of an increased risk of cutaneous melanoma and in some cases, direct precursor lesions.<sup>7</sup> The annual transformation rate of a single mole into melanoma seems extremely low, with an estimate of 0.0005% or lower for individuals younger than 40 years.<sup>7</sup> Nonetheless, melanocytic nevus cells were seen histologically in proximity to MM in 51% of cases in one study.<sup>8</sup> Genetic analyses of nevi and melanoma reveal nonrandom patterns of genetic alteration (loss of heterozygosity), confirming the notion that the former are precursor lesions for the latter.<sup>9</sup> These findings highlight the relevance of close monitoring of melanocytic nevi for atypical features as well as the importance of sun protection education.

Melanocytic nevi are subdivided into types and clinically described based on the microscopic location of the nevus cells. Accordingly they are classified as junctional, intradermal, or compound lesions. Junctional nevi have proliferation of nevocytes at the dermal–epidermal junction, compound nevi reveal cells at the junction and in the dermis, and intradermal nevi reveal loss of the epidermal component with nests of cells limited to the dermis. Interestingly, these histologic subtypes progress in parallel to the natural history of nevus maturation (junctional nevi early in life, then compound nevi, and finally intradermal nevi with eventual atrophy of the dermal component during later adulthood).<sup>10</sup> Melanocytic nevi have a wide range of clinical appearances. They may occur anywhere on the cutaneous or mucocutaneous surface and may be flat, slightly elevated, dome-shaped, nodular, verrucous, polypoid, cerebriform, or papillomatous.

#### Junctional Nevi

Junctional nevi usually occur as hairless, light to dark brown or black macules (Fig. 9-1). They range from 1 mm to 1 cm in diameter, with a smooth and flat (nonpalpable) surface and preservation of skin furrows. Although most junctional nevi are round, elliptical, or oval and show a relatively uniform pigmentation, some may be slightly irregular in configuration and color. Most junctional nevi represent a transient phase in the development of compound nevi and are found only in children. An exception to this rule, however, is seen on the palms, soles, and genitalia where the lesions often retain their junctional appearance.

**Figure 9-1** Junctional melanocytic nevus. A well-demarcated, tan macule.

**Figure 9-3** Compound melanocytic nevus. Note the coarse, terminal hairs within the nevus.

**Figure 9-2** Compound melanocytic nevus. A well-demarcated, tan papule with some darker speckling centrally.

**Figure 9-4** Intradermal melanocytic nevus. A tan, fleshy papule with adjacent intradermal nevus.

### Compound Nevi

Compound nevi are more common in older children and adults but may also be present in younger children. They may appear similar to junctional nevi but tend to be more elevated and accordingly vary from a slightly raised papule to a larger, papillomatous papule or plaque. They are flesh-colored to brown (Fig. 9-2), may have a smooth or verrucous surface, and may have dark coarse hairs within them (Fig. 9-3), especially when occurring on the face. During later childhood and adolescence, compound nevi tend to increase in thickness and depth of pigmentation. It is at this stage that many children are brought to the physician for evaluation.

### Intradermal Nevi

Intradermal nevi are seen most commonly in adults. They are usually dome-shaped, soft, "fleshy" papules (Fig. 9-4). They may be sessile (attached by a broad base) or more pedunculated (attached by a more narrow base) and range from a few millimeters to 1 cm or more in diameter. Intradermal nevi may be clinically indistinguishable from compound nevi, and their color varies from nonpigmented (flesh-colored) lesions to those of varying shades of brown. They may occur anywhere on the skin surface and are often found on the head and neck; coarse hairs often are present. After the third decade of life, as nevus maturation continues, there is destruction and replacement of nevus cells by fibrous or fatty tissue, and by 70 years of age most individuals have few remaining nevi. In fact, nevi that persist into old age appear to have an increased risk of malignant degeneration.<sup>7</sup>

Treatment decisions regarding melanocytic nevi are usually related to their cosmetic appearance, repeated irritation of the lesion, or fear

of potential malignant transformation. The majority of melanocytic lesions require no treatment; by careful clinical evaluation the patient can often be reassured as to their benign nature. Removal of nevi, when indicated, is best achieved by punch biopsy or complete surgical excision. Any nevus being removed because of concern for malignant degeneration should be removed with a full-depth excision, because microscopic tumor depth is the primary prognostic indicator in MM. Every excised nevus should be subjected to histopathologic examination.

Many authors advocate for the routine excision of pigmented lesions in certain anatomic locations (i.e., palms, soles, scalp, and genitalia), owing to the belief that the likelihood of malignant transformation is greater in these areas. It seems that prophylactic excision of all nevi in these locations is unwarranted. However, lesions in acral sites may reveal atypical clinical and histologic features,<sup>11,12</sup> possibly in relation to repetitive trauma. Recognition of these histologic variations is vital in order to avoid the misdiagnosis of the "acral lentiginous" subtype of MM, which occurs primarily after the seventh decade of life. Additionally, scalp nevi in children (and particularly adolescents) may commonly reveal mild clinical atypia, both clinically and histologically, although the vast majority behave in a biologically benign fashion (see more below).<sup>13</sup> Scalp nevi that reveal significant atypia and/or that may be difficult to monitor clinically, however, may merit excision.

Occasionally, pigmented nevi show recurrence after excision, which may be a significant source of anxiety for the patient, parent, and at times the physician. Recurrent lesions (which have been called *pseudomelanoma* by some) present as circumscribed pigmentation within

**Figure 9-5** Recurrent melanocytic nevus (within a surgical scar). The initial nevus had been incompletely excised.

the surgical scar (Fig. 9-5). This finding is usually not an indication of malignancy but instead represents proliferation of nevus cells from the peripheral epidermis, sweat ducts, or hair follicles. Options for management include close clinical follow-up care (assuming the original pathologic examination revealed no atypical findings) or repeat excision.

#### Meyerson Nevus

The term *Meyerson nevus* (also known as *Meyerson phenomenon* or *halo dermatitis*) refers to a localized eczematous eruption that occurs in the region of a melanocytic nevus and was originally described by Meyerson in 1971.<sup>14</sup> The inflammatory reaction does not appear to be a marker for atypia within the nevus, although there are reports of the phenomenon in association with dysplastic lesions.<sup>15</sup> The Meyerson phenomenon may be associated with acquired or congenital melanocytic nevi (CMN).<sup>16</sup> It has also been described in association with non-melanocytic lesions including nevus sebaceous, dermatofibroma, and smooth muscle hamartoma.<sup>17–19</sup> The Meyerson nevus presents clinically as a scaly erythematous plaque overlying a pigmented nevus. The overlying dermatitis may be treated with a topical corticosteroid, which often leads to complete resolution, enabling closer inspection of the underlying nevus (Fig. 9-6). If left untreated, the dermatitis often resolves spontaneously over time.<sup>20</sup>

#### MELANONYCHIA STRIATA

Melanonychia striata (also known as *longitudinal melanonychia*) is most commonly seen in individuals with darker skin complexions, especially African-Americans, of whom up to 90% may have at least one such streak. It is significantly less common in children with white skin. Melanonychia striata presents as a brown to brown/black linear band of pigmentation on a fingernail (Fig. 9-7) or toenail. The pigmentation extends from the proximal nailfold to the distal margin of the digit, and the width may vary from less than 1 mm to several millimeters. Drugs, pregnancy, trauma, and human immunodeficiency virus (HIV) infection may all be associated with melanonychia striata, although the majority of patients have no underlying association.

Melanonychia striata may represent benign melanocytic hyperplasia (i.e., melanocytic nevus or lentigo) or a nail matrix melanoma. In children, the majority of cases seem to be related to benign lesions,<sup>21,22</sup>

**Figure 9-6** Meyerson nevus. (A) This 9-month-old boy sought treatment for this scaly plaque on the proximal forearm (note the faint outline of the underlying pigmented nevus). (B) At the follow-up examination, the congenital melanocytic nevus can be clearly appreciated after 2 weeks of treatment with a topical corticosteroid.

**Figure 9-7** Melanonychia striata. A 2-mm, evenly pigmented band. Note the absence of pigmentation of the proximal nailfold (negative Hutchinson sign).

**Figure 9-8** Hutchinson sign. Note pigmentation involving both the proximal nailfold and the distal nailfold regions. This patient underwent nail matrix biopsy; the lesion was a compound nevus without atypia.

**Figure 9-9** Early congenital melanocytic nevus. Note the various shades of brown and red in this 2-week-old infant boy.

although the possibility of melanoma must always be entertained. The presence of multiple bands, as occasionally seen in darker races, is reassuring and mitigates against malignancy. Worrisome features may include very dark, broad bands and extension of the pigmentation onto the proximal or lateral nailfolds (Hutchinson sign; Fig. 9-8).<sup>23</sup> Dermatoscopic evaluation may be useful for monitoring in the hands of clinicians experienced in its use, but the patterns and accuracy remain to be confirmed in this setting.<sup>24,25</sup> In patients with melanonychia striata and any such atypical or concerning features, nail matrix biopsy for histologic evaluation should be highly considered. Although this procedure may result in permanent nail plate dystrophy, this risk is justified when concerns for possible melanoma exist.

### CONGENITAL MELANOCYTIC NEVI

CMN represent a special group of melanocytic lesions with an increased risk of transformation to MM. By strict definition, these lesions are present at birth. However, in some patients with small and medium-sized lesions, they may be initially noted sometime during the first year of life rather than immediately at birth. Congenital nevi have been classified traditionally according to their greatest diameter in adulthood. According to this nomenclature, they have been traditionally defined as *small* (<1.5 cm in greatest diameter), *medium-sized* (1.5 to 19.9 cm), or *large* ( $\geq 20$  cm) congenital nevi. An interdisciplinary group of experts in the field developed a consensus-based categorization scheme for CMN that includes modified size categories (again, based on projected adult size) as follows: *small* (<1.5 cm), *medium* (M1: 1.5 to 10 cm; M2: >10 to 20 cm), *large* (L1: >20 to 30 cm; L2: >30 to 40 cm), and *giant* (G1: >40 to 60 cm; G2: >60 cm).<sup>26</sup> This classification includes other descriptors of CMN, including number of satellite nevi, anatomic localization, color heterogeneity, surface rugosity, hypertrichosis, and presence of dermal or subcutaneous nodules. Such a standardized classification scheme will hopefully facilitate collaborative international studies and database development for the study of large and giant CMN.<sup>26</sup>

It is estimated that approximately 1% of newborns have a small congenital nevus, and large lesions occur in around 1 in 20,000 newborns.<sup>27-30</sup> Giant melanocytic nevi occur in 1 in 500,000 newborns.<sup>31</sup> Nevus spilus, or speckled lentiginous nevus (see below), may represent a distinct subtype of congenital melanocytic nevus that presents early in life as a café-au-lait macule, with the development of the more characteristic nevi a bit later in life.<sup>32</sup> Whereas malignant potential may be a primary concern with CMN, the potential psychosocial consequences, especially with large or giant lesions, are significant and may include social difficulties, psychologic morbidities, behavioral and emotional impairment, and predisposition to taunting or bullying.<sup>33</sup>

**Figure 9-10** Congenital melanocytic nevus. A well-demarcated, brown plaque with some pigment variation and hypertrichosis.

Congenital nevi have some characteristic histopathologic features, including extension of nevus cells into the deeper dermis and subcutis, between the collagen bundles (as single cells), and in association with appendages, nerves, and vessels.<sup>34,35</sup> These features may be useful when histologic confirmation of a congenital lesion is desired, but such findings may not be noted in every congenital nevus. This pattern of deep extension is important to keep in mind when surgical intervention of such a lesion is being considered. Activating mutations in the NRAS gene have been noted within congenital nevi, distinct from nevi developing after birth (acquired nevi), which are more likely to reveal mutations in BRAF (see also below).<sup>36,37</sup> In a series of large and giant CMN, NRAS mutations were noted in nearly 95% of cases, whereas in small- and medium-sized CMN, 70% bore NRAS mutations and 30% revealed BRAF mutations.<sup>38</sup> In a series of patients with multiple CMN and neurocutaneous melanosis (see below), both the cutaneous and neural lesions contained missense mutations in codon 61 of NRAS, whereas unaffected tissues and blood were negative for this mutation, suggesting postzygotic mutation in a progenitor cell within the neuroectoderm.<sup>39</sup>

Small and medium-sized CMN usually present as flat, light- to dark-brown or pink macules (Fig. 9-9) or papules or as brown to dark brown, well-circumscribed patches or plaques. They may reveal some pigment variation and the surface may have hair (Fig. 9-10). With time they tend to become more elevated, and coarse dark brown hairs may become more prominent. When an extremity is circumferentially involved with a medium- or large-sized congenital nevus, limb underdevelopment may occur (Fig. 9-11).<sup>10</sup>

**Figure 9-11** Congenital nevus of the lower extremity. Note the limb hypoplasia in the ankle region associated with this circumferential lesion.

**Figure 9-13** Giant congenital melanocytic nevus. Note the marked hypertrichosis and adjacent satellite lesions.

**Figure 9-12** Large congenital melanocytic nevus.

Large CMN are uniformly present at birth and present as dark brown to black plaques, often with a verrucous or cobblestoned surface and hypertrichosis (Fig. 9-12). Color variation is common in these lesions and may make clinical examination for concerning features more challenging. Giant CMN often occur on the posterior trunk and may occupy a significant portion of the skin surface. They may have a dermatomal distribution and may involve an entire upper or lower extremity or the scalp. These lesions have been variably named *coat-sleeve*, *stocking*, *bathing trunk*, or *giant hairy nevi*, depending on their site(s) of involvement. As with large CMN, giant nevi present as large, brown to black plaques with varying degrees of nodularity, color variation, and hypertrichosis (Fig. 9-13). Erosions or ulcerations in these giant lesions may occur (Fig. 9-14), and although once believed to be consistently ominous findings, are often benign and usually not indicative of MM.<sup>40</sup> Large and giant congenital nevi may be associated with cosmetic disfigurement, an increased risk of MM, and underlying neurocutaneous melanosis (see below). These lesions often have associated "satellite" nevi that may be disseminated over the entire skin surface. Satellite nevi are usually tan to brown macules or papules, with varying degrees of hypertrichosis (Fig. 9-15). They may be present at birth or continue to develop during infancy.<sup>30</sup>

**Figure 9-14** Giant congenital melanocytic nevus with erosions. Surface erosion and crusting was present at birth and healed rapidly over a few weeks with topical care.

The congenital nature of nevi is one of several known risk factors for MM, but the exact magnitude of risk remains controversial, especially for small and medium-sized lesions. All congenital nevi should be considered as potential precursors to melanoma. The risk in small and medium-sized lesions seems low, and if melanoma occurs it tends to occur during adulthood.<sup>10,41,42</sup> Factors that might increase the level of concern include atypical clinical features (e.g., deeply or irregularly pigmented or rapidly growing), an abnormal nevus phenotype, or a strong family history of MM. The risk of malignant transformation of congenital nevi in African-American patients is extremely small.<sup>43</sup>

**Figure 9-15** Satellite melanocytic nevi. This patient had a giant nevus of the scalp.

The risk of MM in large and giant CMN appears to be significantly greater than that for small and medium-sized lesions, with melanoma often (but not always) occurring before the age of 5 years.<sup>44,45</sup> It is unclear whether axial lesions pose a greater risk than those occurring on the extremities, as traditionally suggested.<sup>46</sup> When melanoma occurs in patients with large or giant CMN, it may occur within the skin or in extracutaneous sites such as the central nervous system.<sup>47,48</sup> Development of melanoma in satellite lesions is exceedingly unlikely.<sup>47</sup> The overall lifetime risk of development of MM in patients with large CMN has been reported to range from 0% to 31% but is best estimated at between 2% and 10%.<sup>44,45,49–51</sup> In two large systematic reviews of the published data on melanoma risk in CMN, the rate of melanoma was 2% to 2.5% in large CMN and 3.1% in giant CMN.<sup>50,51</sup> In addition to melanoma, other malignancies may occur with increased rates in these patients, including rhabdomyosarcoma, liposarcoma, malignant peripheral nerve sheath tumor, and other sarcomas.<sup>28,47</sup>

Large and giant CMN, particularly those on the head, neck and back, may be associated with a condition termed *neurocutaneous melanosis* (NCM). NCM, as well as melanoma risk, appears to be more common in patients with greater numbers of satellite nevi.<sup>52,53</sup> Patients with NCM have a proliferation of nevus cells in the central nervous system (leptomeningeal melanocytosis), and are predisposed to seizures, MM of the central nervous system (CNS), and neurologic symptoms related to increased intracranial pressure or spinal cord compression. They often seek treatment for symptoms during the first 3 years of life, including lethargy, irritability, headache, recurrent vomiting, seizures, increased head circumference, bulging anterior fontanel, photophobia, papilledema, neck stiffness, and occasionally nerve palsies, particularly of cranial nerves VI and VII. Magnetic resonance imaging (MRI) of NCM reveals focal areas of high signal on T1-weighted images in one or multiple areas of the brain, including the temporal lobes, cerebellum, pons, and medulla.<sup>54,55</sup> T2 shortening may also occur.<sup>55</sup> In one study, 45% of neurologically asymptomatic children with giant congenital nevi had these radiologic findings.<sup>54</sup> However, a questionnaire-based study of 186 patients with large congenital nevi who were imaged revealed that only 4.8% of those with positive MRI findings for NCM were asymptomatic.<sup>56</sup> Hence the exact prevalence of asymptomatic NCM remains unclear. Other findings in children with NCM may include dorsal spinal arachnoid cysts and amygdalar neuromelanosis (that may be associated with intractable seizures).<sup>57–61</sup> Overall, the prognosis for *symptomatic* NCM is poor, with more than 90% of patients dying of the disease and around 70% of those dying before 10 years of age.<sup>48,62</sup>

The management of CMN must be individualized for each patient. There are many factors that must be considered in the decision-

making process regarding surgical excision of such lesions. These include location of the nevus, size, cosmetic issues (and potential psychosocial ramifications), and the risks of anesthesia, MM, and neurocutaneous melanosis.<sup>63</sup> There appears to be less consensus regarding the role of surgical excision of small and medium-sized CMN than that of large lesions. Small congenital nevi with uniform pigmentation, smooth texture, and lack of nodules can be clinically monitored, whereas lesions with atypical or deep pigmentation or uneven textures may warrant surgical excision given the heightened difficulty of melanoma detection in this setting.<sup>28</sup> Other risk factors, such as a strong family history of MM or the presence of numerous atypical-appearing nevi, may influence the decision regarding surgical removal of small and medium-sized CMN. Lesions located in areas that may be difficult to follow clinically, such as the scalp or groin, may be better served by excision, although in the case of benign-appearing lesions, this decision may be delayed until the child is older and the procedure can be performed under local anesthesia.

Large CMN are often treated with full-thickness surgical excision. The primary reason for this recommendation is the potentially decreased risk of malignant transformation, although controlled studies supporting this hypothesis are lacking.<sup>63,64</sup> Unfortunately, excision of large lesions does not usually result in complete removal of all nevus cells, and melanoma may still develop from this residual tissue. In addition, melanoma may develop with increased incidence at extracutaneous sites in these patients, and the significance of neurocutaneous melanosis (if present) must also be factored into this decision. Nonetheless, most still advocate for surgical excision in an effort to reduce the risk of malignancy.<sup>65,66</sup> Removal of these lesions has been refined with the use of tissue expanders and skin grafting, but multiple procedures are usually required. Partial thickness removal techniques (i.e., dermabrasion, dermatome excision, curettage, chemical peels and laser therapy) have been advocated by some, but the impact of these procedures on malignant transformation or clinical surveillance of the lesion must be further defined. They may, however, be reasonable considerations when more aggressive procedures are impractical. There is no consensus on the timing of surgical procedures for large and giant CMN. Although many experts advocate for early referral and initiation of excisional therapy, other considerations may come into play, including anesthesia concerns surrounding neurocognitive effects on the developing brain. Ongoing prospective studies in this arena will hopefully clarify the optimal use and timing of sedation and anesthesia in young children.<sup>64,67,68</sup>

Close periodic clinical surveillance is important for all patients with CMN. Parent education in the importance of sun protection, sunscreen use, and danger signs of atypical nevi or melanoma (see below) is vital. Risks of malignant transformation should be discussed, and parents and patients should be allowed to reach an informed decision regarding therapy. Educational materials regarding moles, melanoma, and sun protection are useful and may be obtained from the American Academy of Dermatology ([www.aad.org](http://www.aad.org)). A multidisciplinary approach must be employed for families of children with large congenital nevi. This includes the primary care physician, dermatologist, plastic surgeon, and diagnostic radiologist. Emotional support should be provided, and the family should be given information on support groups. One such organization is Nevus Outreach ([www.nevus.org](http://www.nevus.org)), which was founded by parents of children with large CMN and offers an annual family conference, newsletters, and a social support network.

### ATYPICAL NEVI/FAMILIAL ATYPICAL MULTIPLE MOLE–MELANOMA SYNDROME

Atypical nevi, also known as *dysplastic nevi*, are defined based on their clinical and/or histologic appearance. These acquired nevi, which often do not present until at or after puberty, are regarded as markers and potential precursors for MM. The incidence of histologically confirmed atypical nevi in patients under 18 years of age is very low,<sup>69</sup> although in children who come from melanoma-prone families, their incidence seems much higher.<sup>70</sup> Clinically these lesions share some or all of the features of MM (Box 9-1). These include larger size and irregularities of color, texture, or borders (Fig. 9-16). Atypical nevi are often larger than common acquired nevi, usually measuring 6 to

**Figure 9-16 (A–C)** Atypical melanocytic nevi. These lesions revealed clinically atypical features, including asymmetry and border and color irregularity. All of them were benign histologically.

**Figure 9-17** “Fried egg” melanocytic nevus. Note the elevated, dark brown papule centrally and surrounding tan macular area.

**Figure 9-18** Cockade nevus. This pattern refers to a central darkly pigmented portion surrounded by an intervening rim of minimal to no pigmentation and an outer rim of darker pigment, giving a target-like appearance. These nevi are usually benign.

15 mm in diameter, and display marked lesion-to-lesion variability, often with a cobblestone appearance or a dark, central papular component surrounded by a lighter tan flatter periphery (the “fried egg” appearance, Fig. 9-17). Other patterns of clinically atypical nevi include the eclipse nevus (tan to hypopigmented center with a darker brown peripheral rim and irregular outer border) and the cockade nevus (target-like morphology with a central pigmented region, an intervening hypopigmented area, and an outer rim of pigmentation; Fig. 9-18).<sup>71</sup> These patterns may occur more with greater incidence on the scalp of children (see below).

Atypical nevi may occur anywhere, especially on sun-exposed sites, but also commonly occur on covered areas such as the back and in unusual locations such as the buttocks, breasts, and scalp.<sup>72</sup> In fact, a fairly high proportion of nevi removed from the scalp may demonstrate histologic features of atypical nevi.<sup>21,73</sup> Individuals with atypical nevi have been demonstrated to have an increased risk of melanoma despite the presence or absence of a family history of melanoma.<sup>74,75</sup> A distinct clinical phenotype characterized by numerous (>100) small, darkly pigmented atypical nevi has been described and termed the *cheetah* phenotype.<sup>76</sup> Longitudinal follow-up study of such patients is very challenging given the similar clinical appearance of several histologic patterns ranging from benign to cytologically atypical.<sup>76</sup>

Scalp nevi in children deserve special mention, as they may be a source of anxiety for parents and clinicians alike. These lesions, which are more common in boys, tend to be somewhat larger in size and may often reveal irregular borders and some color variations (Fig. 9-19).

**Figure 9-19** Scalp nevus. These nevi may be larger and often reveal irregular borders and color variation, although the majority of them are histologically benign.

The observed patterns may include the fried-egg, cockade, and eclipse phenotypes discussed previously, as well as clinically benign nevi patterns. Although scalp melanoma does occur in children, it seems that the majority of these lesions are benign; however, they may reveal mild to moderate atypia microscopically. Dermatoscopic (magnified light) examination may be helpful in demonstrating benign patterns (i.e., globular or reticular–globular pigmentation and perifollicular hypopigmentation).<sup>77</sup> It should be remembered that although the majority of scalp nevi in children are benign, their presence may suggest an increased risk for the development of numerous melanocytic nevi, which itself is a risk factor for MM.<sup>78</sup>

The familial atypical multiple mole–melanoma (FAMMM) syndrome is a disorder of autosomal dominant inheritance in which atypical nevi develop during the late second to third decade of life.<sup>79</sup> It was originally described in 1978 by Clark and colleagues when they noted individuals with increased numbers of melanocytic nevi that displayed atypical clinical and histologic features.<sup>80</sup> Since the original description, FAMMM syndrome has been better characterized as a hereditary cancer predisposition syndrome, entailing not only an increased risk of MM but also other cancers in some kindreds, especially pancreatic cancer.<sup>81–83</sup> FAMMM syndrome is characterized by the familial occurrence of melanoma in combination with multiple dysplastic nevi (>50) in first-degree relatives, although around 10% of the melanoma patients may have very few to no dysplastic nevi.<sup>84,85</sup> It has been estimated that individuals with a family history of FAMMM syndrome and atypical nevi have nearly a 100% lifetime risk of acquiring MM. In addition to melanoma of the skin, these individuals may develop intraocular melanoma. Recent observations of families displaying the association of pancreatic cancer and melanoma have led to the alternative terminology of *FAMMM–pancreatic cancer (FAMMM–PC) syndrome*. The phenotype of these families is variable, however, with several reported members lacking the dysplastic nevus phenotype. Some have therefore suggested the possibility of two distinct hereditary cancer syndromes, FAMMM–PC and the pancreatic cancer/melanoma syndrome (PCMS).<sup>86</sup>

The classic features of FAMMM syndrome are high numbers of melanocytic nevi, often more than 50, some of which are atypical and often have large variability in size (Fig. 9-20), that occur in the setting of a family history of MM in one or more first- or second-degree relatives.<sup>72</sup> Identification of at-risk children is vital, because melanoma may occur before 20 years of age in up to 10% of individuals.<sup>10</sup> Although most of the atypical nevi develop during or after adolescence, prepubertal children may occasionally show the atypical nevus phenotype, particularly in scalp nevi. In fact, the development of scalp nevi during childhood, as well as large nevus counts early in life, may represent early indicators of increased risk for the atypical mole phenotype later in life.<sup>70,87</sup>

There are several known melanoma susceptibility loci, most notably the p16 CDKN2A gene on chromosome 9, which is a tumor-

**Figure 9-20** Multiple atypical melanocytic nevi (familial atypical multiple mole–melanoma [FAMMM] type). This adolescent male had a family history of atypical nevi and malignant melanoma.

suppressor gene responsible for melanoma susceptibility in some kindreds with FAMMM syndrome.<sup>79</sup> Deletion of p16 may play a role in the development of atypical nevi as an early event, as well as in the development of MM (see below).

Management of the patient with atypical nevi should include a thorough family history, total body inspection, and a regular clinical follow-up examination every 6 to 12 months, depending on the individual patient. Patients (and parents) should be educated regarding sun protection, regular skin self-examination, and atypical features of nevi, and surgical excision should be performed for lesions with concerning features. A helpful guideline in monitoring children with many nevi is the “ugly duckling” principle, which dictates that a lesion that stands out from the rest (i.e., markedly darker pigmentation, more irregularity of texture or borders) should be more closely scrutinized and considered for removal. Epiluminescence microscopy (dermatoscopy) is a useful noninvasive instrument that provides magnification of nevi and may be useful in differentiating benign from atypical lesions. It is most often used by dermatologists, and its use requires training and experience in order to provide acceptable sensitivity and reliability. Serial photography of nevi may also be a useful adjunct in the longitudinal follow-up study of patients with multiple or atypical nevi.

## MALIGNANT MELANOMA

The incidence of MM, the most deadly form of skin cancer, continues to rise, and although childhood MM continues to be rare, the incidence in this population may also be rising.<sup>88,89</sup> The lifetime incidence of melanoma is estimated at around 1 in 58 individuals,<sup>90</sup> which is an alarming increase from the incidence of 1 in 1500 estimated in

1935.<sup>91</sup> The challenges of diagnosing MM in children are multiple and include lack of recognition, hesitancy to perform skin biopsies in children, and poor reliability in making the histopathologic diagnosis in this population.<sup>92</sup> Melanoma in individuals under 20 years of age accounts for only 1% to 3% of all MM, and prepubertal cases are even rarer, accounting for 0.3% to 0.4% of all cases.<sup>93-95</sup> Despite this rarity, the course of melanoma, when it does occur in a child, bears the same prognosis as it does in adults.<sup>94,96,97</sup> Importantly, the incidence of pediatric melanoma is increasing at an estimated 1% to 4% per year.<sup>98</sup> Interestingly, many lesions previously thought to be melanomas of childhood are now recognized to be benign Spitz nevi (see below). Congenital MM represents a small subset of all pediatric MM and is extremely rare, with only 23 cases reported in the English literature between 1925 and 2002.<sup>94</sup> It most commonly arises in a congenital melanocytic nevus and less commonly is *de novo* or related to transplacental transmission of MM from the mother.

MM most commonly affects individuals with fair skin, blue eyes, and red or blond hair, particularly those of Celtic origin whose pigment cells have a limited capacity to synthesize melanin. Approximately one-half to 65% of MM arises in a preexisting nevus. Although melanomas may occur in African-American individuals, the incidence is extremely low when compared with that of Caucasians. In African-Americans, tumors usually arise in areas that are lightly pigmented, especially the mucous membranes, nailbeds, or the sides of the palms and soles. Exposure to high levels of sunlight in childhood seems to be a strong determinant of risk for MM, although adult sun exposure also plays a role.<sup>99</sup> Some studies have not supported this “critical risk period” hypothesis of ultraviolet radiation exposure, suggesting that sun protection education should be directed at the entire population with equal effort rather than concentrating solely on younger age groups.<sup>100</sup> However, maintaining a stringent focus on childhood sun protection still seems reasonable, because a large proportion of overall lifetime sun exposure is likely to occur during these years.<sup>101</sup>

The genetics of MM continue to be elucidated, and it is now established that molecular defects in both tumor-suppressor genes and oncogenes may be pathogenetically linked to melanoma.<sup>102</sup> Mutations in the *CDKN2A* (p16) gene predispose a patient to the FAMMM syndrome and have also been noted in families in which only one or two individuals are affected by MM.<sup>103</sup> A subset of melanoma-prone families with *CDKN2A* mutations also manifests an increased risk of pancreatic cancers (as discussed earlier).<sup>83,102</sup> Activating mutations in one of two Ras/mitogen-activated protein kinase pathway genes, *BRAF* or *NRAS*, are present in up to 80% to 90% of melanomas.<sup>104,105</sup> Some of the other genes potentially mutated in melanoma include *PTEN*, *CDK4*, *CCND1*, *KIT*, *p53*, *EphA2*, *ERBB4*, *GRIN2A*, *GRM3*, *MEK1*, *MEK2*, *MITF*, *β-catenin*, and various apoptosis genes.<sup>104-106</sup>

Melanoma is classically categorized according to its clinical and histologic features. The most common forms are superficial spreading, nodular, lentigo maligna (usually confined to adults), and acral lentiginous melanoma. However, pediatric cases of MM often cannot be neatly classified into one of these categories. Pediatric melanoma seems to follow the same distribution patterns as adult melanoma, with head and trunk lesions predominating in boys, and arm and leg lesions predominating in girls. Risk factors for pediatric MM are listed in Box 9-1.

The classic signs of MM are summarized in Table 9-1. Melanoma typically presents with a rapidly enlarging papule or nodule, most often brown to brown-black in color (Fig. 9-21), although blue, red, or white discoloration may also be noted. Importantly, a significant proportion of pediatric melanomas may present in an amelanotic (i.e., pink, white, red, or a combination of these colors) fashion.<sup>107</sup> A halo of hypopigmentation or depigmentation may be present around a primary lesion of MM, although most often these halos occur in the setting of benign nevi (see Halo Nevus section). Melanomas often reveal asymmetry and irregularity of the borders, especially scalloping or notching, and tend to be larger than benign nevi, often (but not always) larger than 10 mm in diameter. Bleeding, itching, ulceration, crusting, and pain may be present. In a recent single-center retrospective review of 70 children (<20 years of age) with melanoma or other atypical melanocytic tumors, several clinical features were highlighted that may contradict the traditional “ABCD” portion of the ABCDE criteria (as shown in Table 9-1). These include the amelanotic

**Table 9-1** Clinical Features (ABCDE Signs) of Malignant Melanoma

Clinical Feature*	Comment
A Asymmetry	The two halves of the lesion are not alike
B Border irregularity	Borders notched, scalloped, irregular
C Color changes	Especially blue, red, black, white
D Diameter >6 mm	Size of a pencil eraser; not applicable to congenital nevi, which are often >6 mm early in their evolution
E Enlargement	Evolutionary change in the lesion

\*See text for important discussion of features that may be more specific to pediatric melanoma.

**Figure 9-21** Malignant melanoma (MM). This small, black papule was noted on this 10-year-old male with fair skin and red hair; excision confirmed a nodular malignant melanoma.

(flesh-colored, pink, or red) nature of the lesions, bleeding, uniformity of color, small diameter (often <6 mm) and *de novo* development (as opposed to arising in an existing nevus).<sup>108</sup> These characteristics should be kept in mind when evaluating children with atypical “bumps” and may facilitate earlier recognition of (and hence therapy for) pediatric MM.

Lymph nodes may be palpable and if present, are an ominous prognostic sign, suggesting metastatic spread. When MM goes undetected and undiagnosed, the lesion proliferates locally and may spread by satellite lesions or extend through the lymphatics or bloodstream, from which it may eventually invade any organ of the body. Once metastatic disease occurs, the prognosis of MM significantly declines.

Early detection of melanoma is germane to long-term survival. The survival rate for children and adults seems to be similar, and the primary determinants of prognosis have traditionally been tumor thickness and depth of invasion.<sup>91,96</sup> The presence or absence of ulceration has been added to the American Joint Committee on Cancer (AJCC) staging system for MM as another important prognostic criterion (the presence of ulceration correlating with poorer prognosis).<sup>109</sup> The pediatrician (or other primary care provider of children) is in good position to observe pigmented skin lesions over time in their patients. Early referral should be considered for any melanocytic lesion that displays substantial growth changes, especially if asymmetry, ulceration, or other atypical features are present. Melanoma is diagnosed by histopathologic examination of skin tissue from biopsy. When MM is suspected, full-thickness excision of the lesion should be performed, as depth of the lesion must be fully visualized in order to assess this prognostic indicator. Shave biopsies or excisions should be avoided in the removal of concerning pigmented lesions.

Surgical excision is the initial step in melanoma management, along with adequately staging the disease. Once the diagnosis of MM is confirmed, the site is reexcised with appropriate margins (0.5 to 3 cm), depending on tumor depth in the initial specimen. Clinically suspected lymph nodes are surgically removed and histologically evaluated. Developments in tracer techniques have enabled sampling of the first lymph node draining the affected skin site (the “sentinel” lymph node), which assists in determining whether to proceed with regional lymph

node dissection for further staging and therapy. This technique, which is usually performed concurrently with reexcision of the primary lesion, allows for accurate staging of the regional lymph nodes with minimal morbidity.<sup>96</sup> In a series of 126 patients younger than 21 years of age who were diagnosed with MM, sentinel lymph node metastases were present in 29%, yet the survival was equal to or better than that reported for adults, suggesting that the biology of pediatric melanoma may be different than that in adult melanoma.<sup>98</sup> It appears that lymph node metastases and thicker tumors may be more common in younger children (<10 years of age) with MM.<sup>110</sup> In addition to histopathologic analysis and lymph node examination, staging for pediatric MM may also include computed tomography (CT), positron emission tomography (PET) and PET-CT scanning in patients with thicker lesions to evaluate for distant metastases.<sup>111</sup>

Treatment of more advanced stages of MM includes chemotherapy, radiotherapy, and immunotherapy, although the results have been somewhat discouraging.<sup>112</sup> Adjuvant interferon  $\alpha$ -2b therapy has received much attention in the treatment of high-risk melanoma in adults, with reports of improved disease-free survival and overall survival rates with use of the Kirkwood regimen (high-dose therapy for 4 weeks followed by a lowered dose for 48 weeks). Recommendations for use of this agent in children have primarily been extrapolated from the adult data, and although its use is potentially effective, it may be associated with some toxicities at higher doses, which may be limiting when treating the pediatric melanoma patient.<sup>113,114</sup> Immunotherapeutic approaches to MM include melanoma vaccines, cytokine therapy, and passive immunotherapy with monoclonal antibodies, and these and other approaches continue to be the topics of active investigation.<sup>115</sup> Traditional chemotherapy regimens have shown minimal activity against melanoma.<sup>89</sup> Biologic agents such as high-dose interleukin (IL)-2 have resulted in durable responses in some adult patients, but experience in children is limited.<sup>116</sup> More recently, treatments that target growth-factor pathways or molecular targets have received increasing attention, including *BRAF* inhibitors such as dabrafenib and vemurafenib, and MEK inhibitors such as trametinib.<sup>116</sup> The combination of *BRAF* and MEK inhibition appears to provide greater benefit than *BRAF* inhibitor monotherapy in adults.<sup>117</sup> These treatments have not yet been well studied in pediatric melanoma.

The prognosis for pediatric melanoma is strongly correlated with initial stage. In a review of data from the National Cancer Database of 3158 patients aged 1 to 19 years with melanoma, average 5-year survival rates were 98.7% (*in situ* disease), 93.6% (localized invasive disease), 68% (regionally metastatic disease), and 11.8% (distant disease).<sup>118</sup> Some studies have found decreased survival in prepubescent patients with MM, whereas others have found no difference or a better prognosis in this group.<sup>111</sup> Hence there still exists no consensus on the overall prognosis for pediatric MM.

## SPITZ NEVUS

Spitz nevus is a distinct subtype of melanocytic nevus that occurs primarily in children. The importance of the Spitz nevus, which was formerly known as *benign juvenile melanoma*, lies in its histologic differentiation from MM. This lesion was originally recognized in 1948 when Dr. Sophie Spitz realized that a subset of juvenile melanomas did not behave in the same fashion as adult melanomas.<sup>119</sup> Spitz nevi have subsequently been identified as a distinct nevus variant, occurring most commonly on the face of children and adolescents.

Spitz nevi present usually as a smooth-surfaced, hairless, dome-shaped papule or nodule with a distinctive red-brown color (Fig. 9-22). They are most often solitary, although multiple clustered (agminated, Fig. 9-23) or disseminated lesions have been described.<sup>120,121</sup> They may vary in size from a few millimeters to several centimeters, although most range from 0.6 to 1 cm in diameter. The lesion may be so red that the differential diagnosis for some includes pyogenic granuloma or early juvenile xanthogranuloma. The presence of brown pigmentation (Fig. 9-24), either with regular clinical examination or when examined through a glass slide compressing the surface (diascopy), may be useful in confirming the melanocytic nature of the lesion. Surface telangiectasia may also be a prominent feature. In some lesions, particularly those on the extremities, the red color is replaced by a mottled brown to tan or black appearance, often with verrucous

**Figure 9-22** Spitz nevus. This patient had the erythematous type of Spitz nevus on her nose.

**Figure 9-23** Agminated Spitz nevi. This child had multiple lesions of the lateral cheek, ear, and neck, several of which were excised, revealing characteristic histologic features of Spitz nevus.

surface changes and irregular borders. Clinically it is this type of lesion that is most easily confused with MM (Fig. 9-25).

Although most Spitz nevi behave in a benign fashion, local recurrence after excision may occur in as many as 5%.<sup>122</sup> It has been suggested by some that occasional Spitz nevi are malignant in origin and have the potential for more aggressive biologic behavior. Whether these represent a subtype of Spitz nevus or a "spitzoid" MM is unclear. It is obvious that some Spitz nevus-like lesions may pose substantial diagnostic difficulties especially when atypical features are present, even among dermatopathology experts.<sup>123</sup> These lesions have been variably called *spitzoid tumor of uncertain malignant potential* or *atypical spitzoid tumor*. A grading system has been proposed for Spitz nevi with atypical features, and application of such a system may be useful in guiding management for patients with atypical Spitz tumors.<sup>124</sup> *BRAF* mutations have occasionally been observed in a subset of Spitz nevi, suggesting that this finding should not be relied upon for distinguishing Spitz nevus from melanoma.<sup>125</sup> The expression of cell cycle and

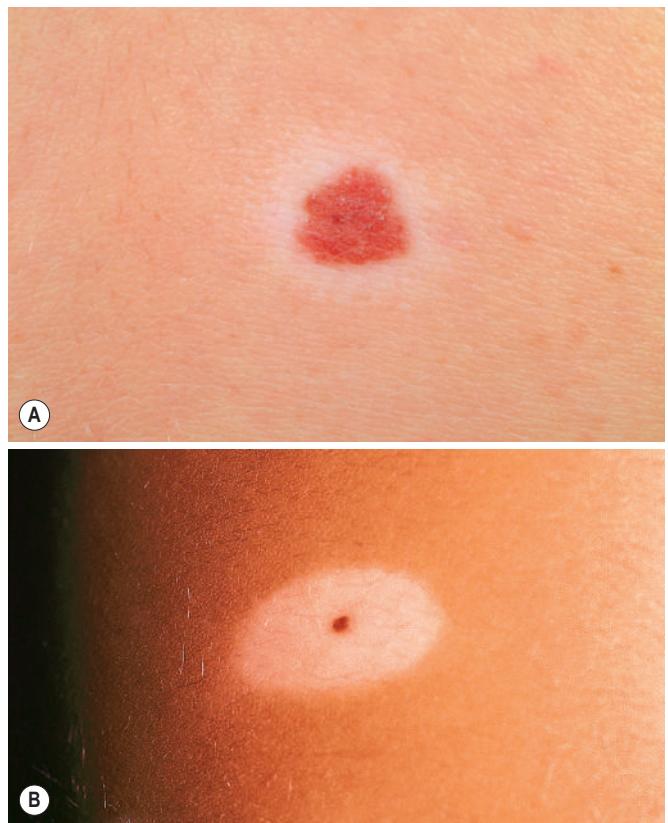

**Figure 9-24** Spitz nevus. This pink papule reveals brown speckling, which was easier to see when pressure was applied with a glass slide (diascopy).

**Figure 9-25** Spitz nevus. The dark brown or black type is most often confused clinically with MM.

apoptosis regulators in Spitz nevi appears to more closely parallel the findings in benign nevi rather than melanoma.<sup>126</sup> More recently, fluorescent *in situ* hybridization (FISH) using probes for chromosomal loci has been used in an attempt to predict biologic behavior in atypical spitzoid tumors; gains in 6p25 or 11q13 and deletions in 9q21 have been shown to correlate with more aggressive clinical behavior.<sup>127</sup> Deletions in 9q21 appear to correlate most with lymph node spread and distant metastasis.<sup>128</sup>

The management of Spitz nevi is controversial. Many experts recommend excision of these lesions on the basis of uncertainty in their biologic behavior, occasional reports of aggressive potential, and the increasing observation of the amelanotic nature of many melanomas in children. Others advocate for watchful waiting, reserving excision for lesions that demonstrate atypical features or those of psychosocial significance. When these lesions are excised, however, complete removal is advisable. More importantly, surgical specimens should be

**Figure 9-26** Halo nevi. **(A)** Small halo surrounding a small congenital nevus. **(B)** Larger halo surrounding an acquired compound nevus.

examined by a dermatopathologist or pathologist experienced in the diagnosis of melanocytic lesions and familiar with Spitz nevi. If an excised lesion is diagnosed unequivocally as a Spitz nevus without atypical features, no further therapy is necessary. However, because incompletely removed lesions may recur and result in a histopathologic appearance that may be more likely to be misinterpreted as MM, conservative reexcision is recommended for lesions with positive margins noted on the initial biopsy.

### HALO NEVUS

A halo nevus is a unique skin lesion in which a centrally placed, usually pigmented nevus becomes surrounded by a 1- to 5-mm halo of hypopigmentation or depigmentation (Fig. 9-26). These lesions are common in children and young adults. The cause of the spontaneous loss of pigmentation is unknown but appears to be related to an immunologic destruction of melanocytes and nevus cells.<sup>129,130</sup> Adding support to this hypothesis is the fact that several patients with halo nevi have a tendency toward the development of vitiligo (see Chapter 11; Fig. 9-27). Histologic examination of halo nevi reveals reduction or absence of melanin and a dense inflammatory infiltrate around the central nevus. Although compound or intradermal nevi are the tumors most commonly associated with the halo phenomenon, it may also occur around blue nevi, Spitz nevi, neurofibromas, melanomas, and metastatic lesions of melanoma. Giant CMN may also reveal the halo phenomenon with pigment regression and at times, self-destruction.<sup>131,132</sup>

Typical halo nevi are notable for loss of pigmentation in the nevus, with a pink appearance and commonly, eventual disappearance of the original melanocytic lesion. Occasionally, darkening of the central nevus may occur.<sup>133</sup> Halo nevi may appear on almost any cutaneous surface, but the site of predilection for most lesions is the trunk, particularly the back. In most patients, eventual repigmentation of the halo occurs over a period of months to years.

**A****B**

**Figure 9-27** Halo nevus with vitiligo. **(A)** Small halo nevus in the inferior ear crease. **(B)** The same patient had generalized depigmented macules and patches consistent with vitiligo, as seen here on the flank.

Halo nevi tend to be benign, although the halo phenomenon may occur around lesions revealing varying degrees of histologic atypia.<sup>134</sup> Potential concern has been raised over reports of MM exhibiting the halo phenomenon and the increased incidence of halo nevi in adults with melanoma.<sup>135</sup> In a survey of pediatric dermatologists, no diagnoses of MM in pediatric patients with halo nevi were noted.<sup>135</sup> Clinical features that may suggest an increased probability of an atypical melanocytic lesion within a halo include the ABCDE diagnostic criteria of melanoma (see Table 9-1) and asymmetry or irregularity of the surrounding depigmentation. Any patient with a halo nevus, especially if multiple halo lesions are present, should receive a complete skin and mucous membrane examination to assess for melanocytic lesions revealing atypical features. Patients with the halo nevus phenomenon, concomitant vitiligo, and ocular melanoma have been described,<sup>136</sup> but in general ophthalmologic evaluation is not routinely indicated. If the melanocytic lesion in the central portion of a halo reveals concerning or atypical features, complete excision should be performed. If, on the other hand, the central lesion has benign characteristics, excision is unnecessary and the lesion may be observed at intervals until it has resolved.

**Figure 9-28** Nevus spilus. A tan patch is studded with numerous darker brown macules and papules.

**Figure 9-29** Nevus spilus. This larger patch on the chest of a young boy reveals numerous superimposed nevi along with mild hypertrichosis.

## NEVUS SPILUS

Nevus spilus is a solitary, nonhairy, flat, brown patch of melanization dotted by smaller dark brown to black macules (Fig. 9-28). This relatively common lesion, although usually present at birth, may first become noticed during infancy, childhood, or even later. However, clinical and histologic data suggest that these lesions are most likely a subtype of CMN.<sup>32</sup> The earliest findings are usually similar to a café-au-lait patch, with eventual development of the secondary superimposed darker melanocytic lesions. Nevi spili may vary in size from 1 to 20 cm in diameter and may appear on any area of the face, trunk, or extremities without relation to sun exposure. Subtle hypertrichosis may occasionally be present (Fig. 9-29). Although the darker melanocytic components of these lesions have the potential to develop MM, the incidence of this transformation appears to be low.<sup>137,138</sup> Histologic evaluation of a nevus spilus usually reveals components of junctional and congenital nevi.<sup>32,137</sup> Patients with nevus spilus should be monitored longitudinally with serial clinical examinations and if possible, photographic surveillance. Any areas revealing atypical clinical features should be selectively excised and subjected to histologic evaluation, but widespread prophylactic excision seems unwarranted.<sup>30</sup> These lesions (especially when larger) have also been called *speckled lentiginous nevi* (SLN). Although they usually occur in isolation, they may sometimes be associated with other organ abnormalities as part of a syndrome such as phakomatosis pigmentovascularis (see Chapter 12), phakomatosis pigmentokeratotica (PPK), or SLN syndrome (see below).

**Figure 9-30** Becker melanosis. This adolescent boy has hyperpigmentation of the upper back and shoulder with extension onto the right upper chest in association with surface hypertrichosis.

### BECKER MELANOSIS

Becker melanosis, also known as *Becker nevus*, is an acquired, unilateral hyperpigmentation usually involving the upper trunk of adolescent males. Occasionally it may present very early in life (as early as birth) and may be distributed in other locations, including the extremities.<sup>139</sup> This pigmentation, which is caused by increased melanization of the epidermis and not by nevocellular proliferation, may be associated with hypertrichosis (Fig. 9-30) and occasionally proliferation of smooth muscle derived from erector pili muscles. Becker melanosis is discussed in more detail in Chapter 11.

## Tumors of the Epidermis

Tumors of the epidermis range in spectrum from benign lesions to those that are malignant. Benign tumors appear much more often than malignant lesions in children, and the latter, when they do occur, may be overlooked and/or the diagnosis delayed.

### EPIDERMAL NEVI

Epidermal nevi (EN) are benign congenital lesions characterized by hyperplasia of epidermal structures. They are usually apparent at birth or become noticeable during early childhood, affect both sexes equally, and are known by several descriptive names, including *nevus verrucosus*, *nevus unius lateris*, and *ichthyosis hystrix*. In addition, EN can be divided into nonorganoid (keratinocytic) nevi and organoid EN, such as *nevus sebaceous* or *follicular nevi*. Although the exact etiology of EN is unknown, activating fibroblast growth factor receptor 3 (*FGFR3*) mutations have been demonstrated in some,<sup>140,141</sup> as have mutations in the p110  $\alpha$ -subunit of *PI3K* (*PIK3CA*), *HRAS*, *KRAS*, and *NRAS*.<sup>142–144</sup>

Keratinocytic EN (often referred to simply as *EN*) may be slightly or darkly pigmented and unilateral or bilateral in distribution. They often favor the extremities, although they may occur anywhere on the cutaneous surface. EN are usually distributed in a mosaic pattern of alternating stripes of involved and uninvolved skin. This pattern is termed *Blaschko lines* and occurs as a result of migration of skin cells during embryogenesis. Disorders that occur along the Blaschko lines usually reveal a linear pattern on the extremities and a wavy or arcuate pattern on the trunk. Although a single EN is most common, multiple

**Figure 9-31** Epidermal nevus. This multifocal, verrucous plaque was present since birth.

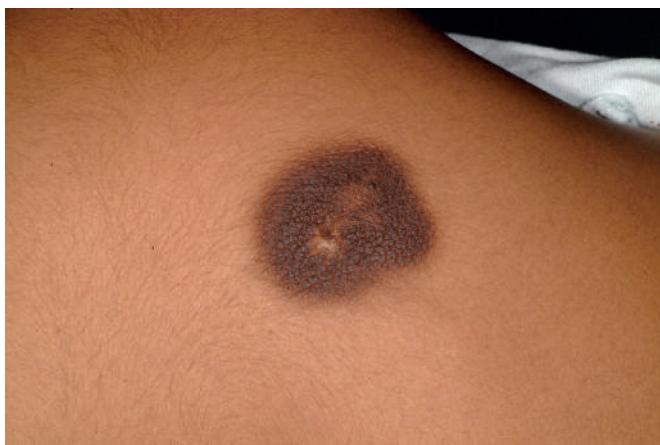

**Figure 9-32** Epidermal nevus. Note the warty nature and linear configuration.

lesions may be present, sometimes in association with the epidermal nevus syndrome (ENS; see below). The localized form is often present at birth and presents as a tan to brown, velvety or verrucous (warty) papule or plaque. There may be a single lesion (Fig. 9-31) or multiple lesions, and a linear configuration is common (Fig. 9-32). One subtype of epidermal nevus has been termed the *acanthosis nigricans form* of EN and is characterized by a clinical (Fig. 9-33) and histologic resemblance to acanthosis nigricans.<sup>145</sup>

The term *nevus unius lateris* has been used traditionally to describe extensive unilateral lesions. Nevus unius lateris may present as a single or spiral linear, verrucous lesion or at times as an elaborate, continuous, or interrupted pattern affecting multiple sites (Fig. 9-34) and occasionally involves more than half of the body. *Systematized epidermal nevus* has been used to describe extensive lesions that are bilateral and in which truncal involvement predominates.

EN may reveal a variety of histologic features. Importantly, those that reveal epidermolytic hyperkeratosis, a distinct pattern of clumping of keratin filaments in the suprabasal cells of the epidermis, imply a mosaic disorder of keratin genes. Patients with this condition, especially when skin involvement is extensive, may transmit these mutations to offspring, resulting in a more widespread ichthyosiform condition termed *epidermolytic ichthyosis* and *epidermolytic hyperkeratosis* (also known as *bullous congenital ichthyosiform erythroderma*; see Chapter 5).<sup>146</sup> These EN may be clinically indistinguishable from other EN (Fig. 9-35).

**Figure 9-33** Acanthosis nigricans form of epidermal nevus. This form of epidermal nevus reveals a well-demarcated area of velvety thickening, as classically seen with more widespread acanthosis nigricans.

**Figure 9-35** Epidermal nevus. This lesion demonstrated epidermolytic hyperkeratosis on histologic evaluation (see text).

**Figure 9-34** Nevus unius lateris. Numerous linear and "whorled" lesions were present on the right side of this 10-year-old female.

EN are challenging to treat, given the observation that most superficial destructive therapies are followed by recurrence of the lesions. These superficial therapies have included cryotherapy with liquid nitrogen, dermabrasion, electrodesiccation, and laser ablation. In a series of 71 treated lesions, cryotherapy of small EN resulted in an excellent response in 90%.<sup>147</sup> Carbon dioxide (CO<sub>2</sub>) laser therapy may offer excellent results, but response to therapy is unpredictable.<sup>148</sup> Staged CO<sub>2</sub> laser ablation has been used successfully, both with and without preceding surgical debulking.<sup>149</sup> Topical therapies used with variable success include retinoids, 5-fluorouracil, steroids, and podophyllin, among others. Photodynamic therapy with methylaminolevulinate was reportedly successful in a young girl, although hypertrophic scarring occurred.<sup>150</sup> Full-thickness surgical excision or deeper destructive procedures (such as deep dermabrasion) appear effective at removing these hamartomas but are generally limited to smaller, more localized lesions. Since these lesions may continue to extend during childhood, surgical intervention should be delayed until the full extent of the process is determined.

## EPIDERMAL NEVUS SYNDROME

ENS is a sporadic association of EN with abnormalities in other organ systems. Some believe that this syndrome is actually a group of several syndromes, each with distinguishing cutaneous and extracutaneous features. Happle suggests that the five well-defined ENSs are Schimmelpenning syndrome, nevus comedonicus syndrome, pigmented hairy ENs, Proteus syndrome (see Chapter 12), and congenital hemidysplasia with ichthyosiform nevus and limb defects (CHILD) syndrome (see Chapter 5).<sup>151</sup> Keratinocytic ENS also merits inclusion on this list.<sup>152</sup> Regardless, patients who fall into the spectrum of having an ENS generally have organoid or nonorganoid EN in conjunction with defects in the CNS, eyes, musculoskeletal system, connective tissue and occasionally other organ systems. The manifestations of ENS are believed to represent genomic mosaicism with the effects of the genetic defect(s) and timing of the mutation during development determining the spectrum of clinical involvement.<sup>152</sup>

*Phakomatosis pigmentokeratotica (PPK)* has been used to describe the association of speckled lentiginous nevus with an epidermal nevus that has sebaceous differentiation and is accompanied by skeletal and neurologic abnormalities.<sup>153</sup> It has been suggested that patients with PPK may have systemic features suggestive of either Schimmelpenning syndrome (extensive sebaceous nevi, mental retardation, seizures, coloboma, lipodermoids of the conjunctiva, skeletal defects, and vascular abnormalities) or what has been termed *SLN syndrome* (presenting with SLN, hyperhidrosis, sensory and motor neuropathy, nerve palsy, and spinal muscular atrophy).<sup>154,155</sup>

Examples of extracutaneous abnormalities seen in patients with ENS include seizures, mental retardation, hemiparesis, hypotonia, cranial nerve palsies, developmental delay, deafness, kyphosis, scoliosis, limb hypertrophy, hemihypertrophy, facial bone deformity, macrocephaly, ocular lipodermoids, coloboma, corneal changes, cortical blindness, cataracts, and retinal changes.<sup>151,152,156,157</sup> CNS imaging may reveal hemimegalencephaly, agenesis of the corpus callosum, cerebral heterotopia, cortical agyria or microgyria, or Dandy–Walker malformation; brainstem and cerebellar malformations and neonatal medulloblastoma have also been reported.<sup>158,159</sup> In addition, hypophosphatemic vitamin D-resistant rickets has been observed in patients with ENS, and in some reports the hypophosphatemia improved after surgical revision of the EN.<sup>160–162</sup> It has been suggested that some EN may produce a phosphaturic substance that contributes to this association.<sup>160,161</sup> Hyponatremia has also been observed as an early manifestation in a patient with ENS.<sup>163</sup> Cardiac and genitourinary defects may also be associated.

The features of the cutaneous lesions in ENS range from large unilateral nevus unius lateris-like lesions to diffusely distributed, whorled lesions (Figs. 9-36 and 9-37) involving variable degrees of the skin surface or linear, orange-yellow plaques as seen in nevus sebaceous of Jadassohn (see *Nevus Sebaceous* section). Plaques of dilated follicular pits filled with keratin may be seen in the nevus comedonicus type of

**Figure 9-36** Epidermal nevus syndrome. This infant had numerous widespread epidermal nevi in conjunction with multiple congenital anomalies.

**Figure 9-37** Epidermal nevus syndrome. Multiple, whorled verrucous plaques are present in this child with multiple musculoskeletal, CNS, and ophthalmologic defects as well as profound developmental delay.

ENS, and extensive Becker nevus is seen in the pigmented hairy type of ENS. In the CHILD syndrome, a unilateral inflammatory epidermal nevus with a sharp midline demarcation and an affinity for body folds is seen in conjunction with the characteristic ipsilateral hypoplasia of limbs and other organ defects. Patients with Proteus syndrome have verrucous EN in association with partial gigantism, macrocephaly, and vascular malformations.

Patients with large or extensive EN require careful medical, family, and developmental histories and thorough physical evaluation, with particular emphasis on the musculoskeletal, neurologic, ocular, and cardiovascular examinations. Management of ENS should be multidisciplinary including a dermatologist, pediatrician, neurologist, ophthalmologist, and plastic surgeon, with utilization of other subspecialists as necessary. EN can be treated as noted earlier, although treatment is even more challenging given their extensiveness in this setting. Malignant transformation of EN is rare but may occur, both in syndromic and nonsyndromic lesions, and includes basal cell carcinoma (BCC) or squamous cell carcinoma (SCC), depending on the type of epidermal nevus.

### INFLAMMATORY LINEAR VERRUCOUS EPIDERMAL NEVI

Inflammatory linear verrucous epidermal nevi (ILVEN) appear to be a unique variant of epidermal nevi that presents as a chronic pruritic

**Figure 9-38** Inflammatory linear verrucous epidermal nevus (ILVEN). Multiple red, scaly papules coalescing into a linear plaque on the medial leg, malleolus, and foot of a 7-year-old girl.

process with erythematous, scaly, and verrucous papules that coalesce into linear plaques (Fig. 9-38). These lesions are often present at birth or may appear during early childhood and most often occur on an extremity. They are notable for their chronic and intermittent course and resistance to therapy.<sup>164</sup> Occasionally lesions may spontaneously improve or resolve only to eventually reappear. The differential diagnosis of ILVEN includes linear psoriasis, lichen striatus, linear lichen planus, and verrucous epidermal nevus. ILVEN can usually be confirmed by the clinical course, morphologic appearance of lesions, intense pruritus, and resistance to therapy.

Treatment of ILVEN is difficult, as discussed previously for EN. Topical or intralesional corticosteroids may reduce inflammation and pruritus and produce a temporary remission, but the lesions generally recur. Topical retinoids, 5-fluorouracil, calcineurin inhibitors (i.e., tacrolimus or pimecrolimus), CO<sub>2</sub> laser therapy, and vitamin-D derivatives (i.e., calcitriol) have been used with varying results.<sup>165–167</sup> Photodynamic therapy with methyl-aminolevulinate was reportedly successful in an adult with ILVEN.<sup>168</sup> Patients with extensive and symptomatic ILVEN have been treated surgically, with tissue expansion, serial full-thickness excisions, and split-thickness skin grafting with excellent outcomes.<sup>169</sup>

### BASAL CELL CARCINOMA

Basal cell carcinoma (BCC) is a slow-growing, usually nonmetastasizing but invasive malignant skin tumor with varying clinical patterns that may be triggered by ultraviolet radiation exposure. This disorder arises from the basal cells of the epidermis or its appendages and is most commonly seen in persons of middle age. BCC is the most common form of skin cancer, and although rarely seen in children, it can occur in childhood and must be considered even in the very young.<sup>170,171</sup> However, misdiagnosis must also be considered in a child, as several benign hamartomas of follicular differentiation (trichoepithelioma, trichoblastoma, trichofolliculoma) may histologically appear similar to BCC to the inexperienced pathologist.

When the diagnosis of BCC is confirmed in a child, one must consider an associated predisposing condition such as basal cell nevus syndrome (BCNS, or Gorlin syndrome, see below), xeroderma pigmentosum (see Chapter 19), Bazex syndrome, and Rombo syndromes

(see Chapter 7), albinism (see Chapter 11), or an underlying nevus sebaceous of Jadassohn (see [Nevus Sebaceous](#) section). Other genetic skin disorders that may entail an increased risk for BCC include Bloom syndrome, Werner syndrome, Rothmund–Thomson syndrome, Muir–Torre syndrome, Brooke–Spiegler syndrome (BSS), Cowden syndrome (CS), and some immunodeficiency disorders.<sup>172</sup> Children treated with irradiation for malignancy or with solid organ transplantation may develop BCC years to decades after the treatment.<sup>170,173</sup> In a review of childhood cancer survivors who were subsequently diagnosed with BCC, the majority of tumors developed between 20 and 39 years of age, and the risk was noted to be increased when patients received radiation doses to the skin of more than 1 Gy.<sup>174</sup> BCC lesions have occasionally been reported as sporadic cases in children without any underlying predisposition and appear to be most often located on the head, back, and chest.<sup>170,175,176</sup> The diagnosis of BCC in childhood is often delayed because of a low index of suspicion.

The majority of BCCs have a predilection for the upper central part of the face. Although they may arise without apparent cause, prolonged exposure to the sun is a predisposing factor, particularly in individuals with a fair skin phenotype. BCC may occur in several clinical forms. Nodoulcerative BCC, the most common type, begins as a small, elevated, translucent papule or nodule with telangiectatic vessels on its surface. It may enlarge, develop central necrosis, and result in an ulceration surrounded by a pearly rolled border. Although this form usually occurs as a single lesion, patients who develop this form of basal cell tumor often are likely to develop other such lesions. Superficial BCC presents as an erythematous, scaly, minimally elevated papule or plaque that may have superficial crusting. Often multiple, these lesions tend to occur on the trunk or extremities, expand slowly, and are easily mistaken for lesions of psoriasis, dermatitis, or tinea. Pigmented BCCs are similar to nodoulcerative lesions but also contain irregular brown pigmentation that may simulate the appearance of a nevus or MM. Sclerosing or morphaform BCC presents as a firm, yellow-white waxy papule or plaque with an ill-defined border and absence of the translucent rolled edge. Tumors of this type have been known to arise in early childhood and may grow for years before attracting medical attention.

In the pediatric patient who is diagnosed with a BCC, a thorough history and physical examination should be performed with attention to the regional lymph node examination. An evaluation for an associated predisposing condition should be performed when indicated. No single method of therapy is applicable to all BCC lesions. The goal, as with any skin tumor, is for permanent cure with the best functional and cosmetic result. Curettage and electrodesiccation is a simple office therapy most commonly used by dermatologists for low-risk, small BCC in areas without a dense hair pattern. Excision (with or without Mohs micrographic surgery [MMS]) is the treatment of choice for childhood-onset BCC.<sup>170</sup> Radiation therapy can be an effective treatment but is not desirable in children (and contraindicated in the setting of BCNS, discussed later in this chapter, because it may increase the risk for invasive BCC).<sup>171</sup> Other treatment modalities include cryotherapy, CO<sub>2</sub> laser therapy, photodynamic therapy, systemic retinoids, topical chemotherapy (i.e., topical 5-fluorouracil), and biologic-response modifiers. The latter include imiquimod, a topical immune-response modifier demonstrated to be effective against superficial BCCs and small nodular BCCs.<sup>177</sup> This agent promotes innate immune responses and exhibits antitumor as well as antiviral effects, having been initially approved for the treatment of anogenital condylomata. Experience with these therapeutic methods in childhood BCC is primarily anecdotal. Sun protection and skin self-examination education is vital.

## BASAL CELL NEVUS SYNDROME

BCNS (also known as *Gorlin syndrome* or *nevroid BCC syndrome*) is an autosomal dominant disorder with complete penetrance and variable expressivity characterized by childhood onset of multiple BCCs and associated with other abnormalities, including odontogenic jaw cysts, bifid ribs, and intracranial calcification.<sup>178–181</sup> The most obvious cutaneous feature in patients with BCNS is the appearance of multiple BCCs early in life. These basal cell epitheliomas are indistinguishable on histopathologic examination from ordinary BCCs. The diagnostic

## Box 9-2 Diagnostic Criteria for Basal Cell Nevus Syndrome\*

### Major criteria

- Multiple basal cell carcinomas (>5 in a lifetime or a BCC before 30 years)
- Lamellar calcification of the falx (or clear evidence of calcification in an individual younger than 20 years)
- Jaw keratocyst (odontogenic keratocyst, confirmed histologically)
- Palmar or plantar pits (>2; may be most easily seen after soaking of the hands and feet in warm water)
- First-degree relative with BCNS

### Minor criteria

- Macrocephaly
- Childhood medulloblastoma
- Cleft lip/palate
- Rib/vertebral anomalies: bifid, splayed, missing or extra ribs; bifid, wedged, or fused vertebrae
- Preaxial or postaxial polydactyly
- Cardiac or ovarian fibroma
- Lymphomesenteric or pleural cysts
- Ocular anomalies (cataract, coloboma, microphthalmia)

Modified from High A, Zedan W. Basal cell nevus syndrome. *Curr Opin Oncol* 2005; 17:160–6, and Evans DG, Farndon PA. Nevoid basal cell carcinoma syndrome. *Gene Reviews* (Internet), Seattle (WA): University of Washington, Seattle; 1993–2015. 2002 (updated 2013). Accessed April 2015.

BCC, Basal cell carcinoma; BCNS, basal cell nevus syndrome.

\*Diagnosed when an individual has two major criteria and one minor criterion, OR one major criterion and three minor criteria.

<sup>†</sup>See text for further discussion.

criteria for BCNS are shown in [Box 9-2](#). In a consensus statement from an international colloquium on BCNS, a modification of the diagnostic criteria was suggested such that medulloblastoma, typically desmoplastic, be included as a major (rather than a minor) criterion.<sup>182</sup>

The skin lesions of BCNS may appear as early as the first year of life but have a mean age of onset of around 20 to 23 years.<sup>180,181</sup> They involve, in decreasing order of incidence, the face, neck, back, trunk, and upper extremities. The distribution of BCCs may differ by gender, with male patients having more in the facial M-zone (forehead, temples, periorbital areas, and nose), upper back, neck, and upper extremities, and female patients having more lesions located in the scalp, upper and lower back, and lower extremities.<sup>183</sup> The BCCs in BCNS may range in number from one to well over a thousand. In addition, patients with BCNS may develop skin lesions that appear similar to nevi or seborrheic keratoses and tend to follow a more benign course, although after puberty the cutaneous lesions of BCNS tend to be more aggressive. The BCC lesions appear as flesh-colored to pink or tan dome-shaped papules that measure 1 to 10 mm ([Fig. 9-39, A](#)). Secondary changes such as ulceration, crusting, and bleeding rarely occur before puberty, but if left untreated these lesions can become extremely destructive. Unlike ordinary BCCs, BCNS-associated lesions do not appear to be induced by prolonged exposure to sunlight.

In addition to nevoid BCCs, affected individuals have a characteristic facies with coarse features, broad nasal root, hypertelorism, and other cutaneous stigmata. These include multiple small facial milia, comedones, large epidermal cysts, lipomas, fibromas, and café-au-lait macules. Shallow 2- to 3-mm palmar and plantar pits ([Fig. 9-39, B](#)), a characteristic feature of the syndrome, are seen in 70% to 90% of affected individuals. They may become more prominent after immersion of the hands or feet in water. These defective areas of keratinization usually first appear during the second decade of life or later. Palmar and plantar pits tend to have associated erythema, which on casual observation appears as multiple small red spots on the palms and soles.

Odontogenic jaw cysts occur in around 75% of patients and may present with painless swelling, jaw pain, abnormal taste, or a discharge in the mouth. The first jaw cyst often occurs before the age of 20 years, and symptoms referable to these lesions are often the presenting complaint. Jaw cysts occurring in patients with BCNS present earlier in life than those occurring in patients without BCNS.<sup>184</sup> The cysts may be multiple and may result in loosening and loss of teeth. Patients with BCNS may become edentulous at an early age.

**Figure 9-39** Basal cell nevus syndrome (BCNS). **(A)** Pigmented basal cell carcinoma on the scalp of a 12-year-old girl. **(B)** Shallow erythematous depressions (pits) on the plantar surface of an adult female with BCNS.

Musculoskeletal anomalies present in 60% to 80% of patients and include macrocephaly, frontoparietal bossing, high-arched palate, and broad nasal bridge.<sup>180</sup> Other abnormalities include splayed or bifid ribs, mandibular and maxillary bone cysts, prognathism, kyphoscoliosis, Sprengel deformity, cervical or thoracic vertebral anomalies, spina bifida, pectus excavatum and carinatum, and shortened fourth metacarpals.

The most common neurologic abnormality is calcification of the falx cerebri, which is seen in up to 90% of patients with BCNS. In addition, mental retardation, electroencephalographic abnormalities, agenesis of the corpus callosum, seizures, hydrocephalus, and deafness may occur. Other associations include anosmia, renal malformations, endocrinopathy, and blindness. Patients with BCNS appear to have a predisposition to malignancy, especially medulloblastoma, which may present early in life.<sup>185</sup> The desmoplastic subtype of medulloblastoma in children younger than 2 years of age is considered by some a major diagnostic criterion for the diagnosis of BCNS.<sup>185,186</sup> This desmoplastic variant has a favorable prognosis.<sup>187</sup> Ovarian and cardiac fibromas and meningiomas also occur at an increased rate in these patients.

The molecular cause of BCNS has been elucidated. Mutations in the human patched gene (*PTC*) have been identified in patients with BCNS as well as in those with sporadic BCCs.<sup>188–190</sup> *PTC* is located on chromosome 9q and encodes a transmembrane receptor that represses growth-factor gene transcription. The gene product of *PTC* functions as a tumor suppressor, and *PTC* mutations results in dysregulation of several genes known to play a role in both organogenesis and car-

cinogenesis.<sup>191</sup> Sequence analysis to detect mutations as well as deletion testing are both clinically available to assist in diagnosis of BCNS.

The management of patients with BCNS must be multidisciplinary and individualized. Genetic counseling is important given the autosomal dominant mode of inheritance. Family members judged to be at risk may be screened with skeletal surveys, dental radiographs, and neurologic evaluation (both clinical and radiographic). Molecular diagnosis is also possible (GeneDx, Gaithersburg, MD), with a sensitivity around 60% to 75%. Removal of cutaneous BCC may be accomplished with the same techniques as discussed earlier, and general anesthesia may be required for treatment of multiple lesions. Systemic retinoids (i.e., isotretinoin) may be useful in preventing BCCs, but its use must be balanced by potential side effects and in females the known teratogenicity. In addition, if the retinoid is discontinued, the patient may show rapid disease progression. Vismodegib, an inhibitor of the hedgehog signaling pathway approved for treatment of locally advanced or metastatic BCC, has been shown to reduce the BCC tumor burden and block growth of new lesions in patients with BCNS, though its potential benefit has been limited by adverse events that led to discontinuation by more than 50% of patients in recent study.<sup>192</sup>

It is recommended that all pediatric patients with BCNS be monitored by a medical geneticist who ensures all appropriate referrals and follow-up evaluations. Patients require regular follow-up examinations with a dermatologist, pediatric dentist/oral surgeon, and ophthalmologist, as well as referral to a neurologist and psychologist as indicated. Annual vision, hearing, and speech screenings; routine developmental screening at well-child visits; and baseline brain MRI, digital Panorex of the jaw, and spinal films are also recommended.<sup>182</sup>

## SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is a malignant tumor of the epidermis rarely seen in children. Occasionally it may arise in normal skin, but generally it is seen in skin that has been injured by sunlight, trauma, thermal burn, or chronic inflammation. Children who develop SCC often have an underlying predisposing condition, including xeroderma pigmentosum (see Chapter 19), human papillomavirus infection (especially in the immunocompromised host), or a history of organ transplantation, chemotherapy with immunosuppression, or radiation therapy. In addition, scars related to dystrophic epidermolysis bullosa (see Chapter 13) may be predisposed to the development of SCC. Although these tumors generally do not present until the third or fourth decade, they may occasionally occur during childhood.<sup>193</sup> SCC has also been reported to occur within the lesions of pansclerotic morphea of childhood.<sup>194</sup>

The most common sites for SCC are the face (in particular the lower lip and pinna of the ear) and the dorsal aspect of the hands and forearms. Lesions usually present as red, scaly papules or plaques, often with induration. Telangiectasias may be present, as may ulceration or necrosis. Lesions that arise *de novo* usually appear as solitary, slowly enlarging, firm nodules with central crusting, underlying ulceration, and an indurated base. The histologic evaluation of SCC offers prognostic information based on the depth of the lesion and the cytologic features and degree of differentiation of the cells.

The prognosis for SCC of the skin is quite variable. Easily cured small lesions arising in sun-damaged skin have a low propensity to metastasize. Lesions arising in burn scars, prior radiation fields, and chronic wounds (i.e., ulcers or epidermolysis bullosa scars; see Chapter 13) tend to be more aggressive with higher rates of metastases. Complete excision is the treatment of choice for SCC. Other treatment options that may be considered include electrodesiccation and curettage, cryotherapy, photodynamic therapy, and MMS. Sun protection and skin self-examination education is again vital.

## KERATOACANTHOMA

Keratoacanthoma (KA) is an epithelial tumor that may be clinically and histologically indistinguishable from SCC. These lesions are considered by many to be benign, and they often involute spontaneously without therapy. However, given rare reports of extensive local destruction and metastases, some consider KAs to be a variant of SCC.

KAs are usually seen in older adults with rare reports of neonatal or childhood involvement.<sup>195,196</sup> Multiple KAs characteristically have their onset in adolescence or early adult life and may occur in several clinical settings such as Ferguson Smith, Muir–Torre, or Witten–Zak syndromes. Generalized eruptive KA with the sudden onset of multiple lesions may also occur (termed the *Grzybowski type*).<sup>197</sup>

KA presents as a firm, dome-shaped nodule that generally measures 1 to 3 cm or more. The center contains a horny plug or is covered by a crust that conceals a central keratin-filled crater. The nodule generally grows rapidly and reaches its full size within 2 to 8 weeks. After a period of quiescence that may last for 2 to 8 weeks, most lesions heal spontaneously over several months with only a slightly depressed, somewhat cribriform scar in the previously affected area.

The main problem in the diagnosis of KA is its differentiation from SCC. In most cases, the rapid evolution and typical clinical appearance help to establish the correct diagnosis. Because the architecture of the lesion is as important as the cellular characteristics, full excisional biopsy is recommended to enable appropriate histopathologic evaluation. The treatment of KA is usually approached with a view toward its spontaneous resolution. Its close resemblance to SCC, however, often results in excisional biopsy. Other reported treatment options include intralesional corticosteroids, topical imiquimod, intralesional methotrexate, topical 5-fluorouracil, electrodesiccation and curettage, and radiation therapy.<sup>198–201</sup>

## Tumors of the Oral Mucosa

### WHITE SPONGE NEVUS

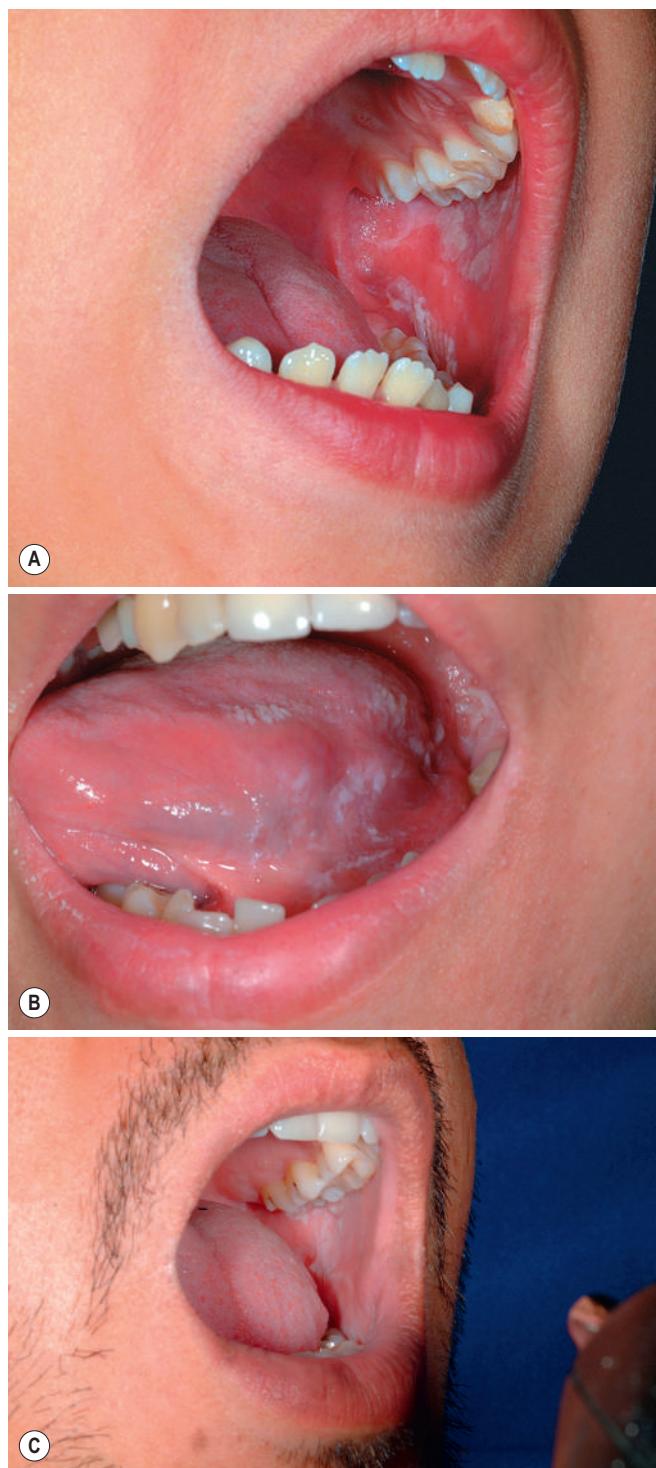

White sponge nevus is a rare, autosomal dominant condition that most often affects the oral mucosa and less commonly the mucosae of other regions. It presents as exuberant, asymptomatic white plaques on the buccal mucosae (Fig. 9-40), palate, gingivae, or sides of the tongue. Other regions that may be involved include the nasal, vaginal, labial, and anal mucosae. In some instances, the plaques may be quite thickened with fissures and folds, and occasionally a raw, denuded surface may be evident. White sponge nevus may be present at birth or may have its onset any time from infancy through adolescence. The lesions are most commonly misdiagnosed as candidiasis in young children.<sup>202</sup> It reaches its maximum severity during adolescence or early adulthood, and the lesions are entirely asymptomatic and often noted incidentally during examination. Both genders are equally affected. The differential diagnosis of white sponge nevus may include oral leukoplakia, pachyonychia congenita, dyskeratosis congenita, cheek biting, chemical burn, syphilis, betel nut or tobacco use, and lichen planus.

Defects in the genes for keratins 4 and 13 have been demonstrated to be responsible for white sponge nevus.<sup>203,204</sup> This disorder is generally benign and asymptomatic and requires no specific therapy. White sponge nevus should not be confused with focal epithelial hyperplasia (Heck disease), a rare disorder of the oral mucosa of children believed to be caused by infection with human papillomavirus, especially types 13 and 32. In patients with Heck disease, the mucosa of the lower lip is most commonly involved and reveals soft papules and plaques that tend to regress spontaneously over several months.

### LEUKOPLAKIA

*Leukoplakia* is a term generally used to describe a white plaque involving the oral mucosa that cannot be easily removed by scraping or rubbing with a cotton swab or tongue blade. It is a nonspecific term inconsistently applied to a variety of different etiologic lesions, including white sponge nevus, pachyonychia congenita, dyskeratosis congenita, hereditary benign intraepithelial dyskeratosis, hereditary mucoepithelial dysplasia, and many others. It is also used to describe white changes on the vulva of females, where its use is equally nonspecific.

*Oral leukoplakia* is the terminology usually used to describe a condition seen most often in adults and is related to a variety of factors including trauma, poor oral hygiene, chronic irritation, and use of tobacco products. It may occasionally be seen in children and has been

**Figure 9-40** Oral white sponge nevus. This 4-year-old boy (A), his two brothers, one of whom is pictured in (B), father (C), and uncle all had similar white plaques of the oral mucosa.

reported in pediatric patients with HIV infection.<sup>205,206</sup> The clinical presentation is notable for either focal or more diffuse involvement with white plaques of the buccal mucosae, hard or soft palate, lateral surfaces of the tongue, and the floor of the mouth. Mucosal biopsy with histopathologic evaluation is usually necessary to confirm the exact diagnosis, and treatment depends on the etiology. Meticulous attention to oral hygiene is useful regardless of the cause. Since oral leukoplakia may have malignant potential (eventuating into SCC),

**Figure 9-41** Nevus sebaceous. Yellow-orange, hairless plaque on the scalp.

**Figure 9-43** Nevus sebaceous. The lesion in this adolescent male demonstrates verrucous (warty) changes that are common with older age.

long-term follow-up observation is indicated, with repeat tissue biopsy when necessary.

## Tumors of the Epidermal Appendages

### NEVUS SEBACEOUS

Nevus sebaceous of Jadassohn is a common congenital lesion that occurs mainly on the face and scalp. These lesions are usually solitary and present as a well-circumscribed, hairless plaque. They are generally present at birth but may first be noted during early childhood and rarely in adult life. Although rare familial forms have been reported, these hamartomas tend to be sporadic. Multiple nevi sebaceos may occur in association with cerebral, ocular, and skeletal abnormalities as part of an ENS. This association has been termed *Schimmelpenning syndrome*.<sup>151</sup> Recently, somatic mutations in *HRAS* and *KRAS* were demonstrated in lesions of nevus sebaceous.<sup>144,207</sup>

Classic nevus sebaceous presents as a hairless, yellow to tan plaque on the scalp or face (Figs. 9-41 and 9-42). The surface may be verrucous or velvety, and the lesions are often oval or linear. In some patients hyperpigmentation may be a prominent feature, making the distinction from a verrucous epidermal nevus difficult. Nevus sebaceous may vary in size from a few millimeters to several centimeters in length. Their yellow color is related to sebaceous gland secretion, and often this color becomes less prominent after infancy. The lesions tend to enlarge proportionate with growth of the child, until puberty when they may become significantly thicker, more verrucous, and

more greasy in appearance (Fig. 9-43) as a result of hormonal stimulation of the sebaceous glands within them. Papillomatous projections may occur, sometimes simulating the appearance of verruca vulgaris.

Surgical excision, the treatment of choice for nevus sebaceous, has traditionally been recommended out of concern for the development of secondary malignant neoplasms within these lesions. Multiple secondary appendageal neoplasms may occur within nevus sebaceous, including syringocystadenoma papilliferum (the most common secondary benign neoplasm, Fig. 9-44), apocrine cystadenoma, spiradenoma, and trichoblastoma.<sup>208–210</sup> The secondary tumor that raises the most concern, however, is BCC, which in the past was estimated to occur in anywhere from 6.5% to 50% of lesions depending on the source.<sup>211</sup> More recent investigations have documented that the incidence of BCC is actually quite low, and in fact trichoblastoma (a benign proliferation that appears to be quite common) may be easily mistaken for BCC.<sup>209,212–214</sup> Other tumors that have been reported within lesions of nevus sebaceous include KA, leiomyoma, piloleiomyoma, SCC, apocrine carcinoma, and malignant eccrine poroma. Malignant degeneration is usually heralded by the appearance of a discrete nodule with or without ulceration.

The timing of surgery in those patients for whom it is chosen is controversial. Many factors need to be considered, including size and location of the nevus, its cosmetic significance, and the risk-to-benefit ratio of general anesthesia (needed early in life) versus local anesthesia (a possibility when surgery for smaller lesions is delayed until later childhood or adolescence). These decisions must be made by the

**Figure 9-45** Nevus comedonicus. Multiple open (blackheads) and closed (whiteheads) comedones in a linear distribution.

parents (and patient, where appropriate) with input from the involved physician(s). The practitioner should provide parents with the objective data and allow them to make this personal decision, offering support and guidance as necessary.

### NEVUS COMEDONICUS

Nevus comedonicus is a rare type of organoid nevus with a hair follicle origin. These lesions are often present at birth, or they may become evident over the first decade of life. There is no racial or sexual predisposition. Nevus comedonicus presents as a plaque composed primarily of hyperkeratotic papules and horny plugs (resembling the comedones of acne vulgaris) with varying degrees of erythema (Fig. 9-45). Lesions are most common on the face, neck, trunk, and upper extremities and are often linear or band-like in distribution. They tend to grow as the child matures, and large lesions extending above the surrounding cutaneous surface may give a grater-like feeling to the skin. There is a spectrum of involvement with nevus comedonicus, from simple comedonal lesions to those with significant inflammation, cysts, and even scarring.<sup>215</sup> Secondary infection and abscess formation rarely occur.

The differential diagnosis of nevus comedonicus includes nevus sebaceous, acne neonatorum, and in older patients, comedonal acne. Although the lesions usually occur as a sporadic finding, multiple or extensive lesions may be associated with abnormalities in other organ systems as part of the nevus comedonicus type of ENS.<sup>151,216</sup>

Management of nevus comedonicus is challenging. Topical retinoids, ammonium lactate lotion, or topical antibiotics may each be useful for some patients. Pore strips have been reported useful for removal of the keratin plugs.<sup>217</sup> However, most medical therapies are ineffective, and the definitive therapy for cosmetically significant lesions is surgical excision.

### TRICHOEPITHELIOMA

Trichoepitheliomas may occur as a benign, autosomal dominantly inherited disorder characterized by the presence of multiple small lesions occurring primarily on the face or as a solitary nonhereditary tumor seen in early adult life or occasionally during childhood. BSS has traditionally been used to describe an autosomal dominant disorder characterized by numerous trichoepitheliomas, cylindromas (see also *Cylindroma* section) and spiradenomas, all benign skin appendageal tumors. *Multiple familial trichoepithelioma* (MFT) refers to an autosomal dominant disorder characterized by numerous trichoepitheliomas involving the central face and often starting during childhood. The term *trichoblastoma* has been used to denote benign

**Figure 9-46** Multiple trichoepitheliomas. Multiple flesh-colored papules of the medial cheek and nose. (Courtesy of Keren Horn, MD.)

neoplasms of follicular differentiation. Some now consider these two conditions to be interchangeable, with others considering trichoepithelioma to be one type of trichoblastoma.

Multiple trichoepitheliomas generally begin during early childhood or around puberty as small, firm, flesh-colored papules and nodules on the face (Fig. 9-46), particularly in the nasolabial folds and over the nose, forehead, upper lip, and eyelids and occasionally the scalp, neck, trunk, scrotum, and perianal area. The lesions measure 2 to 5 mm in diameter, are firm, and have a translucent sheen. Occasionally, telangiectatic vessels are present over the rounded translucent surface of larger lesions. Trichoepitheliomas may enlarge slowly, reaching up to 5 mm on the face and ears and up to 2 to 3 cm in other sites; they often coalesce to form nodular aggregates. Mutations in the CYLD gene, a tumor-suppressor gene, appear to be the genetic basis for MFT, BSS, and familial cylindromatosus (FC; also known as *turban tumor syndrome*), a disorder characterized by multiple cylindromas as the only tumor type (see also *Cylindroma* section).<sup>218–220</sup>

Solitary, nonhereditary trichoepitheliomas usually develop during the second or third decade of life and generally appear on the face. They may also be distributed on the scalp, neck, trunk, upper arms, or thighs. Solitary lesions appear as firm, flesh-colored papules and papulonodules and generally reach 5 mm or slightly larger in diameter.

Desmoplastic trichoepithelioma is a variant that presents as an indurated, flesh-colored to red papule or plaque with an elevated annular border and central depression. It occurs most commonly on the face, especially the cheek. Although most commonly seen in early adulthood, desmoplastic trichoepitheliomas may appear during the second decade, are much more common in females, and may occur in a familial fashion.<sup>221</sup> In one report, desmoplastic trichoepithelioma was initially mistakenly diagnosed as SCC.<sup>222</sup>

Although trichoepitheliomas are benign lesions, treatment may be cosmetically desirable, and at times biopsy is indicated to differentiate the lesion from other cutaneous neoplasms. Surgical excision is the treatment of choice, although electrodesiccation, cryotherapy, radiotherapy, dermabrasion, and laser therapy have also been utilized.<sup>220</sup>

### TRICHILEMMOMA

Trichilemmoma is another benign appendageal neoplasm derived from the hair follicle. These lesions may be solitary or multiple and present as flesh-colored papules or nodules, occasionally with a verrucous (wart-like) surface. The most common location for trichilemmomas is the face, although genitals are another common site and they can occur anywhere on the cutaneous surface. A desmoplastic form (desmoplastic trichilemmoma) may occur, and at times the

deeper component of these lesions may histologically simulate invasive carcinoma.<sup>223</sup> Treatment of these benign lesions may be accomplished with surgical excision or ablative procedures when desired.

Multiple trichilemmomas may be seen in the setting of the multiple hamartoma syndrome, CS. This autosomal dominant disorder is characterized by hamartomas in multiple organ systems including skin, breast, thyroid, gastrointestinal (GI) tract, endometrium, and brain.<sup>224</sup> Mucocutaneous lesions, which are present in nearly all patients, include multiple trichilemmomas, palmoplantar keratoses, oral papillomatosis, and sclerotic fibromas.<sup>224,225</sup> Pigmented macules of the genitalia, café-au-lait macules, acanthosis nigricans, skin tags, lipomas, and vascular malformations may also occur in CS.<sup>226</sup> Other benign extracutaneous manifestations include fibrocystic breast disease, breast fibroadenomas, thyroid adenomas, goiter, neuromas, meningiomas, and intestinal polyposis. Lhermitte–Duclos disease, considered to be a component of CS, results in hamartomatous growths arising in the cerebellum and presents with headache, ataxia, and visual disturbance. Patients with CS also have an increased risk of certain malignancies, including those of the breast (up to 30% to 50% of female patients) and thyroid gland (nonmedullary thyroid carcinoma, 3% to 10%).<sup>224,227</sup> The potentially increased risk of other cancers, including renal cell carcinoma, MM, and colon cancer is less clear.<sup>227</sup> Skeletal abnormalities may include macrocephaly, scoliosis, and pectus excavatum. Patients may also have mental retardation.

Management of patients with CS consists of early recognition, specialist referral, treatment for cutaneous lesions (as needed/available), genetic counseling, and appropriate cancer surveillance, which should include breast self-examination, regular physician examinations, mammography, breast MRI, and thyroid ultrasound.<sup>228</sup>

Mutations in the tumor-suppressor gene *PTEN*, which encodes a tumor-suppressor phosphatase involved in cellular regulation, have been detected in patients with CS as well as in patients with Bannayan–Riley–Ruvalcaba syndrome (BRRS; see below and Chapters 11 and 12), Proteus or Proteus-like syndrome (see Chapter 12), adult Lhermitte–Duclos disease, and autism-like disorders associated with macrocephaly.<sup>227</sup> CS and BRRS share many similarities, including the mucocutaneous findings of facial trichilemmomas, acanthosis nigricans, lipomas, palmoplantar keratoses, pigmented macules of the genitalia, and oral papillomatosis.<sup>226</sup> Mucocutaneous neuromas have been highlighted as another overlap finding that may be seen in both CS and BRRS.<sup>229</sup> Macrocephaly and developmental delay are also seen in BRRS. The identification of kindreds with both diseases in the family, as well as identical *PTEN* mutations and overlapping clinical features, suggested that CS and BRRS may represent different phenotypic expressions of the same disease.<sup>224,226,230</sup> Recently the disorders thus far attributable to *PTEN* mutations have been collectively referred to as *PTEN* hamartoma tumor syndrome.<sup>231</sup> In a prospective study of 368 individuals meeting criteria for CS and with confirmed germline *PTEN* mutation, incidence ratios were elevated not only for breast and thyroid cancer, but also for colorectal cancer, kidney cancer, and melanoma, suggesting the need for surveillance for these malignancies in this patient cohort as well.<sup>232</sup>

## TRICHOFOLLICULOMA

Trichofolliculoma is an uncommon benign appendageal neoplasm, again of hair follicle derivation, that usually occurs as a solitary lesion. Trichofolliculomas most often involve the head and neck regions of adults but may occur during childhood. Trichofolliculomas present as a 2- to 10-mm, slow-growing, flesh-colored or pearly papule or nodule with a smooth surface. There is often a central pore with a protruding woolly or cotton-like tuft of hair (a highly diagnostic clinical feature). On occasion, the protruding hairs may be so fine that a magnifying lens may be required to detect their presence. Treatment of trichofolliculoma by local surgical excision generally produces a good cosmetic outcome.

## PILOMATRICOMA

Pilomatrixoma (also known as *calcifying epithelioma of Malherbe* or *pilomatixoma*) is a benign tumor derived from the hair matrix that usually develops within the first two decades of life. Pilomatrixomas

usually present as solitary lesions of the face, neck, upper trunk, or upper extremities. The two most common locations in studies appear to be the head and neck and the upper extremities.<sup>233,234</sup> Clinically, pilomatrixomas appear as flesh-colored to white, firm papules or papulonodules that may have an overlying pink to blue hue (Fig. 9-47). They are generally very hard, owing to calcification, and may demonstrate a positive “teeter-totter sign,” whereby downward pressure directed at one end of the lesion causes the other end to spring upward in the skin. Another useful sign is the “tent sign,” whereby multiple facets and angles (resembling a tent) are visualized when the skin overlying the lesion is stretched (Fig. 9-48).

Pilomatrixomas range in size from 5 mm to over 5 cm in diameter. Although pilomatrixomas are usually not hereditary, familial cases have been recognized, and some familial forms have been associated with myotonic dystrophy, an uncommon autosomal dominant disorder characterized by hypotonia, muscle wasting, cataracts, hypogonadism, progressive mental retardation, and frontal baldness.<sup>235–237</sup> Multiple pilomatrixomas have also been noted in patients with Gardner syndrome, Rubinstein–Taybi syndrome, and trisomy 9.<sup>238–241</sup> Other

**Figure 9-47** Pilomatrixoma. This preauricular blue papulonodule was very firm to palpation.

**Figure 9-48** Pilomatrixoma. This lesion exhibits the “tent sign” as the adjacent skin is stretched.

variants include cystic-appearing pilomatrixomas, in which hemorrhage may result in blue-red translucent nodules with rapid enlargement; perforating pilomatrixomas; pilomatrix carcinoma (extremely rare); and extruding pilomatrixomas (draining lesions that spontaneously discharge a chalky material containing calcium). Activating mutations in  $\beta$ -catenin, a participant in the Wnt signaling pathway, have been identified in pilomatrixomas.<sup>242</sup> In patients with multiple pilomatrixomas, mutations in the adenomatous polyposis coli (*APC*) gene have been identified.<sup>243</sup>

Pilomatrixomas may occasionally develop inflammation or swelling and may be painful when subjected to pressure on the affected region of skin. Definitive therapy is accomplished by surgical excision. Patients with multiple lesions or familial disease should be examined and monitored closely for potentially associated disorders, especially myotonic dystrophy and Gardner syndrome. Importantly, the onset of myotonic dystrophy may not occur until adulthood, and molecular diagnosis is possible.<sup>236</sup>

### SYRINGOMA

Syringomas represent benign tumors of eccrine (sweat gland) structures and are predominantly seen in females. The lesions may occur at any age but commonly present initially during puberty or adolescence as small, firm, flesh-colored to yellow, translucent 1- to 3-mm papules (Fig. 9-49). They are usually multiple but may occasionally be solitary. In more than half of the patients the lesions are located on the lower eyelids. Other common locations include the lateral neck, chest, abdomen, back, upper arms, thighs, and genitalia. Syringomas occur with increased incidence in patients with Down syndrome. They may occasionally occur in an eruptive fashion and tend to be influenced by hormones, as evidenced by increased size during pregnancy or the premenstrual period and enlargement in women receiving hormone therapy.

Syringomas gradually enlarge until they attain their full size and then persist, with little tendency for spontaneous resolution. Although they are benign, they may be of significant cosmetic concern. Treatment, however, is difficult. Therapeutic options include electrode desiccation, cryosurgery with liquid nitrogen, or local surgical excision. CO<sub>2</sub> laser ablation and trichloroacetic acid have also been found useful.<sup>244</sup>

### ECCRINE POROMA

Eccrine poromas are benign cutaneous tumors that generally arise from the intraepidermal eccrine sweat duct unit. They occur most often during middle age or later but have been noted to develop as early as 15 years of age. Eccrine poromas present as firm papules, plaques, or nodules, and may be flesh-colored to red. They are usually solitary, and range in size between 2 and 12 mm in diameter. They

**Figure 9-49** Syringomas. These multiple, flesh-colored small papules were present bilaterally in the inferior periorbital regions of this young girl with Down syndrome.

most commonly occur on the plantar surface of the foot and occasionally on the palms, fingers, neck, or trunk. In some lesions, the appearance is quite vascular and may simulate pyogenic granuloma. A striking clinical feature is the presence of a cup-shaped shallow depression from which the tumor grows and protrudes. Malignant eccrine poroma, also known as eccrine porocarcinoma, is a very rare tumor usually occurring in adults, although pediatric cases have been reported.<sup>245</sup> The treatment of choice for eccrine poroma is surgical excision.

### CYLINDROMA

Cylindromas (also known as *turban tumors*) are benign neoplasms of either eccrine or apocrine origin and characterized by firm, rubbery, pink to bluish plaques and nodules. They may range in size from a few millimeters to several centimeters and are located primarily on the scalp and occasionally the face, trunk, or extremities. Cylindromas may occur singly or in multiples, and occasionally they coalesce to result in large mosaic tumors. Multiple lesions may occur as part of the autosomal dominant BSS (with multiple trichoepitheliomas and occasionally other appendageal tumors; see also *Trichoepithelioma* section). This disease has been mapped to 16q12-13, and mutations in the *CYLD* gene have been identified in families with this disorder.<sup>246,247</sup> Treatment consists of surgical excision, although CO<sub>2</sub> laser surgery has also been demonstrated useful.<sup>248</sup> Cylindromas are almost invariably benign, although malignant transformation has been rarely reported.

## Dermal Tumors

### ANGIOFIBROMA

Angiofibromas are benign dermal neoplasms that may occur as isolated or multiple lesions. The term *angiofibroma* actually describes the histologic appearance of these lesions (which reveals dermal fibroplasia and dilated blood vessels), but they may present in a variety of clinical fashions. Clinical subtypes include fibrous papules, pearly penile papules, and periungual fibromas. Another presentation pattern is that of multiple facial angiofibromas, which are commonly seen in patients with tuberous sclerosis (see Chapter 11), in which setting they have been erroneously referred to as *adenoma sebaceum*, multiple endocrine neoplasia type 1 (see Chapter 23), and Birt-Hogg-Dube syndrome (characterized classically by fibrofolliculomas, trichodiscomas, and acrochordons).<sup>249</sup>

A fibrous papule presents as a solitary, flesh-colored shiny papule, most often on the nose of adults. The differential diagnosis may include intradermal nevus, BCC, or another appendageal tumor. These lesions are treated with shave excision or electrocautery. Pearly penile papules present as tiny, flesh-colored to white papules on the glans penis of postpubertal men. They are most commonly distributed along the corona, and their importance lies in distinguishing them from genital condylomata (often a source of anxiety for the affected individual). This distinction is usually quite simple given their appearance, multiplicity, and localization. Treatment of pearly penile papules is unnecessary. Periungual fibromas present as flesh-colored filiform growths arising from the proximal nailfold region. Although they occasionally occur sporadically, multiple lesions are pathognomonic for tuberous sclerosis.

### CONNECTIVE TISSUE NEVUS

Connective tissue nevus (also known as *connective tissue hamartoma*) is a localized hamartoma of either dermal collagen or elastic fibers or both. These benign skin lesions may be sporadic or hereditary and can be seen as a component of several syndromes. For instance, the shagreen patch and fibrous forehead plaque seen in tuberous sclerosis (see Chapter 11) are both forms of connective tissue nevi. In addition, the palmoplantar cerebriform hyperplasia that occurs in patients with Proteus syndrome (see Chapter 12) represents excess collagen and thus could also be classified under this umbrella term. This section discusses primarily the sporadic, nonsyndromic form of connective tissue nevus.

**Figure 9-50** Connective tissue nevus. This flesh-colored, dermal plaque on the back of a school-aged boy had been present for several years.

**Figure 9-52** Darier sign in mastocytosis. Edema and surrounding erythema developed within minutes after firmly stroking this lesion.

**Figure 9-51** Connective tissue nevus. A cerebriform, fleshy plaque on the cheek of a newborn male.

These lesions usually present as asymptomatic, flesh-colored dermal plaques composed of multiple papules. They may be quite subtle (Fig. 9-50), or they may be associated with significant thickening, cobblestoning, or cerebriform changes (Fig. 9-51). Solitary plaques may occur anywhere on the cutaneous surface, and multiple lesions are often distributed symmetrically on the back, buttocks, and extremities. The differential diagnosis may include smooth muscle hamartoma (see [Congenital Smooth Muscle Hamartoma](#) section).

Another form of connective tissue nevus, dermatofibrosis lenticularis disseminata, has been reported in association with a specific bone dysplasia termed *osteopoikilosis*. This association is also known as Buschke-Ollendorf syndrome (see Chapter 6). The cutaneous lesions in this setting usually appear in adult life, but their onset has also been reported during the first year or early childhood. They appear as flesh-colored to yellow papules, usually a few millimeters in size, distributed on the trunk, buttocks, and extremities. They often represent hamartomas of elastic tissue (elastomas) histologically. The bony lesions are usually asymptomatic and are often noted incidentally as focal sclerotic areas on bone radiographs. They may occasionally be mistaken for foci of metastatic malignancy, highlighting the importance of familiarity with this disorder and its associated skin lesions.

Connective tissue nevi are generally asymptomatic and not usually of cosmetic significance. If the diagnosis is unclear, incisional biopsy is useful. Surgical excision is otherwise unnecessary.

## MASTOCYTOSIS

The term *mastocytosis* refers to a group of clinical disorders characterized by the accumulation of mast cells in the skin and at times other organs of the body. It may appear at any time from birth to middle age. In approximately 55% of patients, the onset occurs before the age of 2 years, and for 10%, the onset is between 2 and 15 years of age.<sup>250</sup> Mastocytosis may be congenital in up to 25% of pediatric-onset cases. The growth and regulation of mast cells is dependent on stem cell factor, which is the ligand for the protein product of the *c-KIT* gene. Studies have documented *c-KIT* mutations in adult patients with mastocytosis, and activating *c-KIT* mutations have also been demonstrated in pediatric mastocytosis in codon 816 (exon 17) as well as exons 8 and 9.<sup>251</sup> Although mastocytosis is generally a sporadic disorder, familial cases have been reported.<sup>252–254</sup>

The clinical spectrum of cutaneous mastocytosis includes mastocytomas (single or multiple), urticaria pigmentosa, bullous mastocytosis, diffuse cutaneous mastocytosis, and telangiectasia macularis eruptiva perstans (TMEP). The traditional classification of adult disease includes indolent mastocytosis, mastocytosis with an associated hematologic disorder, mast cell leukemia, and lymphadenopathic mastocytosis with eosinophilia.<sup>250</sup> Alternatively, for either pediatric or adults patients, mastocytosis may be divided into cutaneous and systemic forms with the potential for overlap between these two. Although the disease may be classified by several different schemas, there appear to be some fairly consistent differences between adult and pediatric mastocytosis. These include the following for pediatric disease: early onset, usually within the first year of life; rare occurrence of TMEP; tendency toward spontaneous resolution, often before puberty; rare association with hematologic disorders; and rare infiltration of other organs aside from the skin.<sup>255</sup>

Although the classification of mastocytosis is often confusing, it can be somewhat simplified when considering the typical childhood presentations. Children most commonly present with mastocytomas (either solitary or multiple), urticaria pigmentosa, or occasionally diffuse cutaneous mastocytosis. All three of these childhood forms may display vesicular or bullous variants. Vesiculation is presumably related to histamine- or other chemical mediator-induced transudating leakage in a group susceptible to blister formation by less secure attachments of the epidermis to the underlying dermis.<sup>256</sup>

The diagnosis of all forms of cutaneous mastocytosis is aided by the phenomenon known as the Darier sign. This finding, a hallmark of the disorder, is seen in 90% of patients with skin disease and consists of localized erythema and urticarial wheals (Fig. 9-52) that develop after gentle mechanical irritation, such as might be induced by rubbing with a tongue blade or the blunt end of a pen or pencil. This urtication develops within a few minutes after the stimulus and may persist as long as 30 minutes to several hours. Occasionally, blister formation may result. It should be noted, though, that the Darier sign

### Box 9-3 Potential Triggers of Mast Cell Degranulation

#### Physical

Exercise, heat, hot baths, hot beverages, cold exposure, sunlight, stress

#### Medications (systemic)

Aspirin, alcohol, morphine, codeine, dextromethorphan, NSAIDs, opiates, amphotericin B, thiamine

#### Medications (topical)

Polymyxin B

#### Medications sometimes used with general anesthesia

D-tubocurarine, scopolamine, decamethonium, gallamine, pancuronium

#### Local anesthetics

Tetracaine, procaine, methylparaben

#### X-ray contrast

Iodine-containing contrast media

#### Venoms

Snakebites, bee stings, jellyfish stings

#### Foods

NSAIDs, Nonsteroidal anti-inflammatory drugs.

**Figure 9-53** Solitary mastocytoma. An edematous plaque with mild surrounding pigmentation.

may be negative in mastocytosis, especially in patients with entirely flat lesions at baseline.

Mast cell mediators include histamine, prostaglandin D<sub>2</sub>, heparin, tryptase, chymase, leukotrienes, and others. Cutaneous symptoms related to release of these mediators in the setting of mastocytosis may include flushing, blistering, and itching. Systemic symptoms may include nausea, abdominal pain, diarrhea, bone pain, hypotension, and less often, pulmonary signs. Whereas the extent and density of cutaneous lesions may correlate with systemic symptoms in adults, such a correlation is lacking in children with mastocytosis.<sup>257</sup> There are many potential triggers of mast cell degranulation, including physical stimuli, drugs, and foods, and these are listed in **Box 9-3**. Most of these triggers are clinically insignificant in children with more mild forms of the disease, but exposures should be minimized in those at the more severe end of the spectrum or with a history of related systemic symptoms. A disease severity index, referred to as the *Scoring Mastocytosis (SCORMA) index*, has been developed and was demonstrated to correlate with the serum tryptase level in pediatric and adult cutaneous mastocytosis.<sup>258</sup> This index incorporates extent of surface area involvement, lesion intensity, and subjective symptoms (i.e., flushing, diarrhea, pruritus).

Mastocytomas are a common type of childhood mastocytosis. They may be either solitary or multiple and present as flesh-colored to yellow-orange-tan papules (**Fig. 9-53**) or plaques. Some lesions may have a bruise-like appearance, and others may present in similar fashion to café-au-lait macules.<sup>255</sup> They may range in size from a few

**Figure 9-54** *Peau d'orange* appearance of a mastocytoma. This plaque-like mastocytoma shows the characteristic surface changes.

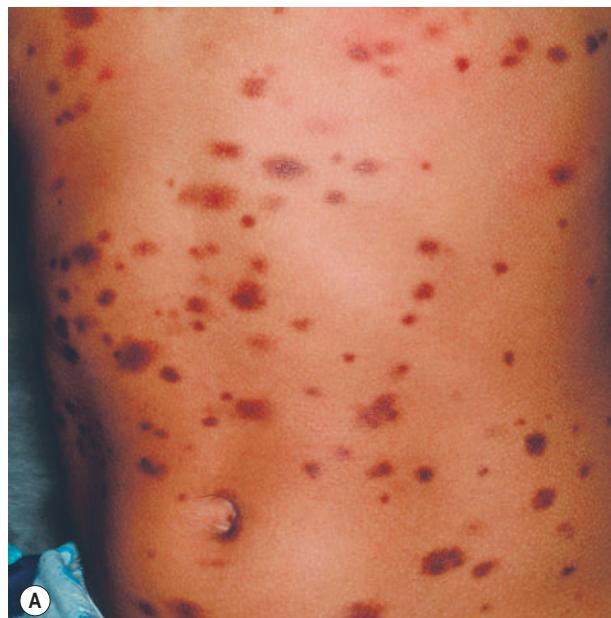

millimeters to several centimeters and are present at birth in around 40% of patients.<sup>259</sup> In the remainder, they generally appear by one year of age. The surface of the lesion often reveals a *peau d'orange* (orange peel-like) appearance (**Fig. 9-54**), and the Darier sign is notoriously positive. Occasionally stroking or rubbing of even a solitary lesion may provoke symptoms of flushing or colic. Mastocytomas may occur on any part of the body but are noted most often on the arms, neck, and trunk. A history of intermittent blistering of the affected area may be obtained, and in this setting misdiagnosis of bullous impetigo or herpes simplex infection is common. The tendency toward vesiculation tends to disappear within 1 to 3 years. Although the course of mastocytomas is generally benign and the lesions usually involute over several years, there have been reports of solitary mastocytosis eventuating in generalized urticaria pigmentosa.<sup>260</sup>

Urticaria pigmentosa is the most common presentation of mastocytosis. It presents with multiple, well-demarcated, tan to red-brown macules and papules (**Fig. 9-55**) that may occur anywhere on the cutaneous surface. Mucous membranes may be involved, and palms and soles are usually spared. Some lesions may have a purpuric quality, and occasionally a yellow coloration is noted. There may be tens to hundreds of lesions ranging in size from a few millimeters to several centimeters. The Darier sign is positive, and dermatographism may be present in 30% to 50% of patients. The lesions of urticaria pigmentosa may become vesicular or bullous (**Fig. 9-56**), a presentation termed *bullous mastocytosis*. These blisters may result in pain and secondary infection but generally heal without scarring. Beyond the age of 2 years, bullous changes are unusual.<sup>250</sup>

Diffuse cutaneous mastocytosis is a less common variant of mastocytosis, especially in children. This presentation is characterized by diffuse infiltration of the skin by mast cells with skin that may appear grossly normal, thickened, doughy, reddish-brown, or *peau d'orange* in texture (**Fig. 9-57**). There may be a yellow, carotenemia-like color present, and occasionally these patients present with extensive bullous eruptions. Patients with the diffuse cutaneous form appear to have the highest rate of systemic disease and may experience intense generalized pruritus, flushing, temperature elevation, vomiting, diarrhea, abdominal pain, GI ulceration, or respiratory distress. Overt shock may occur in this form of mastocytosis.

TMEP is a variant of mastocytosis seen usually in adults and only rarely reported in children. Patients with TMEP have an eruption of small, red-brown, telangiectatic macules on the trunk and extremities with little or no tendency toward urtication.

Systemic mastocytosis is markedly more common in adults than in children with mastocytosis. The most commonly involved systems are GI and skeletal, although the lungs, kidneys, lymph nodes, myocardium, pericardium, liver, spleen, and bone marrow may also be affected. Skeletal lesions may consist of radiopacities, radiolucencies, or a mixture of both. These changes are quite rare in children with the disorder.<sup>261</sup> Hepatomegaly, splenomegaly, and lymph node

enlargement may also occur. GI symptoms include abdominal pain, diarrhea, nausea, and vomiting. GI hemorrhage may occasionally occur and is often secondary to gastritis or peptic ulcer disease. Children with the diffuse cutaneous form of mastocytosis may be at particular risk for this complication.<sup>250</sup> The "mastocytosis syndrome" results from massive histamine release with symptoms including bronchospasm, headache, flushing, diarrhea, pruritus, and hypotension. It occurs most often in infants or young children with the diffuse cutaneous form of the disease, and death may occasionally result.

The increased risk of development of a hematologic malignancy is a major concern in adults with mastocytosis, but significant hematologic consequences in children are extremely rare.<sup>262</sup> In a series of 15 patients with pediatric mastocytosis who were observed for approximately 20 years, some bone marrow specimens revealed increased mast cells, but this finding was not predictive for disease severity or persistence of symptoms. Furthermore none of the patients in this series developed hematologic malignancy. The authors recommended bone marrow studies only in children with evidence of systemic disease including organomegaly, elevated tryptase, or unexplained peripheral blood abnormalities.<sup>263</sup>

Anesthetic management of pediatric patients with mastocytosis has traditionally been viewed as complex and risky given the nature of the disease, the degranulation effects of some anesthetic agents, and the reported adult literature. Recent reports, however, suggest that pediatric patients with cutaneous (vs. systemic) mastocytosis are at fairly low risk for major anesthesia-related complications.<sup>264,265</sup> Anesthesia considerations for patients with pediatric mastocytosis are listed in Box 9-4.

The diagnosis of pediatric mastocytosis is often based on the characteristic cutaneous findings and a positive Darier sign. Although it is usually a straightforward diagnosis, atypical or unusual presentations or those lacking skin involvement may pose a diagnostic challenge. When skin lesions are present, the diagnosis can be confirmed with skin biopsy, which reveals an accumulation of mast cells in the dermis. Special immunohistochemical stains such as Giemsa, toluidine blue, or tryptase antibodies may be useful in confirming the mast cell nature of the infiltrate. Biopsy of the bone marrow or GI tract may be necessary if such organ involvement is suspected and the patient lacks cutaneous lesions.

Indirect methods for diagnosing mastocytosis are also available. Measurement of serum tryptase, a protease produced by mast cells, is helpful in supporting the diagnosis.<sup>266</sup> Two forms ( $\alpha$  and  $\beta$ ) have been identified, and measuring both of these mediators can be useful for correlation with the extent of mast cell disease. Urinary histamine and its metabolites may also be helpful. High levels of urinary N-methylhistamine may be suggestive of more extensive involvement.<sup>267</sup> Urinary N-methylimidazoleacetic acid is another histamine metabolite that is useful as a chemical marker for the disease.<sup>268</sup>

Extensive laboratory or radiographic studies or invasive diagnostic procedures in pediatric patients with mastocytosis are generally not

**Figure 9-56** Bullous mastocytosis. This 8-month-old female had widespread mastocytosis with blister formation. Note the diffuse distribution of infiltrative plaques, *peau d'orange* changes, superficial erosions, and intact bullae of the shoulders, upper back, and flank.

#### Box 9-4 Anesthesia Considerations in Pediatric Mastocytosis Patients

- Ensure adequate familiarity of anesthesiologist with pediatric mastocytosis and preparedness to treat possible adverse events during anesthesia
- Review detailed history of past clinical drug reactions before anesthesia
- Consider baseline serum tryptase, which may be useful to:
  - Suggest systemic mastocytosis (and concomitant higher risk of anesthetic reaction), if extreme elevation
  - Diagnose possible anesthesia-related adverse events, if significantly elevated from baseline
- Avoid preoperative drug skin testing
- Continue scheduled maintenance mastocytosis medications
- Consider administration of incremental (vs. single boluses) of necessary agents known to be mast cell degranulators
- Administer NSAIDs with caution and only in the absence of a history of sensitivity
- Consider patient positioning to minimize mechanical pressure on skin during anesthesia

Modified from Carter MC, Uzzaman A, Scott LM, et al. Pediatric mastocytosis: routine anesthetic management for a complex disease. *Anesth Analg* 2008;107:422–7, and Ahmad N, Evans P, Lloyd-Thomas AR. Anesthesia in children with mastocytosis: a case based review. *Paediatr Anaesth* 2009;19(2):97–107. NSAIDs, Nonsteroidal anti-inflammatory drugs.

indicated. However, in patients with extensive disease (i.e., extensive urticaria pigmentosa or diffuse cutaneous mastocytosis), complete blood cell count with peripheral smear and blood chemistry studies should be performed with occasional follow-up tests. Other diagnostic studies such as abdominal ultrasound, endoscopy, bone scan, or bone marrow biopsy should be reserved for patients in whom specific symptoms suggest systemic disease.<sup>250,262,263</sup>

The course and prognosis of mastocytosis depends on the clinical subtype, severity of disease, and age of onset. In general, the prognosis for childhood mastocytosis is favorable in most patients. Symptoms are estimated to improve by adolescence in up to 50% of patients,<sup>269</sup> but complete resolution may occur less often than previously believed. In one study, 5 of 33 children had complete resolution, and 21 of the 33 had improvement by adolescence.<sup>270</sup> In the previously mentioned series of 15 pediatric patients with mastocytosis studied longitudinally over 20 years, complete regression of disease occurred in 67%, and another 20% experienced major regression of symptoms.<sup>263</sup>

The treatment of mastocytosis is primarily symptomatic, because no specific therapy or cure currently exists for this disorder. Patients (and/or their parents) should be counseled about the disease, its natural history, differences between pediatric and adult mastocytosis, and possible triggers of mast cell degranulation (see Box 9-3). Nonselecting histamine type 1 (H1) receptor antagonists are a good initial treatment of choice and include cetirizine, levocetirizine, loratadine, and fexofenadine. The long half-life and nonsedating nature of these medications offer advantages over traditional antihistamines. In patients with severe involvement or symptoms, a classic H1 antagonist (i.e., hydroxyzine, diphenhydramine, and cyproheptadine) may be useful. The addition of an H2 antagonist (i.e., cimetidine, ranitidine, famotidine) may be considered, especially in patients with flushing or marked GI symptoms.

Oral cromolyn sodium has been found useful in treating GI symptoms of mastocytosis, although controlled studies in children are lacking. Ketotifen, a mast cell stabilizer unavailable in the oral form in the United States, has shown promise in alleviating symptoms. Psoralen plus ultraviolet A light (PUVA) therapy has been demonstrated useful in urticaria pigmentosa, diffuse cutaneous mastocytosis, and systemic mastocytosis.<sup>271,272</sup> This therapy is more challenging though, and has a higher risk-to-benefit ratio in children. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs), although they may induce mast cell degranulation, may paradoxically be used to reduce prostaglandin-dependent flushing in some patients. Although topical agents are not typically effective, some mastocytomas have been noted to improve or disappear after therapy with a potent topical corticosteroid under occlusion. Additionally, two patients were reported whose mastocytomas responded to topical pimecrolimus cream in

**Figure 9-58** Granuloma annulare. Annular, flesh-colored, non-scaly plaques.

conjunction with a daily oral antihistamine.<sup>273</sup> A brief course of oral corticosteroids (i.e., 1 mg/kg per day of prednisone or prednisolone for 4 to 6 weeks) may be quite effective for symptomatic patients but obviously is not an appropriate long-term therapy. Cyclosporine and interferon  $\alpha$ -2b have been used in some adults with more aggressive forms of mastocytosis, and imatinib (a tyrosine-kinase inhibitor used in the treatment of some malignancies) was reportedly effective in a young adult with pediatric-onset, indolent systemic mastocytosis.<sup>274</sup> Lastly, patients (parents of children) at risk for recurrent hypotensive episodes or mastocytosis syndrome should have a premeasured epinephrine pen kit (EpiPen or EpiPen Jr) with them at all times for emergency use. Information regarding patient support groups and education for pediatric mastocytosis ([www.mastokids.org](http://www.mastokids.org)) should be given.

#### GRANULOMA ANNULARE

Granuloma annulare (GA) is a fairly common skin disorder characterized by papules or nodules grouped in a ring-like or circinate configuration. Although GA may occur on any part of the body, it often involves the lateral or dorsal surfaces of the hands, feet, wrists, and ankles. Patients may have solitary lesions or multiple sites of involvement. GA may occur at any age and is especially common in school-age children.

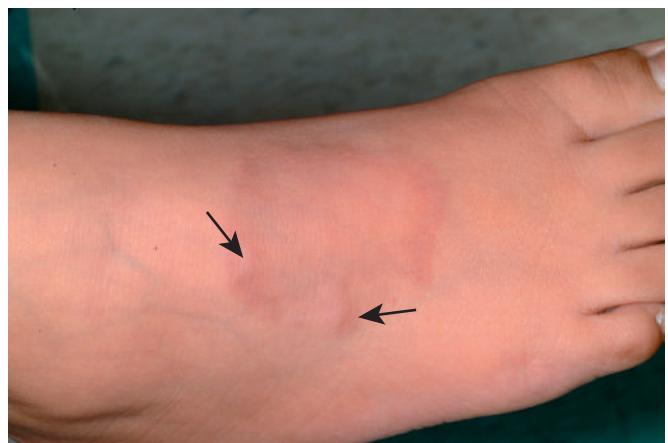

The cause of GA is unknown. Various studies have suggested a possible association between GA and diabetes mellitus, but this hypothesis remains controversial and some studies refute it.<sup>275–277</sup> There appears to be a greater risk of dyslipidemia in adult patients with GA, notably the generalized form; in one case-control study, adults with GA had four times the odds of developing dyslipidemia (including significant differences in total cholesterol, triglycerides and low-density lipoprotein-C levels) compared to age- and sex-matched controls.<sup>278</sup> This association has not been confirmed in children. Other purported associations have included tetanus or bacille Calmette-Guérin (BCG) vaccination, hepatitis B infection, *Borrelia* infection, Hodgkin disease, leukemia, or a hypersensitivity reaction to an unidentified antigen.<sup>279–282</sup> In some individuals GA has been noted following trauma, sun exposure, and insect bites.

GA most classically presents with an annular, smooth, non-scaly plaque with a border composed of numerous small papules (Figs. 9-58 and 9-59). Patients are often misdiagnosed with tinea corporis and have previously failed topical antifungal therapy. Early lesions begin as smooth, flesh-colored to pink papules that slowly enlarge peripherally and undergo central involution to form the classic rings with clear centers and elevated borders. Lesions may range in size from 5 mm to several centimeters.

There are several clinical variants of GA. A generalized form may occur, in which patients have multiple, disseminated, small papular lesions. Perforating GA presents as grouped papules, some of which have a central umbilication or crusting and scaling. This form is seen mainly on the extremities. Subcutaneous GA (Figs. 9-60 and 9-61) is

**Figure 9-59** Granuloma annulare. This patient has a semiannular, flesh-colored to pink plaque on the dorsal foot.

**Figure 9-61** Granuloma annulare. This patient's plaque reveals both cutaneous and subcutaneous (arrows) involvement.

**Figure 9-60** Subcutaneous granuloma annulare. Subcutaneous nodules on the forearm.

an important subtype in children, in whom it is most common. This form presents as subcutaneous nodules, distributed mainly on the feet, anterior tibial surfaces, fingers, hands, and scalp.<sup>283,284</sup> Penis lesions have also been rarely reported.<sup>285</sup> These lesions are usually painless and only occasionally slightly tender. The differential diagnosis of these lesions includes rheumatoid nodules, trauma, infection, malignancy, and tumor. Incisional biopsy is often necessary to confirm the diagnosis, unless there are classic cutaneous GA lesions present elsewhere on the skin surface.

Lesions of GA usually disappear spontaneously without sequelae and within several months to years. There is no satisfactory therapy for GA, but since the lesions are nearly always asymptomatic, watchful waiting is often acceptable. Topical corticosteroids, either ointments, creams, or impregnated into tape may be effective but are limited by their potential in causing skin atrophy. Intralesional corticosteroid

injection has also been utilized in some patients. Cryotherapy has been used, as have a variety of systemic agents (including isotretinoin, prednisone, dapsone, doxycycline and cyclosporine), but the risk-to-benefit ratio is generally not justified for these drugs. Occasionally the lesions spontaneously regress after skin biopsy. Until the association with diabetes mellitus is clearly established or refuted, patients with GA should be monitored by their primary physician for signs or symptoms, and if there is any concern or a strong family history, testing should be considered. Serum lipid testing should be considered in patients with more generalized involvement.

## NEUROFIBROMA

Neurofibromas may appear as isolated, usually single lesions in a healthy individual or as a cutaneous marker of dominantly inherited type 1 neurofibromatosis (NF1, von Recklinghausen disease; see Chapter 11). Lesions not associated with NF1 are discussed here.

Neurofibromas are benign tumors composed of neuromesenchymal tissue, including Schwann cells, endoneurial and perineurial cells, and other cellular components. They often present during young adulthood and occasionally early in life. Clinically, a neurofibroma presents as a soft, flesh-colored, solitary papule or papulonodule. They may occasionally be red, blue, or brown. They range in size from 2 mm to 2 cm, and with further growth they become globular, pear-shaped, pedunculated, or pendulous. Neurofibromas exhibit a positive “buttonhole” sign that is felt to be pathognomonic, whereby direct pressure on top of the lesion results in easy invagination into the dermis. This sign may be useful in differentiating neurofibromas from intradermal nevi or dermatofibromas.

When multiple neurofibromas are present, the diagnosis of NF1 must be considered. The presence of café-au-lait macules, axillary or inguinal freckling, or a plexiform neurofibroma lends further support to this diagnosis. Plexiform neurofibroma presents as a large, lobulated nodular plaque that may have a “bag of worms” consistency on palpation. These lesions are considered pathognomonic for NF1 (see Chapter 11). Sporadic neurofibromas are best treated with surgical excision.

## DERMATOFIBROMA

Dermatofibroma (fibrous histiocytoma) is a benign neoplasm of connective tissue generally seen in adults; occasionally it is seen in children. It presents as a small, well-defined dermal nodule that is firmly fixed to the skin but freely movable over the subcutaneous fat. There is often a tan to brown color of the surface (Fig. 9-62). Dermatofibromas may be found on any part of the body and are common on the extremities, particularly the anterior surface of the leg. They range in size from 1 mm to 2 cm. A useful diagnostic feature is the “dimple sign,” whereby pinching the lesion results in downward displacement.

**Figure 9-62** Dermatofibroma. This gray-brown papule on the right superior buttock was very firm to palpation and showed a “dimple sign” with lateral pinching (see text for discussion).

The differential diagnosis may include melanocytic nevus or cyst. Although treatment of dermatofibromas is unnecessary, surgical excision may be performed for cosmetic purposes or diagnostic confirmation.

### DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans (DFSP) is a slowly growing fibrohistiocytic tumor with intermediate malignant potential seen primarily in adults between the second and fifth decades of life. These lesions tend to be locally invasive, have a high recurrence rate after excision, and occasionally result in metastatic disease. Pediatric and even congenital cases are occasionally observed, although most lesions present during the second to fifth decades of life.

DFSP usually begins as erythematous to blue papules and nodules that increase in size and may ultimately become multinodular and protuberant. Some lesions present as atrophic plaques. Ulceration may be present. The majority of lesions occur on the trunk or proximal extremities (Fig. 9-63), and the scalp, neck, and face are occasionally involved. During infancy or early childhood, DFSP may be misdiagnosed as a vascular malformation or tumor given the vascular appearance of many lesions.<sup>286,287</sup> Other initial impressions may include keloid, dermatofibroma, morphea, scar, or epidermal cyst.<sup>288</sup> Significant variability in presentation appears to be common with congenital lesions, which are rare but well documented.<sup>287</sup>

DFSP has been linked to a chromosomal translocation, t(17;22), which fuses the collagen type 1, alpha 1 (COL1A1) and PDGF $\beta$  genes.<sup>289</sup> The treatment of choice for DFSP is complete surgical excision with adequate margins. In recent years, MMS has evolved as the therapeutic standard of care, and it has been demonstrated to offer superior cure rates, smaller surgical margins, and fewer surgical sessions when compared with wide local excision in treating congenital DFSP.<sup>290</sup> MMS in conjunction with a vacuum-assisted closure system has been reported as useful for treatment of pediatric DFSP, with associated decreased rates of infection and complications.<sup>291</sup> Radiation therapy and imatinib have been recommended when clear surgical margins are unobtainable, the tumor recurs, or there is concern about metastases.<sup>292</sup> In patients with DFSP, lifelong clinical follow-up care is recommended given the risk of recurrence; however, metastatic spread is fortunately quite rare.<sup>293</sup>

### Fibromatoses

The fibromatoses are a group of disorders marked by fibrous and fibrohistiocytic proliferations in the skin. These disorders may represent neoplastic or reactive processes and tend to be benign in nature, although several have the potential for recurrence after excision. In this section, three pediatric fibromatoses are discussed.

**Figure 9-63** Dermatofibrosarcoma protuberans (DFSP). This red nodule was present at birth on the proximal thigh of this young boy. Punch biopsy revealed changes of DFSP, and it was ultimately treated with complete surgical excision.

**Figure 9-64** Recurring digital fibroma of childhood. A firm, erythematous tumor on the lateral surface of the fourth toe.

### RECURRING DIGITAL FIBROMA OF CHILDHOOD

Recurring digital fibroma of childhood (RDFC; also known as *recurring infantile digital fibomatosis*) is a rare, benign childhood fibromatosis. It usually occurs on the dorsal and lateral aspects of the fingers and toes and presents at birth or less commonly during infancy or later childhood. The majority of lesions are present by 12 months of age.<sup>294</sup> Interestingly, the thumbs and great toes are usually spared.

RDFC presents as flesh-colored to slightly erythematous papules and nodules (Fig. 9-64). Lesions are usually multiple and tend to affect multiple digits. They may become as large as 2 cm in size. Joint deformities and lateral deviation or flexion deformities may occasionally be associated.<sup>294,295</sup>

The etiology of RDFC is unknown, and although a viral etiology was once postulated based on eosinophilic inclusion bodies seen on histologic examination, there appears to be little evidence in support of this

**Figure 9-65** Solitary myofibroma. This lesion was congenital and spontaneously resolved by 1 year of age.

**Figure 9-66** Multiple myofibromas. Firm, rubbery nodules and plaques on the thigh of an infant.

hypothesis.<sup>296</sup> Management of RDFC is controversial. Arguments in favor of a conservative watchful waiting approach include the observation that many lesions spontaneously regress over a few years, that excision of the lesions does not alter the natural history of the joint disease (when present), and that excision is often followed by recurrence.<sup>297</sup> However, some assert that surgical excision is indicated to prevent continuous growth and involvement of deeper tissues and because some lesions do not spontaneously resolve. Medical approaches including topical imiquimod, intralesional fluorouracil, and topical or intralesional corticosteroids have yielded inconsistent results.<sup>298</sup> For smaller lesions without functional impairment, it seems that conservative management of RDFC is most appropriate.

### INFANTILE MYOFIBROMATOSIS

*Infantile myofibromatosis* is a term used to describe two fibrous disorders (infantile myofibromatosis and congenital generalized myofibromatosis) that represent two variants of the same process. Patients with these conditions have neoplasms composed of myofibroblasts, a distinct cell type that appears to also be involved in RDFC (see the previous section). Some cases of infantile myofibromatosis may mimic congenital infantile fibrosarcoma, and in these patients, molecular analysis for the *ETV6–NTRK3* gene fusion transcript (present in some infantile fibrosarcomas) may be useful.<sup>299</sup> Both autosomal recessive and autosomal dominant forms of infantile myofibromatosis have been reported. Missense mutations in *PDGFRB*, which encodes the platelet-derived growth factor receptor-β, have been identified in several families with autosomal dominant infantile myofibromatosis.<sup>300</sup>

In infantile myofibromatosis, fibrous nodules may occur in skin, subcutaneous tissue, skeletal muscle, and bone. Most patients have solitary lesions, and the most common sites of involvement are the head and neck regions.<sup>301</sup> The myofibromas, which are often congenital,<sup>302</sup> appear as flesh-colored to purple, firm or rubbery papules (Fig. 9-65), nodules, or plaques. The differential diagnosis of a solitary myofibroma may include infantile hemangioma, histiocytoma, mastocytoma, and infantile digital fibroma. Visceral involvement is rare when the cutaneous lesion is solitary.

Multiple myofibromas, a condition that has also been termed *congenital generalized myofibromatosis*, presents with scattered cutaneous and subcutaneous tumors (Fig. 9-66) in addition to lytic bony lesions. Radiography reveals multiple radiolucent areas in the metaphyseal regions.<sup>303</sup> These patients may also have muscle and visceral involvement, with lesions in the GI tract, lungs, kidneys, spleen, lymph nodes, meninges, nerves, thyroid, adrenal gland, and heart. Spinal canal involvement has also been reported.<sup>304</sup> Although the lesions do not tend to be locally aggressive or metastasize, their space-occupying nature in some anatomic regions may interfere with vital functions. The differential diagnosis of multiple myofibromas includes heman-

**Figure 9-67** Fibrous hamartoma of infancy.

giomatosis, juvenile xanthogranulomas, cutaneous metastases (i.e., from neuroblastoma or leukemia), mastocytosis, and sarcomas.

Since the cutaneous and subcutaneous nodules of infantile myofibromatosis tend to regress spontaneously, surgical excision is indicated only for diagnostic confirmation, to alleviate obstruction or potential trauma, or to treat lesions in which the clinical course is prolonged and progressive. Patients with lesions limited to skin and/or bone have a good prognosis. Those with disseminated multiorgan involvement have a higher incidence of morbidity and mortality. Chemotherapy has been utilized for patients with severe involvement, and a regimen of low-dose vinblastine and methotrexate has been reported as useful while minimizing chemotherapy-related toxicity.<sup>305</sup>

### FIBROUS HAMARTOMA OF INFANCY

Fibrous hamartoma of infancy is a rare, benign, soft-tissue tumor that usually presents during the first 2 years of life. One in four cases is congenital, and around 90% occur within the first year of life.<sup>306</sup> It appears to be more common in boys and has a predilection for the upper trunk, axillae, upper extremities, groin, or genitalia.<sup>307</sup>

Fibrous hamartoma presents as a painless, flesh-colored subcutaneous nodule or nodular plaque (Fig. 9-67). Most cases are solitary, although multiple lesions may occur. They may be mobile or appear to be fixed to underlying tissues. The size of fibrous hamartoma is usually under 4 to 5 cm, although significantly larger lesions have been reported.<sup>308</sup> The clinical differential diagnosis may include infantile myofibromatosis (see previous section), calcifying aponeurotic fibroma, fibrolipoma, juvenile hyaline fibromatosis, and malignant

**Figure 9-68** Nevus lipomatosus superficialis. This soft, multilobulated plaque was present at birth in the superior gluteal cleft region.

soft-tissue sarcomas such as fibrosarcoma or rhabdomyosarcoma.<sup>309</sup> The natural history of fibrous hamartoma is characterized by slow growth, although rapid growth of lesions has been reported.<sup>306</sup> Histologic examination of biopsy tissue reveals the characteristic triad of tissues: adipose, fibrous, and myxoid mesenchymal tissue.

The treatment of choice for fibrous hamartoma of infancy is full surgical excision, although for excessively large lesions this may not be a feasible option. Local recurrence may occur in up to 15% of cases and is often noted within a few months after the primary surgery.<sup>310</sup> In lesions left untreated, growth continues until around 5 years of age, at which time it plateaus.<sup>311</sup>

## Tumors of Fat, Muscles, and Bone

### LIPOMAS

Lipoma, one of the most common benign tumors, is composed of mature fat (adipose) cells. It can be seen at any age but usually occurs at or after puberty. Lesions may be present on any part of the body but predominantly involve the subcutaneous tissues of the neck, shoulders, back, and abdomen. They may be single or multiple, and their size is variable with a characteristic soft, rubbery or putty-like consistency. Microscopic examination reveals encapsulated tumors of adipose tissue with essentially the same appearance as that of normal subcutaneous fat.

A rare nevoid variety, nevus lipomatous superficialis (Fig. 9-68), is characterized by clusters of soft, flesh-colored to yellowish papules, nodules, or plaques often located on the buttocks, lumbosacral region, or thighs. These lesions are often present at birth or develop over the first decade of life. Another lipoma variant, angiolioma, is clinically indistinguishable except that the lesions are often tender or painful and have a greater tendency to be multiple. Angiolipomas occur primarily in teenagers and young adults and commonly present on the upper extremities or trunk.

Lipomas and the discussed variants are benign lesions. Surgical excision is generally curative and is indicated for lesions that are painful or of cosmetic significance or for those lesions for which the diagnosis is uncertain (although incisional biopsy is another option in this setting). Three syndromes that have lipomas as a component will be briefly discussed: BRRS, encephalocriocutaneous lipomatosis (ECCL), and the Michelin tire baby syndrome.

### Bannayan–Riley–Ruvalcaba Syndrome

BRRS, or Bannayan–Zonana syndrome is an autosomal dominant, multiple hamartoma syndrome shown to be caused by mutations in the *PTEN* gene. The hallmark of BRRS is macrocephaly. Patients also have multiple subcutaneous or visceral lipomas and vascular malformations. Pigmented macules of the penis are common. Facial trichilemmomas as described in CS may also be seen, and the same *PTEN* mutations have similarly been described in this syndrome (see earlier this chapter). *PTEN hamartoma tumor syndrome* is the terminology currently used to describe a collection of rare syndromes (including BRRS, CS, and possibly Proteus syndrome) characterized by germline mutations in this tumor-suppressor gene.<sup>312,313</sup> Other clinical findings in BRRS include oral papillomas, acral (palmarplantar) keratoses,

acanthosis nigricans, joint hyperextensibility, scoliosis, pectus excavatum, and downslanting palpebral fissures. Hypotonia, developmental delay, and hamartomatous intestinal polyps may also occur.<sup>324</sup> The latter may result in chronic anemia, diarrhea, failure to thrive or small bowel intussusception.<sup>314</sup> Careful phenotyping has suggested that BRRS and CS represent one condition with variable expression and age-related penetrance.<sup>315</sup>

### Encephalocriocutaneous Lipomatosis

ECCL is a rare neurocutaneous syndrome characterized by mental retardation and unilateral skin and ocular lesions with ipsilateral cerebral malformations. The cutaneous lipomas in ECCL are most often limited to the scalp and may be accompanied by alopecia. A smooth, hairless fatty tissue nevus of the scalp is considered a hallmark finding and has been termed *nevus psiloliparus*.<sup>316</sup> Other cutaneous lesions may include skin tags, especially on the eyelids or along a line from the outer canthus to the tragus. Various ocular abnormalities including eyelid defects, epibulbar or limbal dermoids (also called *choristomas*), scleral desmoid tumors, and corneal clouding may occur.<sup>317,318</sup> CNS malformations are variable and include intracranial/spinal lipomas (most common), hemisphere asymmetry, cortical dysplasia, cysts, ventricular dilation, calcifications, and corpus callosum abnormalities.<sup>319</sup> Seizures are common and tend to start during infancy, and the developmental status of affected patients is varied, ranging from normal to profoundly delayed.<sup>316</sup> MRI of the brain and spine in patients with ECCL may reveal intracranial lipomas (often at the cerebellopontine angle), spinal lipomas, enlarged ventricles, widening of arachnoid spaces, arachnoid cysts, cortical dysplasia, and asymmetric cerebral atrophy.<sup>320</sup> The differential diagnosis includes Proteus syndrome, epidermal nevus (nevus sebaceous) syndrome, and oculocerebrocutaneous syndrome.

### Michelin Tire Baby Syndrome

*Michelin tire baby syndrome* (*Michelin tire syndrome*) is a term used to describe a very rare disorder of newborns characterized by numerous, conspicuous cutaneous folds (Fig. 9-69), presumably caused by excessive fat. Elastic fiber abnormalities have also been noted on ultrastructural examination of lesional skin (see Chapter 6).<sup>321</sup> The terminology is derived from the resemblance of affected patients to the mascot for the tire manufacturer Michelin. Recently, this disorder has also been referred to as *congenital symmetrical circumferential skin creases*, and it has been reported in both autosomal dominant and recessive forms.<sup>322</sup> Other histologic abnormalities that have been noted in these patients include nevus lipomatosis and smooth muscle hamartoma. A variety of extracutaneous defects including developmental delay/mental retardation, facial dysmorphism, microcephaly, musculoskeletal anomalies (including rocker-bottom feet, metatarsus abductus, and lax joints), hirsutism, hemiplegia, hemihypertrophy, chromosomal abnormalities, abnormal ears, and neurologic abnormalities may be associated, although there is significant phenotypic variability. Michelin tire baby syndrome may represent a nonspecific clinical presentation related to a variety of different causes.<sup>323</sup> Spontaneous improvement in the numerous folds often occurs with increasing age.<sup>324</sup>

### CONGENITAL SMOOTH MUSCLE HAMARTOMA

Congenital smooth muscle hamartoma is a benign skin disorder characterized by a proliferation of smooth muscle within the reticular dermis. It may be seen within or without an associated Becker nevus (see *Pigmented Lesions* section). Smooth muscle hamartoma, when presenting independent of Becker nevus, appears as a localized, slightly elevated, flesh-colored to faintly hyperpigmented plaque. The lesions may be extremely subtle on examination, but a useful feature is mild overlying hypertrichosis (Fig. 9-70) that may best be visualized with side lighting using a penlight or otoscope head. Rubbing of the plaque may cause a “pseudo-Darier” sign, with transient piloerection and the appearance of gooseflesh-like surface changes.

Although most lesions are congenital, they may not be noted until childhood or even early adulthood. Smooth muscle hamartoma is nearly always asymptomatic and rarely of cosmetic significance. Surgical excision is curative but rarely necessary.

**Figure 9-69** Michelin tire syndrome. This young girl had excess skin folds since early infancy (**A**), with gradual normalization as she aged (**B–D**). Her history was otherwise notable only for mild linear growth delay, which also improved.

## LEIOMYOMAS

Leiomyomas represent benign tumors principally derived from cutaneous smooth muscle. The majority of these lesions arise from arrector pili muscles, the media of blood vessels, or smooth muscle of the scrotum, labia majora, or nipples. Although found among all age groups, leiomyomas generally occur during the third decade of life and are relatively uncommon in childhood.

Cutaneous leiomyomas may be solitary or multiple and generally present as pink, red, or dusky brown, firm dermal nodules of varying size. They are subject to episodes of paroxysmal spontaneous pain. When multiple, leiomyomas are usually red-brown to blue, firm

intradermal nodules (Fig. 9-71) with a translucent or waxy appearance. They tend to occur on the back, face, or extensor surfaces of the extremities and are usually arranged in groups. Enlarging lesions may coalesce to form plaques with an arcuate or linear configuration. Multiple leiomyomas may be associated with common uterine fibroids, an autosomal dominant association termed *multiple cutaneous and uterine leiomyomatosis syndrome* (formerly known as *Reed syndrome*). This disorder, as well as another hereditary leiomyoma syndrome, hereditary leiomyomatosis and renal cell cancer, are both caused by heterozygous mutations in the fumarate hydratase (*FH*) gene.<sup>325,326</sup>

**Figure 9-70** Smooth muscle hamartoma. Note the mild hypertrichosis overlying this flesh-colored, dermal plaque.

**Figure 9-71** Leiomyomas. This 5-month-old male had clusters of flesh-colored to pink dermal papules in the popliteal region and the inguinal crease, confirmed on histology to represent piloleiomyomas.

Leiomyomas may be classified as hereditary or nonhereditary types and are characterized by unencapsulated tumors of smooth muscle bundles and masses with an irregular arrangement. Cutaneous leiomyomas have been divided into three types:

1. Piloleiomyomas, the most common type
2. Solitary genital or mammary leiomyomas, derived from the smooth muscle of the nipple and genital regions (referred to as the *dartoic type*)
3. Angioleiomyomas, arising from the tunica media of the blood vessels and embryonic muscle rests and most often found on the lower leg.

Leiomyosarcoma, a rare soft-tissue sarcoma, occurs primarily in older individuals and may have histologic overlap with leiomyoma. Clinically, these sarcomas are larger than leiomyomas and present as nondescript subcutaneous masses that may enlarge rapidly and ulcerate. Metastases, when they occur, generally spread through the bloodstream and lymphatics, and lung involvement is common. The histologic features most useful in distinguishing these tumors from benign leiomyomas are high cellularity, cytologic atypia, and obvious mitotic figures.

Leiomyomas are benign but have a high incidence of recurrence after removal. Surgical excision is the treatment of choice and is curative for smaller, localized tumors. When multiple leiomyomas are present, therapy is challenging and has included CO<sub>2</sub> laser ablation.

**Figure 9-72** Calcinosis cutis in juvenile dermatomyositis. This patient had painful, firm nodules of both knees and both elbows.

## MYOBLASTOMA

Myoblastoma (granular cell tumor) is an uncommon tumor that occurs most often as a solitary nodule in the head and neck regions and especially on the tongue. It is rare overall in children. Laryngeal involvement may occur in the posterior or anterior larynx, vocal folds, and arytenoids.<sup>327</sup> Patients with multiple tumors have been reported, occasionally in association with NF1.<sup>328</sup> Congenital epulis represents a granular cell tumor of the gingivae in a newborn that is usually marked by spontaneous involution. The origin of granular cell tumors is believed to be neural, with a Schwann cell derivation hypothesized but not proven. Surgical excision is the treatment of choice.

## CALCINOSIS CUTIS

*Calcinosis cutis* is a general term for calcium deposition in the skin. It may be related to abnormal calcium or phosphorus metabolism or damage to the dermal collagen, or it may be idiopathic in origin.<sup>329</sup> It may be focal or widespread. Calcinosis cutis has traditionally been divided into the following subtypes: dystrophic, idiopathic, metastatic, and iatrogenic. Tumoral calcinosis is another distinct subtype. Calcinosis occurring in association with some inherited disorders (such as pseudoxanthoma elasticum, Ehlers–Danlos syndrome, and Werner syndrome) is discussed elsewhere.

Dystrophic calcinosis cutis occurs after trauma or inflammation in the skin. This form may also be noted in the setting of diseases that predispose to deposition of calcium in the skin, such as juvenile dermatomyositis (Fig. 9-72; see Chapter 22, Figs. 22-30 and 22-31) scleroderma, and systemic lupus erythematosus. Calcium deposition in the skin may occur years before other stigmata of dermatomyositis become noticeable,<sup>330</sup> although more typically the calcifications occur years after the disease onset. In dystrophic calcinosis cutis, calcium and phosphorus metabolism are normal. Clinically, patients exhibit firm to rock-hard papules or larger subcutaneous plaques. Elbows, knees, and shoulders are common locations. Secondary ulceration and transepidermal elimination of calcium may occur (presenting as white, chalky material protruding from the affected area). In calcinosus universalis, as may be seen in juvenile dermatomyositis, extensive

**Figure 9-73** Calcinosis cutis in CREST (calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) syndrome. Painful, firm deposits with overlying skin breakdown on the distal digits of this teenaged girl with CREST syndrome.

**Figure 9-74** Heel-stick calcinosis cutis. Firm, white papulonodule at the site of prior heel-stick procedures.

subcutaneous deposits of calcium occur, and patients may appear to have an exoskeleton. This form has a particularly poor prognosis. Patients with the calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia (CREST) variant of scleroderma present with painful, calcified papules and nodules over bony prominences and distal digits (Fig. 9-73). Dystrophic calcinosis cutis can also be seen in the setting of some porphyrias, notably porphyria cutanea tarda, which is rarely encountered in children.<sup>331</sup>

A common setting for dystrophic calcinosis cutis is in infants after heel-stick procedures. These calcifications appear as firm, white to yellow papules on the heels (Fig. 9-74) and are most often seen in high-risk neonates after multiple needle sticks to these locations.<sup>332</sup> They can also occur in healthy neonates after only a single heel stick.<sup>333</sup>

Idiopathic calcinosis cutis occurs in individuals who have normal calcium and phosphorus metabolism and have no history of trauma or underlying inflammatory diseases. It may occur in various areas of the body, most commonly the scrotum (scrotal calcinosis), face, and female genitalia. Labial calcinosis cutis presents as white papules or nodules on the labia majora and is important to recognize, because it may be misdiagnosed as a condition associated with potential sexual abuse (i.e., condylomata or mollusca).<sup>329</sup> A subepidermal calcified nodule is a solitary, white to flesh-colored, firm papule or papulonodule (Fig. 9-75), most commonly occurring in children. These lesions are often seen on the face. Milia-like idiopathic calcinosis

**Figure 9-75** Subepidermal calcified nodule. Solitary, firm, white to flesh-colored papulonodule on the cheek.

**Figure 9-76** Milia-like idiopathic calcinosis cutis in Down syndrome. These firm, white papules were asymptomatic.

cutis presents with small, white papules that may discharge a chalk-like substance. These lesions occur most commonly on the hands (Fig. 9-76) and feet, and are usually seen in patients with Down syndrome.<sup>334,335</sup>

Metastatic calcinosis cutis occurs when calcium deposits form in the skin and soft tissue of patients who have altered metabolism of calcium and/or phosphorus. One association is chronic renal failure, which results in hypocalcemia with resultant secondary hyperparathyroidism with increased mobilization of both calcium and phosphate. Hypervitaminosis D and milk-alkali syndrome are other potential causes of metastatic calcinosis cutis. Calciphylaxis, or calcifying panniculitis, is a severe disorder characterized by vascular calcification with resultant ischemic necrosis of skin and soft tissue. It may result in gangrene and sepsis, and the mortality rate is high.

Tumoral calcinosis presents with calcifications in juxtaarticular sites, predominantly on extensor surfaces. These grow over months to years and often recur after surgical removal.<sup>336</sup> These lesions may attain a fairly large size (up to 20 cm) and may result in disfigurement or impaired function. This disorder may occur sporadically or in an autosomal dominant fashion and usually affects otherwise healthy adolescents.

Iatrogenic calcinosis cutis occurs when there is a precipitation of calcium salts in the skin. It most commonly occurs after extravasation of calcium gluconate or calcium chloride. It presents as yellow-white plaques (Fig. 9-77) that often reveal secondary inflammation. Lesions are most commonly (but not always) located around sites of prior intravenous line insertions.<sup>337</sup> Central ulceration may occur. These lesions tend to resolve over 4 to 6 months. Calcinosis cutis has also been reported after application of calcium chloride-containing electrode paste for electroencephalography, electromyography, and auditory-brainstem evoked potential recordings.<sup>338</sup>

Treatment of calcinosis cutis is challenging and may include surgical excision, curettage, low calcium and phosphate diet, and administration of aluminum hydroxide, diltiazem, colchicine, or etidronate (a

**Figure 9-77** Calcinosis cutis after extravasation injury.

bisphosphonate). Systemic warfarin therapy has been shown to be helpful for small calcified deposits but not with larger or long-standing lesions. Other reported treatments in various settings have included minocycline, ceftriaxone, intravenous immunoglobulin, probenecid, intralesional steroid injection, and CO<sub>2</sub> laser.<sup>339</sup> The underlying disorder, if present, should obviously be treated.

### OSTEOMA CUTIS

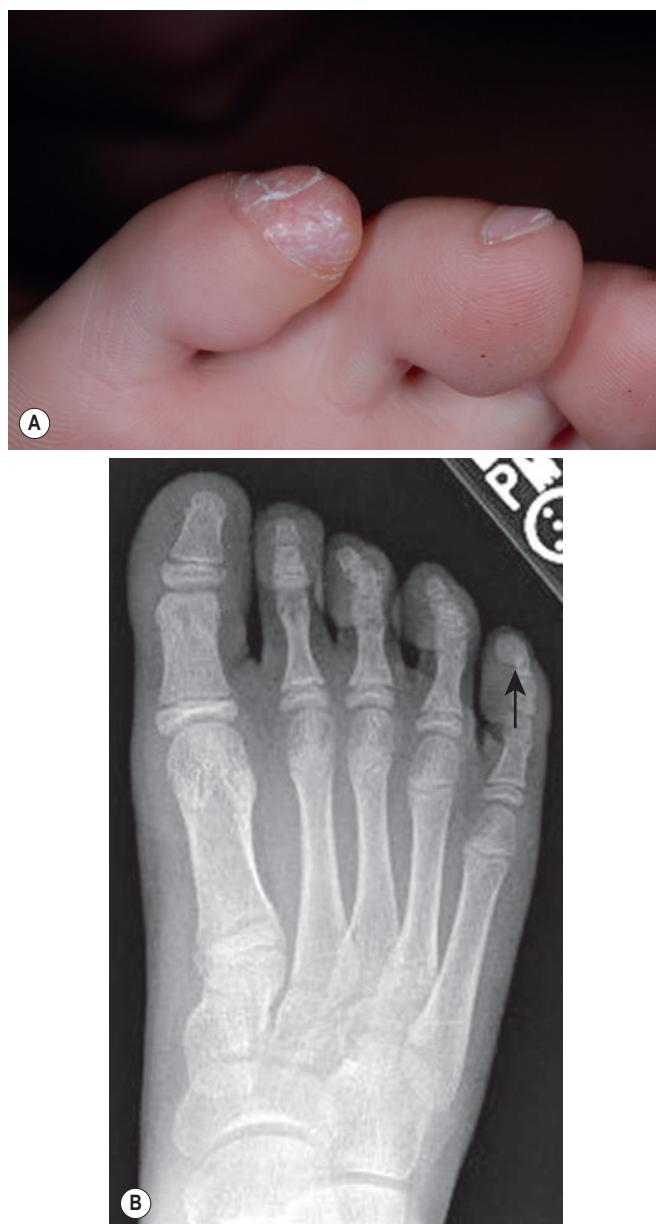

Cutaneous ossification (bone formation) is a rare phenomenon, especially in children, that may occur in a variety of settings. It may be primary or secondary. The term *osteoma cutis* is nonspecific but has traditionally been used to refer to a primary form of spontaneous bone formation in the skin associated with Albright hereditary osteodystrophy (AHO) or as an isolated idiopathic occurrence. Secondary cutaneous ossification occurs in areas of inflammation or neoplastic tissue and may also be seen in any disorder where calcification is present and in benign skin tumors or cysts.

AHO (see Chapter 23) is a genetic condition that may present with diffuse cutaneous ossification in conjunction with pseudohypoparathyroidism or pseudo-pseudohypoparathyroidism. These patients tend to be short and obese with a variety of dysmorphic features, including a classic foreshortening of the fourth and fifth metacarpals and metatarsals.

Progressive osseous heteroplasia (POH) is a rare disorder characterized by progressive ossification of skin, muscle, and connective tissue that may result in significant functional and cosmetic deformity. It usually begins in infancy and tends to be progressive.<sup>340</sup> It can be distinguished from another ossification disorder, fibrodysplasia ossificans progressiva (FOP), by the presence of cutaneous ossification, the absence of congenital malformations of the skeleton, the absence of tumor-like swellings, the asymmetric distribution of lesions, and the predominance of intramembranous rather than endochondral ossification.<sup>341</sup> In both of these disorders, calcium and phosphorus metabolism are normal, in distinction to patients with AHO. The prognosis of FOP is poor, whereas the prognosis of POH is variable. Plate-like osteoma cutis (POC) presents in infancy with one or a few areas of cutaneous ossification. These lesions tend to remain fairly localized, and these patients do not have abnormalities in calcium or phosphorus metabolism or other associated defects. The prognosis in POC tends to be good.

As can be seen, disorders of ossification may have a variety of presentations. Some of these disorders may be linked in some patients to mutations in the *GNAS* gene (also known as *GNAS1*), including isolated osteoma cutis, AHO, pseudohypoparathyroidism type 1a, pseudo-pseudohypoparathyroidism, and POH.<sup>342–344</sup>

Miliary osteomas of the face present as small, firm, flesh-colored to white or blue papules on the face. They have been observed in patients both with and without a history of acne vulgaris.

**Figure 9-78** Subungual exostosis. **(A)** This rock-hard nodule of the distal fifth digit was painful. **(B)** Radiographic evaluation revealed a well-demarcated bony projection projecting off the tip of the affected phalanx (arrow). Surgical excision was curative, with histology revealing trabecular bone with a cartilage cap, consistent with osteochondroma.

### SUBUNGUAL EXOSTOSIS

Subungual exostosis is a solitary hard nodule that occurs on the terminal border of the distal phalanx of a finger or toe. Although the great toe tends to be the most commonly afflicted, this disorder may involve other toes or occasionally a finger. However, fifth-toe involvement is unusual.<sup>345</sup> Subungual exostosis is a benign osteochondroma that occurs primarily in the second or third decade of life. Patients may report a history of preceding trauma, although for many this history is lacking.

Subungual exostosis presents as a pink or flesh-colored, 5- to 15-mm exophytic papulonodule that projects from the distal portion of the affected digit (Fig. 9-78, A). The surface of the lesion may become hyperkeratotic. Pain is common, and the portion of the nail overlying the lesion may be lifted and in some instances become detached. The

differential diagnosis includes wart, pyogenic granuloma, glomus tumor, epidermoid carcinoma, and amelanotic melanoma. The bony consistency upon palpation will usually suggest the correct diagnosis, and plain radiography (Fig. 9-78, B) can usually confirm it, revealing an exostotic tumor arising from the dorsal aspect of the tip of the distal phalanx.<sup>345</sup>

Surgical excision, with curettage of the base, is the treatment of choice for subungual exostosis. Recurrences happen occasionally.

## Miscellaneous

### EPIDERMAL CYST

Epidermal cyst (epidermoid cyst, epidermal inclusion cyst) is a discrete, slow-growing nodule that may appear any time after puberty and most commonly occurs on the face, scalp, neck, trunk, or scrotum. This is a true cyst with an epithelial lining. The term *sebaceous cyst* is an antiquated misnomer for this common tumor.

Epidermal cysts present as well-demarcated, firm to slightly compressible nodules, measuring from a few millimeters to several centimeters. An overlying central punctum, through which keratinous, foul-smelling debris may be extruded, is characteristic. Occasionally the lesions become inflamed, but true secondary infection is quite rare. Such inflammation occurs when rupture of the cyst wall occurs, and this is a common scenario prompting a visit to the physician.

Tiny epidermal cysts are termed *milia* (see Chapter 2). These lesions tend to be multiple, 1 to 2 mm in size, and white in color. In addition to occurring sporadically in healthy newborns, they may occur after abrasion trauma to the skin or in the course of bullous disorders such as epidermolysis bullosa and porphyria. Multiple cysts on the scrotum may occur and occasionally result in calcinosis cutis (see *Calcinosis Cutis* section). Pilar cysts (trichilemmal cysts, wens) are epidermal cysts that occur on the scalp, and chalazions represent analogous cystic tumors of the eyelids that develop from meibomian glands.

An important association with multiple epidermal cysts is Gardner syndrome. This autosomal dominant condition is characterized by cutaneous cysts and intestinal polyposis. Gardner syndrome is a form of familial adenomatous polyposis (FAP), an inherited colorectal cancer syndrome characterized by hundreds of adenomas involving the large bowel with progression (if untreated) to colorectal cancer by the fourth decade.<sup>346,347</sup> The term *Gardner syndrome* is used to describe the extracolonic manifestations that occur commonly in patients with FAP.<sup>348</sup> The epidermal cysts in Gardner syndrome, which are the most common cutaneous manifestation, are usually multiple, often present during early childhood, and can occur in any location, although they tend to occur most often on the face, scalp, and extremities. Multiple pilomatrixomas may also be seen in patients with Gardner syndrome.<sup>349</sup> Other findings include desmoid tumors, osteomas, fibromas, lipomas, abnormal dentition, thyroid tumors, and congenital hypertrophy of the retinal pigment epithelium (CHRPE).<sup>349</sup> The latter finding is often present at birth and as such usually precedes the development of intestinal polyposis.<sup>346</sup> Both FAP and Gardner syndrome have been mapped to the adenomatous polyposis coli (APC) gene, a tumor-suppressor gene.<sup>346,347,350</sup> Genotype–phenotype correlation studies have led some to suggest that the term *Gardner syndrome* is obsolete.<sup>347</sup>

Malignant degeneration (squamous cell or BCC) of epidermal and pilar cysts is rarely reported. Treatment consists of surgical excision with an attempt to remove the entire epithelial lining of the cyst in order to minimize the chance of recurrence.

### MUCOCELE (MUCOUS CYST)

Mucoceles (mucous cysts of the oral mucosa) present as soft, white to blue, solitary asymptomatic lesions, usually on the mucous surface of the lower lip and occasionally on the gingivae, tongue, or buccal mucosa. They are usually less than 1 cm in diameter and translucent (Fig. 9-79), containing a clear viscous fluid. Mucoceles are the result of minor trauma, causing rupture of a mucous duct and extravasation of sialomucin into the tissues. Treatment options include surgical excision, incision, and drainage followed by coagulation of the sac, CO<sub>2</sub> laser ablation, or cryosurgery. Occasionally lesions may rupture

**Figure 9-79** Oral mucocele. This lesion was ultimately excised because of continued enlargement.

**Figure 9-80** Congenital lingual melanotic macule. These dark brown macules on the dorsal tongue were congenital in onset for this 7-week-old healthy male.

spontaneously, although this is usually followed by eventual recurrence.

### CONGENITAL LINGUAL MELANOTIC MACULE

Melanotic macules of the oral mucosae include oral and labial melanotic macules, which are most often seen in young and middle-aged adults. The congenital lingual melanotic macule presents as a well-circumscribed, hyperpigmented macule (or macules) on the dorsal tongue (Fig. 9-80). Histopathologic evaluation reveals increased basal-layer melanin with some pigment-laden macrophages but normal melanocyte number and no nests of melanocytes, as would be expected in a congenital melanocytic nevus.<sup>351</sup> These lesions tend to grow proportionately with the child, and in some cases lightening may be noted with aging.<sup>352</sup>

### DIGITAL MUCOUS CYST

Digital mucous cyst (myxoid cyst) is a focal accumulation of mucin that presents as a soft, translucent, pink to blue, dome-shaped nodule on the dorsal aspect of the distal interphalangeal joint or proximal nailfold. Occasionally, the overlying nail plate reveals a longitudinal depression distal to the cyst. There is controversy over whether these lesions arise from degenerative changes or as a direct extension from the underlying joint space. Regardless, there appears to be a metabolic derangement of fibroblasts with increased production of hyaluronic acid in sites exposed to friction or minor trauma. In some patients,

**Figure 9-81** Steatocystoma multiplex. Yellow-tan, small papules of the forearm in this patient who also had lesions on the chest.

there may be a communication between the cyst and the underlying joint space.

Surgical excision is usually effective, but recurrences are common. Other therapeutic options include corticosteroid injection, cryosurgery, repeated incision and drainage, and CO<sub>2</sub> laser ablation.<sup>353–355</sup>

### STEATOCYSTOMA MULTIPLEX

Steatocystoma multiplex (SM) is a disorder characterized by numerous, 2- to 4-mm moderately firm, yellow to flesh-colored cutaneous cysts located primarily on the chest and occasionally the face, genitals, arms (Fig. 9-81), and thighs. The disorder has a high familial tendency and is often inherited in an autosomal dominant fashion. Lesions often appear or become larger around the time of puberty. In some patients, there may be overlap with eruptive vellus hair cysts (see Chapter 7), and both conditions seem to originate from the pilosebaceous duct.<sup>356</sup> SM may also occur in association with pachyonychia congenita (see Chapter 7), and both conditions may be caused by mutations in keratin 17.<sup>357</sup> In addition, persistent infantile milia may at times be associated with both SM and eruptive vellus hair cysts and may represent a disorder with predisposition to multiple pilosebaceous cystic lesions.<sup>358</sup>

The lesions of SM are rarely symptomatic but may occasionally be of cosmetic concern to the patient. Treatment can be accomplished with surgical excision or cyst puncture with evacuation of the contents. Other reported approaches include CO<sub>2</sub> laser therapy, oral isotretinoin, and cryotherapy.<sup>359</sup>

### KELOID

Keloids, which are benign dermal tumors characterized by invasive growth of fibroblasts and increased synthesis of collagen, represent an exaggerated connective tissue response to skin injury. They are rare in infancy, and their incidence increases throughout childhood, reaching a maximum between puberty and 30 years of age. African-American individuals and other darkly pigmented persons are more susceptible to keloids than individuals with fair skin, and the tendency toward keloid formation often runs in families.

Early lesions are pink, smooth, and rubbery (Fig. 9-82) and may be tender. With increasing age, keloids become less erythematous, more pigmented (Fig. 9-83), and firmer to palpation. Although they may occur anywhere on the skin surface, keloids are most common on the earlobes, upper chest, and back and in wounds located in areas under tension. As opposed to hypertrophic scars, keloids often persist at the site of injury, often recur after excision, and always overgrow the original boundaries of the wound.<sup>360</sup>

Treatment of keloids is notoriously difficult and often ineffective. In fact, lesions not uncommonly become larger after attempts at therapy. Regardless, these lesions are a source of much psychosocial anxiety

**Figure 9-82** Keloid. This early lesion is erythematous and only slightly firm to palpation.

**Figure 9-83** Keloid. This older keloid is very firm and hyperpigmented; it had recurred after an initial attempt at surgical removal.

and suffering for patients, and hence therapy is often attempted. Intralesional injection of corticosteroid (usually triamcinolone acetonide) is the most commonly utilized treatment and often requires multiple injections. This therapy is most effective for smaller lesions. Surgery is generally not recommended, given the propensity for lesions to recur or even worsen, but it is often used given the lack of other consistently effective therapies. It is often combined with adjunctive therapies such as steroid injections, silicone sheeting, and compression. Keloid core extirpation, a surgical approach involving excision of the inner core followed by a keloid rind flap, may be a more effective approach.<sup>360</sup> Other therapeutic options, each used with varying levels of success, include radiotherapy; pulsed dye, argon, or CO<sub>2</sub> laser therapy; and intralesional injections of bleomycin, interferon, mitomycin C (usually topically applied), or fluorouracil. Silicone gel and silicone sheeting have been used with variable success to treat both keloids and hypertrophic scars, but their mechanism of action remains unclear. It appears that the increased wound hydration that occurs with occlusive therapies may prompt keratinocytes to alter growth-factor secretion and thereby may affect fibroblast regulation.<sup>361</sup> Intralesional verapamil injections and topical imiquimod cream have also been used in combination with surgical excision.<sup>361,362</sup> Compression therapy via the use of compression garments may be helpful but can be difficult in terms of patient adherence and tolerability.<sup>363</sup>

# 10 *Histiocytoses and Malignant Skin Diseases*

The histiocytoses are a broad group of disorders characterized by an abnormal proliferation of the histiocyte, a type of progenitor cell in the bone marrow (Box 10-1). Some clinically relevant types of histiocytes include the Langerhans cell, the dermal dendrocyte, and cells of mononuclear cell/macrophage lineage. Malignant disorders to be discussed include hematologic malignancies (including leukemia, lymphoma, and Hodgkin disease), neuroblastoma, and some sarcomas.

## Langerhans Cell Histiocytosis

*Langerhans cell histiocytosis (LCH)* is the term now used to describe a disorder characterized by infiltration of Langerhans cells into various organs of the body. Older synonymous terms, which are now largely obsolete or unnecessary, include histiocytosis X, eosinophilic granuloma, Letterer–Siwe disease, Hand–Schüller–Christian disease, and Hashimoto–Pritzker disease.<sup>1</sup> The term *histiocytosis X* was coined by Lichtenstein in 1953 to identify three related clinical entities of unknown etiology and characterized by histiocyte proliferation.<sup>2</sup> This classification included the triad of Letterer–Siwe disease, Hand–Schüller–Christian disease, and eosinophilic granuloma. The X in this original nomenclature was used to denote the unknown derivation of the histiocyte involved in this disorder. Ultrastructural studies eventually confirmed the relationship of these three different presentations by showing the Langerhans cell to be the proliferative cell in each of them. LCH may occur at any age, from newborn to elderly, although the peak incidence appears to be between the ages of 1 and 4 years.<sup>3</sup>

Langerhans cells are derived from the bone marrow and are a type of dendritic cell found primarily in the epidermis (as well as mucosal epithelia, thymus, esophagus, and lung). They are involved in antigen presentation for the skin- and mucosa-associated immune systems and are identified by strong staining with S100 (a neuronal protein) and cluster designation (CD) 1a (a cell surface marker). Langerhans cells also have a characteristic organelle, the Birbeck granule, which is visible on electron microscopy. The function of this organelle remains unknown. Immunohistochemical demonstration of langerin (CD207), a mannose-specific lectin found in association with Birbeck granules, has also been demonstrated useful for diagnostic confirmation of LCH.<sup>4</sup>

Although numerous etiologies have been proposed for LCH, the pathogenesis remains obscure. Hypothetic causes include somatic mutations, infection (especially viral), immune or cytokine dysregulation, and programmed cell death (apoptosis).<sup>3–6</sup> Whether LCH is a neoplastic versus a reactive disorder also remains debated. The cells in LCH have been demonstrated to be clonal, and such monoclonality has been demonstrated both in multisystem disease and with solitary organ involvement. Although this clonality suggests that LCH may be a neoplastic process with variable biologic behavior, the exact significance and implications remain controversial.<sup>3,4</sup> There are arguments both in favor of and against LCH being a neoplastic process.<sup>7</sup>

LCH may involve multiple organ systems, the most common being the skin and the bones. Table 10-1 lists the spectrum of organ involvement. The older classification system was based on the involved organ systems such that *eosinophilic granuloma* referred to localized bone disease; *Hand–Schüller–Christian disease* the multifocal triad of bone (usually skull) lesions, exophthalmos, and diabetes insipidus (DI); and *Letterer–Siwe disease*, the acute or subacute disseminated form of the disease. Under the more modern classification, LCH is the umbrella term for the disease with notation made of the various organ systems involved. Patients may have unifocal, multifocal, or disseminated

disease. In general, patients with widespread, multiorgan involvement have the poorest prognosis, and those with isolated bone LCH have the best prognosis.<sup>8</sup>

Cutaneous involvement is very common in LCH and is often the presenting complaint. The spectrum of skin findings is listed in Table 10-2. The most classic presentation is that of a seborrheic dermatitis-like eruption with prominent involvement of the scalp, posterior auricular regions (Fig. 10-1), perineum, and axillae. The rash tends to be resistant to standard therapy, which is an important clue that should prompt consideration of the diagnosis. Erythematous, red-brown papules are often seen, especially on the scalp and in flexural areas, and may have secondary erosion, hemorrhage, or crusting (Fig. 10-2). Crusted papules on the palms and/or soles (Fig. 10-3) are another important feature, especially in infants in whom the diagnosis of scabies has been excluded. Although this finding has traditionally been felt to portend a poor prognosis, this observation has not been validated.

In neonates with LCH, vesiculopustular lesions (Figs. 10-4 and 10-5) tend to predominate and may be misdiagnosed as congenital varicella or herpes.<sup>9</sup> These lesions may become hemorrhagic or crusted. Petechiae and hemorrhage may also be present in association with the dermatitis or the papular lesions of LCH, and they may be seen both with and without associated thrombocytopenia. Other less commonly seen cutaneous presentations include nodules and granulomatous, ulcerative lesions.<sup>10</sup> Box 10-2 lists some cutaneous clues to the diagnosis of LCH.

Mucosal involvement may occur in patients with LCH, especially those with more disseminated involvement. Gingival erythema, erosions, and hemorrhage may be seen. In some infants, gingival and oral mucosal erosions with premature eruption of teeth may be the initial manifestations of LCH.<sup>11</sup> Loosening of the teeth may occur as a result of severe gingivitis, especially when there is concomitant bony involvement of the alveolar ridge and jaw. Involvement of the external auditory canals may result in chronic otitis externa.

Bone lesions are very common in patients with LCH. When they occur, pain (with or without swelling) is the most common presenting complaint, and patients may complain of discomfort both during activity and when at rest.<sup>8</sup> Bony involvement occurs most commonly in the skull, followed by the long bones of the extremities and the flat bones (pelvis, vertebrae, ribs). Radiographic studies usually reveal single or multiple lytic lesions of bone (Fig. 10-6) that often have a “punched-out” appearance.<sup>11</sup> Proptosis may result from orbital wall involvement, and the radiographic appearance may simulate mastoiditis when there is involvement of the mastoid process.<sup>3</sup> Middle-ear extension may cause destructive changes with resultant deafness, and chronic otitis media may also occur as a result of mastoid and temporal bone disease. Vertebral body involvement may result in compression with the radiographic finding of vertebra plana (Fig. 10-7). Plain radiographs are usually sufficient for diagnosing bony LCH, but computed tomography (CT), magnetic resonance imaging (MRI), and technetium (Tc)-99 bone scans may also be useful, especially in the setting of multifocal osseous disease.<sup>12</sup>

The classic triad (historically Hand–Schüller–Christian disease) of skull lesions, DI, and exophthalmos is the prototype for multifocal LCH, but many other organs may be involved in this setting. Disseminated LCH (historically Letterer–Siwe disease) is the most serious form of the disorder, differing only in extent and severity from multifocal involvement.<sup>11</sup> Lymph node involvement may be seen with localized or widespread LCH, and most often the cervical nodes are involved. Hepatosplenomegaly, biliary cirrhosis, and liver dysfunction may

**Box 10-1 Histiocytoses**

Langerhans cell histiocytosis  
 Juvenile xanthogranuloma  
 Xanthoma disseminatum  
 Benign cephalic histiocytosis  
 Necrobiotic xanthogranuloma  
 Generalized eruptive histiocytoma  
 Progressive nodular histiocytoma  
 Indeterminate cell histiocytosis  
 Multicentric reticulohistiocytosis  
 Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease)  
 Hemophagocytic syndromes  
 Malignant histiocytic syndromes

**Box 10-2 Cutaneous Clues to Langerhans Cell Histiocytosis**

Recalcitrant seborrheic dermatitis-like eruption  
 Localization of rash to scalp, posterior auricular regions, perineum, axillae  
 Eroded papules in flexural areas  
 Petechial or purpuric papules  
 Crusted papules on palms and/or soles (scabies preparation negative)  
 Any of the above lesions in combination with lymphadenopathy

**Table 10-1** Organ Involvement in Langerhans Cell Histiocytosis

Organ	Comment
Skin	Often the initial presenting sign
Bone	Painful swelling common; incidence: skull > long bones > flat bones (ribs, pelvis, vertebrae)
Lymph nodes	Cervical most common
Liver	
Spleen	
Lungs	Diffuse micronodular pattern on radiography
Gastrointestinal tract	
Thymus	
Bone marrow	Pancytopenia portends a poor prognosis
Gingivae, buccal mucosa	Swelling, erythema, erosions, petechiae
Kidney	
Endocrine glands	Diabetes insipidus most common
Central nervous system	

**Table 10-2** Cutaneous Manifestations of Langerhans Cell Histiocytosis

Presentation	Comment
Scaly red-brown papules	Especially in scalp, flexural areas; may have associated crusting; may be umbilicated or lichenoid; palm and sole involvement common
Erythematous, scaly dermatitis	May simulate seborrheic dermatitis
Erosion or ulceration	Common secondary finding, especially in fold areas
Petechiae, hemorrhage	With or without associated thrombocytopenia
Vesiculopustular lesions	Most common in neonates; may simulate congenital varicella or herpes; often have hemorrhagic crusts
Red nodules or plaques	Less common
Granulomatous plaques	Rare

occur. Pulmonary LCH may present with cough, hemoptysis, dyspnea, or pain and is most common in the third decade of life.<sup>3</sup> Pulmonary involvement may also be asymptomatic, especially in younger children. Chest radiography reveals a diffuse micronodular or reticular pattern, and pneumothoraces may result. Gastrointestinal tract involvement may present as anorexia, malabsorption, vomiting,

**Figure 10-1** Langerhans cell histiocytosis. Erythematous, crusted papules and plaques, with accentuation in the posterior auricular scalp.

diarrhea, and failure to thrive. However, gastrointestinal involvement may be asymptomatic and thus is at times overlooked. Thymus abnormalities have been reported and may present with enlargement of the gland on chest radiography. Bone marrow involvement may result in pancytopenia and with concomitant hypersplenism may contribute to life-threatening sepsis and hemorrhage.<sup>3,11</sup> Nonspecific constitutional symptoms, including fever, weight loss, and malaise, are common in patients with multiorgan involvement.

Central nervous system (CNS) involvement in LCH may include infiltration of the hypothalamic–pituitary regions, which can result in DI even years after the initial diagnosis. DI seems to develop more often in patients with bony involvement of the skull and multisystem disease.<sup>3</sup> Posterior pituitary infiltration may be evident on MRI as absence of a normally bright signal in the posterior pituitary gland or thickening of the pituitary stalk.<sup>13</sup> Growth retardation may result from anterior pituitary involvement, and growth hormone deficiency, which is relatively uncommon, may occur and was noted in 6% of patients in one large series.<sup>14,15</sup> Other manifestations of CNS involvement include hyperreflexia, dysarthria, cranial nerve defects, and rarely seizures. Progressive or rarely, acute ataxia has been observed as a complication.<sup>16</sup> Basilar invagination, which is associated with hydrocephalus and usually occurs as part of the Arnold–Chiari malformation or in patients with diseases that result in bone softening (i.e., osteogenesis imperfecta), has been reported in long-term survivors with LCH.<sup>17</sup> MRI is useful in diagnosing CNS disease. Positron emission tomography (PET) scan has been demonstrated useful in identifying areas with altered metabolism related to CNS LCH and may provide a tool for longitudinal involvement in some patients.<sup>18</sup> Neuropsychologic deficits that may occur in children with LCH include cognitive deficiencies and deficits in memory, attention and concentration, and perceptual–organizational capabilities.<sup>19</sup> Cognitive defects are noted especially in patients with multisystem LCH with CNS involvement.<sup>20</sup> Psychiatric deterioration and cognitive defects may both be more common in patients who develop cerebellar involvement.<sup>21</sup>

Congenital self-healing reticulohistiocytosis deserves special mention. This entity, also known as *Hashimoto–Pritzker disease* (and also as *congenital self-healing LCH [CSHLCH]*), is marked by the congenital presence of LCH lesions, usually papules and nodules,<sup>22</sup> which may break down in the center and form crater-shaped ulcers. Systemic

**Figure 10-2** Langerhans cell histiocytosis (LCH). **(A–C)** Erythematous and eroded papules in the neck fold, inguinal creases, and over the trunk. Note the associated crusting, purpura, and umbilicated nature of some of the papules. **(D)** Eroded, erythematous, and hemorrhagic papules in the groin of this infant with disseminated LCH. Note the associated jaundiced appearance, a result of massive liver involvement.

signs are often absent, and the lesions involute over a few months and are usually gone by 12 months.<sup>22</sup> There may be some distinct histologic features but not always. It is generally accepted that CSHLCH is a variant of LCH and that most patients have a favorable prognosis. However, patients do not always have disease limited to the skin and thus require an evaluation for systemic involvement. In addition, reports of cutaneous and systemic relapse (including DI) months to years after resolution of the skin lesions highlight the importance of vigilant long-term follow-up observation as one would do for patients with classic LCH.<sup>4,23,24</sup>

Erdheim–Chester disease is a rare, non-Langerhans systemic histiocytosis characterized by xanthomatous or xanthogranulomatous infiltration of tissues and a cellular phenotype that is CD68 positive but CD1a and S100 negative.<sup>25</sup> It may present in a fashion similar to LCH, including bony involvement, although it most commonly causes osteosclerosis affecting the metaphyseal regions of long bones (and presenting with bilateral knee and ankle pain). The cutaneous lesions are best characterized as a variant of juvenile xanthogranulomas (JXGs) (see below), and the clinical findings in the skin usually consist of xanthelasma-like lesions on the eyelids.<sup>26</sup> Erdheim–Chester disease occurs predominantly in adults.

LCH is diagnosed by examination of tissue specimens from affected organs. Skin is a readily accessible organ for biopsy in patients who have cutaneous involvement. Routine histologic sections reveal an infiltrate of typical Langerhans cells, which can be confirmed by positive S100, CD1a, or langerin immunostaining. Electron microscopy, although rarely performed now because of the availability of special stains, reveals the characteristic Birbeck granules within the cytoplasm of the cells. The prognosis for patients with LCH is quite variable and dependent on many factors, including the extent of organ involvement. In general, the younger the age at diagnosis, the shorter the event-free survival and overall survival rates, although this association does not appear to be as strong as once believed.<sup>27</sup> Interestingly, neonates with isolated cutaneous lesions tend to do very well.<sup>28</sup> Other prognostic factors include the type and number of disease sites, organ dysfunction, and response to therapy.<sup>29</sup> Morbidity and mortality may be related to progressive disease or late sequelae, which include skeletal defects, dental problems, DI, growth failure or other endocrinopathies, hearing loss, and CNS dysfunction.<sup>24</sup> DI, which presents with polyuria and polydipsia, occurs in around 15% to 25% of patients and may even occur as a late complication in patients who present with “skin-limited” disease or CSHLCH.<sup>27–30</sup>

**Figure 10-3** Langerhans cell histiocytosis (LCH). Erythematous, crusted papules on the palm in this newborn with congenital multisystem LCH.

**Figure 10-5** Neonatal Langerhans cell histiocytosis (LCH). These crusted, vesicular lesions were initially felt to be suggestive of neonatal varicella in this 10-day-old female. Biopsy confirmed LCH.

**Figure 10-4** Neonatal Langerhans cell histiocytosis (LCH). Hemorrhagic papules and papulovesicles in a neonate with congenital cutaneous LCH.

The recommended evaluation for the patient suspected of having LCH is shown in **Box 10-3**. Clinical stratification based extent of disease has been recommended as follows: single-organ-system disease (unifocal or multifocal), multiorgan disease (without organ dysfunction), and multiorgan disease (with organ dysfunction). The latter category, multiorgan disease with organ dysfunction, is further stratified as low risk (skin, bone, lymph node, pituitary) or high risk (lung, liver, spleen, hematopoietic cells).<sup>28</sup> Patients with single-organ-system disease seem to have the best outcome and a low reactivation rate.<sup>15</sup>

Therapy for LCH depends on the extent of disease. In patients with disease limited to the skin, observation alone is often appropriate, because the lesions may resolve spontaneously. Topical corticosteroids are only occasionally effective. Topical treatment with nitrogen mustard may be used, and in patients with severe skin disease, systemic therapy as is given for multiorgan LCH may be considered. Treatment for disease limited to bone is dictated by the extent of bone

### Box 10-3 Recommended Evaluation of the Patient with Suspected Langerhans Cell Histiocytosis

Physical examination, including growth parameters

Laboratory evaluation:

- Complete blood cell count
- Coagulation studies
- Hepatic function testing
- Urine osmolality

Complete skeletal radiographic survey

Chest radiography

More specific studies as guided by initial results (i.e., bone marrow examination, pulmonary function testing, lung biopsy, liver biopsy, panoramic dental films, CT or MRI of the CNS, endocrine evaluation)

Modified from Satter EK, High WA. Langerhans cell histiocytosis: a review of the current recommendations of the Histiocyte Society. *Pediatr Dermatol* 2008;25(3):291–5.

CNS, Central nervous system; CT, computed tomography; MRI, magnetic resonance imaging.

involvement and symptomatology. Single-bone lesions may resolve spontaneously, and simple observation is appropriate in this setting in patients who are not experiencing pain.<sup>3,11</sup> Painful lesions may be treated with curettage, surgical excision, or intralesional steroid injection. Localized radiation therapy is another treatment option.

In patients with more extensive LCH, there are a variety of therapeutic options. Most patients are treated with systemic chemotherapy, most commonly vinblastine or etoposide. These two agents have been found equally effective in the treatment of multisystem LCH.<sup>31</sup> Prednisone or methylprednisolone is commonly used during the induction phase of therapy for patients with multisystem LCH. Other reported therapies include cyclosporine A, 2-chlorodeoxyadenosine, interferon- $\alpha$ , cladribine, cytarabine, and allogeneic bone marrow or cord-blood transplantation.<sup>32–36</sup>

LCH is a potentially fatal disorder that can be recognized and diagnosed early based on the characteristic cutaneous manifestations. The skin signs may appear alone or in combination with systemic disease,

**Figure 10-6** Langerhans cell histiocytosis. Plain radiography reveals multiple lytic lesions in the tibia (**A**) and the skull (**B**) of a 4-year-old child with disseminated disease.

and all patients require a thorough evaluation for extracutaneous involvement before they can be diagnosed as having skin-limited disease. Although there is often a delay in the diagnosis of patients with LCH, becoming familiar with the cutaneous clues (see Box 10-2) will optimally position the pediatrician or other pediatric healthcare providers to recognize the disorder. Patients with LCH are usually treated by a pediatric oncologist, and all patients require long-term surveillance for late sequelae or relapse.

## Juvenile Xanthogranuloma

JXG is a common form of non-LCH. It is generally a benign, self-limited disease of infants, children, and occasionally adults. Lesions occur most often in skin, although extracutaneous disease may occasionally be present. Most JXGs occur early in life, and the true incidence may be underestimated because many of them may go undiagnosed or misdiagnosed as other common skin tumors such as nevi. JXG seems

**Figure 10-7** Langerhans cell histiocytosis. Plain radiography demonstrates vertebral body compression (vertebra plana, arrow) in the same patient as that shown in **Figure 10-6**.

to be derived from dermal dendrocytes, and although the term *xantho*- appears in the name, there is no association of this condition with hyperlipidemia or other metabolic abnormalities.<sup>37</sup>

JXG presents as a firm, round papule or nodule, varying in size from 5 mm to 2 cm, with giant lesions (i.e., up to 5 or 10 cm) occasionally seen. Some authors have divided JXG into a “micronodular” form (lesions <10 mm) and a “macronodular” form (lesions >10 mm). Early JXGs are erythematous (Fig. 10-8) to orange or tan (Fig. 10-9), but with time they become more yellow in color (Figs. 10-10 and 10-11). Lesions may be solitary (up to 90% of all patients with JXG<sup>38</sup>) or less commonly multiple (Fig. 10-12), and they are usually asymptomatic. Ulceration and crusting may occasionally occur. The head, neck, and trunk are the most common areas to be involved. Lesions may also occur on mucous membranes or at mucocutaneous junctions (mouth, vaginal orifice, and perineal area). Oral lesions occur on the lateral aspects of the tongue, gingival, buccal mucosa, and midline hard palate and may ulcerate and bleed. Oral lesions may appear verrucous, pedunculated, umbilicated, or fibroma-like.<sup>39</sup> Typically, the lesions of JXG present at birth (20%) or during the first 6 months of life, and they may persist or continue to erupt for years.<sup>40</sup>

Histologic evaluation of JXG tissue reveals a dense dermal infiltrate of foamy histiocytes, foreign body cells, and the characteristic Touton giant cells, which are virtually pathognomonic for the condition. The Touton giant cell is a giant cell with a central wreath of nuclei and a peripheral rim of eosinophilic cytoplasm.<sup>41</sup> Lymphocytes and eosinophils are often seen, and the histiocytes in JXG are S100 and CDla negative on special staining.

Extracutaneous involvement occasionally occurs with JXG. The eye is the most common organ of involvement second to the skin. The iris is the site most often involved, and potential complications of ocular JXG include hyphema, glaucoma, or blindness.<sup>42</sup> Patients may complain of eye redness, irritation, or photophobia. Children at greatest risk for ocular JXG include those 2 years of age or younger and those with multiple skin lesions.<sup>42</sup> Intramuscular JXG presents as a deep, soft-tissue lesion that may have imaging features similar to those of malignant tumors of infancy.<sup>43</sup> This form tends to affect exclusively infants and toddlers and occurs as a solitary lesion in skeletal muscles of the trunk.<sup>44</sup> Other sites of extracutaneous involvement include lung, liver, testis, pericardium, spleen, CNS, bone, kidney, adrenal

**Figure 10-8** Juvenile xanthogranuloma. An early lesion demonstrates erythema and mild surface scaling.

**Figure 10-10** Juvenile xanthogranuloma. An established lesion revealing the characteristic yellow to orange-brown appearance.

**Figure 10-11** Juvenile xanthogranuloma. Solitary yellow, dome-shaped nodular papule (**A**) and plaque (**B**) both distributed on the scalp.

**Figure 10-12** Juvenile xanthogranuloma. Multiple lesions, with spontaneous involution evident, were present in this 11-year-old boy. Note the fibrofatty tissue residua.

glands, and larynx.<sup>37,41</sup> Solitary as well as multiple intracranial and intracerebral lesions have rarely been reported, including one patient who experienced leptomeningeal spread and several who required therapy with chemotherapy and steroids.<sup>45–49</sup> Intraspinal JXG with spinal-cord compression has been reported.<sup>50</sup> Systemic JXG generally exhibits a benign clinical course but may occasionally be fatal, especially when the liver is involved.<sup>38</sup> There are rare reports of JXG in association with LCH, suggesting a possible common progenitor cell and overlap within the histiocytic spectrum of disorders.<sup>51–53</sup>

An important association is that of JXG and childhood leukemia. The most common association has been with juvenile chronic myelogenous leukemia (JCML), which may be seen with increased incidence in patients with multiple JXG lesions. It has been noted that several such reported patients also had café-au-lait macules and a family history of type 1 neurofibromatosis (NF).<sup>54</sup> A systematic review of the literature revealed that the frequency of the triple association of JXG, JCML, and NF is 30- to 40-fold higher than expected, and it is estimated that children with NF and JXG have a 20- to 32-fold higher risk for JCML than do patients with NF who do not have JXG.<sup>55</sup> However, it should be noted that the vast majority of patients with multiple JXG, even those with associated NF, do not develop JCML. The role of surveillance complete blood cell counts is controversial, and most practitioners monitor these patients primarily with regular, thorough physical examinations.

JXG usually runs a fairly benign course, with spontaneous regression occurring over 3 to 6 years. Pigmentary alteration, atrophy, or “anetoderma-like” changes may persist in areas of prior skin involvement. Although rare cases lasting until adulthood have been reported, generally those that have their onset early in life manifest complete spontaneous healing. The risk of complications is fairly high when ocular involvement is present. For this reason, once disease has been confirmed in the eye, therapy should be initiated. Intraocular JXG is treated with intralesional or systemic steroids, radiation therapy, or excision.<sup>56,57</sup> Lesions limited to skin require no therapy, although surgical excision is occasionally performed for diagnostic or cosmetic purposes. Systemic involvement is treated if it interferes with vital functions and has shown response to chemotherapy regimens similar to those used in LCH.<sup>37,38</sup> Patients with JXG and NF should be monitored for the development of leukemia given the increased risk.

## Xanthoma Disseminatum

Xanthoma disseminatum (XD), a rare disorder of mucocutaneous xanthomatous lesions, is another non-LCH. This disorder usually occurs in adults, although it may have its onset during childhood.<sup>58,59</sup> Patients have numerous (sometimes hundreds) round to oval, yellow-orange or brown papules, nodules, and plaques. They occur primarily on the face and the flexural and intertriginous surfaces, including the neck, antecubital fossae, periumbilical area, perineum, and genitalia. The lips, eyelids, and conjunctivae may be involved, and xanthomatous deposits have also been observed in the mouth and upper respiratory tract (epiglottis, larynx, and trachea), occasionally leading to respiratory difficulty.<sup>60,61</sup> Facial lesions may become exuberant and may cause disfigurement.<sup>62</sup> Osseous lesions, presenting radiographically as well-demarcated areas of osteolysis, may be present.<sup>62</sup> Ocular mucosal lesions may result in blindness. Liver involvement is occasionally present.<sup>63</sup> When XD involves the CNS, it is characterized by infiltration of the pituitary gland and termed *xanthomatous hypophysitis*, and may result in DI, hyperprolactinemia, or hypopituitarism.<sup>64</sup>

As with JXG, there is no perturbation in lipid metabolism in patients with XD, although it has been rarely reported in affected children.<sup>63</sup> DI occurs in many patients with the disorder, and severe laryngeal involvement may necessitate tracheostomy. The lesions of XD often persist indefinitely but have been known to involute spontaneously.<sup>65</sup> Treatment of the cutaneous lesions has been performed with cryotherapy, excision, and carbon dioxide laser ablation.<sup>66</sup> Despite the normolipemic nature of XD, lipid-lowering agents have been utilized in some patients with reported improvement.<sup>67,68</sup> Respiratory tract involvement, when severe, may justify a more aggressive approach with localized radiation therapy or chemotherapy.

## Benign Cephalic Histiocytosis

Benign cephalic histiocytosis (BCH) is a self-healing, cutaneous, non-LCH that classically involves the face and head. The average age of onset is 15 months, and 45% of cases occur in infants under 6 months of age.<sup>69</sup> Clinically BCH is characterized by small, 2- to 6-mm, yellow-brown macules and minimally elevated papules (Fig. 10-13). The lesions may occasionally coalesce to give a reticulate pattern.<sup>70</sup>

**Figure 10-13** Benign cephalic histiocytosis. Faintly tan to erythematous macules and papules on the cheek.

BCH most commonly occurs on the face and head (more than 80% of 45 patients in one review) and less commonly on the neck and trunk.<sup>71</sup> The extremities, buttocks, and pubic area may be involved later in the course.<sup>69</sup> The differential diagnosis may include flat warts, micronodular JXG, LCH, multiple melanocytic nevi, and urticaria pigmentosa.

The diagnosis of BCH can be confirmed by skin biopsy, which reveals a histiocytic infiltrate with negative stains for S100 and CDla. Electron microscopy is useful in confirming the diagnosis, because the cells classically reveal intracytoplasmic comma-shaped or worm-like bodies and the absence of Birbeck granules,<sup>70,72</sup> clearly differentiating it from LCH.

There is significant clinical overlap between some of the non-LCHs. Some authors have considered BCH to be a variant of generalized eruptive histiocytoma (GEH) (see below). In addition, there are reports of BCH progressing into JXG,<sup>73,74</sup> and although BCH tends to be limited to the skin, there are some reports of associated internal involvement. One patient with BCH developed DI 1 year later with infiltration of the pituitary stalk on imaging.<sup>75</sup> In another patient with classic lesions of BCH on the face, lytic lesions in the skull, spine, and tibia were demonstrated to be LCH on tissue examination.<sup>76</sup> These clinical observations again highlight the potential overlap among the histiocytic syndromes.

BCH generally runs a benign course with spontaneous healing, often leaving behind flat or atrophic pigmented scars. Treatment is unnecessary, but given the clinical variation in presentation and overlap with other histiocytic syndromes, clinical follow-up observation for progression or internal involvement is advisable.

## Necrobiotic Xanthogranuloma

Necrobiotic xanthogranuloma, a rare disorder usually reported in adults, is characterized by sharply demarcated, indurated plaques and nodules that are usually yellow to red-brown or violaceous and have a predilection for periorbital areas, the trunk, and proximal extremities.<sup>77</sup> Lesions vary in size, may at times be as large as 10 cm or more in diameter, and often ulcerate and heal with areas of atrophy and telangiectasia. Ocular involvement is fairly common and includes ectropion, ptosis, keratitis, uveitis, proptosis, and orbital masses. Visceral lesions of necrobiotic xanthogranuloma may involve the heart, skeletal muscles, larynx, spleen, and ovary. A hallmark of this disease is an associated paraproteinemia, immunoglobulin (Ig) G monoclonal gammopathy. The course of necrobiotic xanthogranuloma is chronic and progressive and may be associated with proliferation of plasma cells in the bone marrow or multiple myeloma. Treatment options include systemic or intralesional corticosteroids, cytotoxic drugs, radiation therapy, and plasmapheresis. Intravenous immunoglobulin

has been reportedly useful in some patients.<sup>78</sup> Surgical removal of lesions is associated with a high recurrence rate.<sup>79</sup>

## Generalized Eruptive Histiocytoma

Generalized eruptive histiocytoma (GEH) is a rare, self-healing histiocytosis characterized by recurrent crops of small, yellow to red-brown papules on the face, trunk, extensor extremities, and rarely, mucous membranes. The lesions number in the hundreds and tend to occur in a symmetric distribution. They resolve over months with hyperpigmented macules left in their place. As a result of the continuous development of new lesions, however, the disorder may persist indefinitely. Although generally regarded as a disorder of adults, GEH has been seen in childhood and even in infants as young as 1 month of age.<sup>80</sup>

The differential diagnosis includes JXG (which may be very difficult to differentiate histologically from early lesions of GEH), LCH, BCH, and urticaria pigmentosa. XD has developed in a child with the prior diagnosis of GEH.<sup>58</sup> No treatment is generally necessary for this disorder. However, since there is considerable overlap within non-LCH, patients should be monitored carefully for the development of signs or symptoms of other organ involvement. Isotretinoin treatment has been reported in a patient with GEH, with transient improvement but eventual recurrence.<sup>81</sup>

## Progressive Nodular Histiocytoma

Progressive nodular histiocytoma is characterized by a widespread eruption of hundreds of yellow-brown, 2- to 10-mm papules and deeper, larger subcutaneous nodules. Conjunctival, oral, and laryngeal lesions may occur. The face typically is heavily involved with numerous coalescent lesions, which may result in a leonine appearance. New lesions progressively occur, and ulceration is common. Occasionally, bleeding may occur within the subcutaneous nodules, resulting in marked pain.<sup>82</sup> Lesions of progressive nodular histiocytoma histologically show features typical of xanthogranuloma, and some authors suggest that this entity and JXG may represent a variation of the same process.<sup>83</sup> Treatment for this condition is difficult and includes excision of large or symptomatic lesions, chemotherapy with vinblastine, and electron beam therapy.

## Multicentric Reticulohistiocytosis

Multicentric reticulohistiocytosis is a rare systemic disorder of unknown cause. It is characterized by cutaneous lesions and a destructive arthritis and is seen almost exclusively in adults (mean age at diagnosis of 40 to 50 years) with rare reports of pediatric disease.<sup>84–86</sup> The skin lesions present as firm red-brown papules and nodules, most often distributed on the hands, fingers, lips, ears, and nose. Facial disfigurement may occur, with cartilaginous destruction and the appearance of a leonine facies. The coral bead sign refers to the presence of a chain of papules along the cuticle.<sup>82</sup> Nodular lesions on the arms, elbows, and knees may occur and at times resemble rheumatoid nodules.<sup>87</sup> Mucous membrane involvement may occur in up to one-half of patients. They most often present on the lips, buccal mucosa, nasal septum, tongue, palate, and gingivae.

Joint involvement is the presenting sign in more than half of the patients and is highly destructive. It may involve any joint, especially the interphalangeal joints, and coexisting synovitis is common. Shortening of the digits may occur with a “telescopic” or “opera-glass” deformity. Rheumatoid arthritis may be mistakenly diagnosed in some patients. Microscopic examination of skin, bone, or synovial tissue reveals a characteristic histiocytic process with multinucleated giant cells and a “ground-glass” appearance. Visceral involvement may include pleural effusion, pulmonary fibrosis, pericardial effusion, congestive heart failure, salivary gland enlargement, muscle weakness, lymphadenopathy, and gastric ulcer.<sup>88</sup> Multicentric reticulohistiocytosis may regress spontaneously over 6 to 8 years, but for many patients the articular destruction results in permanent joint deformities. The response of this disorder to therapy is often disappointing,

with treatments including nonsteroidal anti-inflammatory agents, corticosteroids, cyclophosphamide, chlorambucil, methotrexate, hydroxychloroquine, infliximab, tocilizumab, and interferon.<sup>82,88–92</sup>

## Hemophagocytic Lymphohistiocytosis

*Hemophagocytic lymphohistiocytosis* (HLH; also known as *hemophagocytic syndrome*) refers to a condition characterized by fever, wasting, jaundice, and hepatosplenomegaly resulting from diffuse infiltration of phagocytizing histiocytes in various tissues.<sup>93</sup> This disorder is heterogeneous in its etiologies, which include a familial form (familial HLH) and a secondary/reactive form that may be associated with a variety of infectious agents (most notably viral, bacterial, or parasitic), malignancy, and collagen vascular disorders.<sup>94,95</sup> These have also been referred to as *genetic* and *acquired* forms of HLH. The infection-associated form is seen primarily in immunocompromised patients with evidence of preceding viral (usually Epstein-Barr virus [EBV]) infection, in which case it is also known as *virus-associated hemophagocytic syndrome*. The other viral agents reported in association with HLH include cytomegalovirus, enterovirus, and parainfluenza virus.<sup>94,95</sup> The term *malignant histiocytosis* has also been used to describe this condition, in response to the cytologic atypia and malignant nature of the infiltrating histiocytes.

HLH has been observed as a complication of allogeneic hematopoietic stem-cell transplantation and in association with hematologic malignancies.<sup>93,96</sup> There also seems to be a relationship between EBV-associated HLH and EBV-associated T-cell lymphoma, with HLH representing the major cause of death in these patients.<sup>93</sup> Lymphoma-associated hemophagocytic syndrome (LAHS) is a rarely reported variant of HLH that has been described in the setting of systemic and cutaneous lymphomas, including subcutaneous panniculitic T-cell lymphoma (SPTCL) and epidermotropic cutaneous T-cell lymphoma, in which case it often occurs several years after the lymphoma diagnosis.<sup>97</sup> The pathway most commonly implicated in familial HLH is that of perforin-dependent cytotoxicity, an essential function of natural killer and cytotoxic T lymphocytes. The genetic forms of HLH have been shown to be related to mutations in any of several genes involved in this pathway, including *PRF1*, *UNC13D*, *Munc18-2*, *Rab27a*, *STX11*, *SH2D1A*, and *BIRC4*.<sup>98,99</sup> HLH may also be related to a primary immunodeficiency syndrome.<sup>100</sup> Macrophage activation syndrome (see Chapter 22) is a severe condition with features very similar to HLH that is seen in association with the systemic form of juvenile idiopathic arthritis and, less often, other autoimmune inflammatory diseases.<sup>101</sup> Box 10-4 summarizes the various subtypes of HLH.<sup>100,102</sup>

The cutaneous manifestations seen in patients with HLH are variable. Most common is a transient, generalized maculopapular eruption. Petechial and purpuric macules, generalized erythroderma, and morbilliform erythema may also occur.<sup>103</sup> Although the skin findings are not specific, their presence in the patient with a supportive history and/or the concomitant findings of fever, lymphadenopathy, hepatosplenomegaly, and cytopenias should prompt consideration for this diagnosis. The most common hematologic findings are leukopenia and thrombocytopenia, and coagulopathy is fairly common.<sup>94</sup> Other findings may include liver dysfunction and elevated triglyceride, lactate dehydrogenase (LDH), and ferritin levels. The clinical differential diagnosis may include extramedullary hematopoiesis (as may be seen with a variety of infectious or malignant disorders) and metastatic lesions from an underlying malignancy. LCH and myofibromatosis may also be in the differential.<sup>103</sup> Skin biopsy may be useful in eliminating some diagnoses, but the histologic findings are often nonspecific and the changes of erythrophagocytosis are often absent in skin specimens. Examination of bone marrow or other solid organ (lymph node, spleen, liver) biopsy tissue may be necessary to confirm the diagnosis. HLH has a high mortality rate, although chemotherapy, steroids, intravenous immunoglobulin, and hematopoietic stem-cell transplantation may offer hope for some patients. Etoposide and dexamethasone often induce clinical remission of the inflammatory symptoms, and improved survival has been noted with newer reduced-intensity transplant conditioning protocols. Cyclosporine A has been utilized to inhibit T-cell activation.<sup>99,100</sup>

#### Sinus Histiocytosis with Massive Lymphadenopathy (Rosai-Dorfman Disease)

Sinus histiocytosis with massive lymphadenopathy (SHML; or Rosai-Dorfman disease) is a rare disorder of reactive proliferation of histiocytes in the sinuses of lymph nodes. It occurs primarily in children, who show massive painless bilateral lymphadenopathy, especially cervical. Extrnodal involvement may occur, and when it does the head and neck region is the most common site, with a predilection for the nasal cavity and paranasal sinuses.<sup>104</sup> Papules and nodules are the most common skin lesions, and purely cutaneous SHML may occasionally occur.<sup>105,106</sup> The lesions of SHML often involute spontaneously, although surgical or medical therapy (that may include radiation, corticosteroids, or chemotherapy) may be indicated for lesions that are symptomatic, extensive, compromising vital organ function, or cosmetically deforming.<sup>104</sup> There are isolated reports of patients with both SHML and lymphoma.<sup>107,108</sup>

#### Cutaneous Pseudolymphoma

Cutaneous pseudolymphoma (CPL; *lymphocytoma cutis*, *lymphadenosis benigna cutis*, *Spiegler-Fendt pseudolymphoma*, *cutaneous lymphoid hyperplasia*) refers to a benign process that may clinically and/or histologically mimic lymphoma. CPL may occur at any age but most characteristically develops during early adult life. The diagnosis of CPL is nonspecific and does not imply the etiology. Some of the various causes of this process are listed in Box 10-5.

One of the most common etiologic categories of CPL is drugs. Many classes have been implicated, including anticonvulsants, antipsychotics, antihypertensives, angiotensin-converting enzyme inhibitors,  $\beta$ -blockers, calcium channel blockers, antibiotics, cytotoxic agents, and even antihistamines.<sup>109</sup> The anticonvulsant hypersensitivity syndrome, or drug rash with eosinophilia and systemic symptoms (DRESS) (see Chapter 20), is a prototype for such a reaction, presenting with fever, lymphadenopathy, edema, hepatosplenomegaly with hepatitis, and a diffuse cutaneous eruption that may reveal histologic changes of pseudolymphoma.

Typically, CPL presents as a more localized process with papules, nodules, and tumors in the skin. The lesions are flesh-colored to red or violaceous (Fig. 10-14) and may be single or multiple. They are

Figure 10-14 Cutaneous pseudolymphoma. Infiltrative, erythematous papules and nodular plaques on the chest of a 7-year-old boy.

usually not associated with a drug ingestion, and they may reach up to 4 or 5 cm in size with continued enlargement. The most common locations are the face, ears, and scalp, with occasional involvement of other body regions. Borrelial lymphocytoma, which follows infection with the Lyme disease agent *Borrelia burgdorferi*, occurs primarily in Europe and usually presents with red nodules involving the ear lobe and areola.<sup>110</sup> CPL resulting from past scabies infestation (scabies nodules) presents as erythematous to red-brown papules and nodules, usually in an infant previously treated for scabies (Fig. 10-15). These lesions may persist for several months after adequate therapy for the infestation. CPL may occasionally be noted in association with *molluscum contagiosum* (see Chapter 15, Fig. 15-42), a common childhood viral infection.<sup>111</sup>

A more disseminated form of CPL may occur; it usually appears in adults and presents with firm, red to violaceous papules and nodules with a more diffuse distribution. These lesions may grow rapidly, are prone to recurrence, and tend to persist throughout life. Actinic reticuloid is a severe, chronic photosensitive dermatosis that occurs primarily in older men and presents with erythematous to violaceous, lichenified papules and plaques on sun-exposed skin. It is categorized as a form of CPL by several authors.

The diagnosis of CPL is based upon the combination of clinical features, histologic evaluation, and often immunohistochemical and/or gene rearrangement studies.<sup>109</sup> At times, the microscopic findings of CPL may be very difficult to differentiate from cutaneous lymphoma and consist of a mixture of B, T, or mixed lymphocytes with macrophages and dendritic cells.<sup>112</sup> Treatment of CPL depends on the underlying etiology. Removal of any offending drug or physical stimulus that is identified may be sufficient. In idiopathic cases, lesions may involute spontaneously over months to years. For persistent lesions, treatment options include topical or intralesional corticosteroids, cryosurgery, surgical excision, local radiation therapy,

**Figure 10-15** Nodular scabies. Erythematous papulonodules with mild scaling in a 10-month-old infant who was treated for scabies 3 months before.

photochemotherapy, and antimarial and cytotoxic agents.<sup>109</sup> Antibiotics appropriate for Lyme disease are indicated for treatment of borrelial lymphocytoma.

## Leukemia Cutis

Leukemia is the most common malignancy of childhood. Cutaneous findings in leukemia may be primary (i.e., leukemic infiltrates in the skin) and secondary (i.e., Sweet syndrome, see Chapter 20; pyoderma gangrenosum, see Chapter 25; opportunistic infections). Cutaneous leukemic infiltrates may be known by a variety of names, including leukemia cutis, granulocytic sarcoma, and chloroma. Myelosarcoma is the more contemporary term for any extramedullary infiltrate with myeloid blasts.<sup>113</sup> Hence leukemia cutis is a form of myelosarcoma that results from infiltration of the epidermis, dermis, or subcutaneous tissues by neoplastic leukocytes or their precursors. Although biopsies of lesions of leukemia cutis may suggest the diagnosis, the findings may mimic a variety of inflammatory or neoplastic diseases. Therefore immunophenotyping and examination of peripheral blood smears and bone marrow aspirates are often required in an effort to confirm the diagnosis.

Cutaneous involvement may be associated with various types of childhood leukemias, including acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML, also called acute nonlymphocytic leukemia [ANLL]), and chronic leukemias (i.e., chronic myeloid leukemia [CML] and chronic lymphoblastic leukemia [CLL]). In general, leukemia cutis is associated with a grave prognosis, the exception being in patients with congenital leukemia (see below). Cutaneous leukemic infiltrates are most common with the myeloid leukemias (between 3% and 30% of patients, depending on the subtype), especially acute myelomonocytic and monocytic leukemia.<sup>113-115</sup> Gingival hypertrophy is a notable feature seen with these subtypes of leukemia, less so with other acute leukemias, and rarely with chronic leukemias.<sup>114</sup> Leukemia cutis is less common in patients with ALL (around 1% to 3%); in these cases it seems to be most common on the head and may be an early manifestation in children in both standard-risk and high-risk categories.<sup>114,116</sup> Leukemia cutis may also occur in patients with myelodysplastic syndrome, usually before or simultaneously with identifiable leukemic transformation in the peripheral blood or bone marrow.<sup>117,118</sup> Rarely leukemia cutis may present as a manifestation of secondary leukemia after prior chemotherapy.<sup>119</sup>

The clinical appearance of leukemia cutis is variable. Lesion types include macules, papules, plaques, nodules, ecchymoses, erythroderma, palpable purpura, ulcers, bullous lesions, and urticaria-like lesions.<sup>114</sup> A “seborrheic-dermatitis-like” presentation with scaling and papules of the scalp was observed in a 7-month-old with AML in remission.<sup>120</sup> Brown macules and nodules exhibiting a positive Darier sign and mimicking mastocytosis have been noted.<sup>117</sup> The most characteristic lesions of leukemia cutis are flesh-colored to red-brown to violaceous papules (Fig. 10-16), nodules, and plaques that may become purpuric (especially with coexisting thrombocytopenia). Leukemia cutis lesions may localize to sites of skin trauma, burns, surgical sites, or sites of cutaneous infections.

The clinical features of the skin lesions are not distinct for the different types of leukemias. However, certain subtypes may be more likely to result in cutaneous infiltrates with certain characteristics. For example, granulocytic sarcoma (or chloroma) presents as a rapidly growing, firm nodule that at times has a green hue. This tumor is usually associated with AML, and the greenish color is related to myeloperoxidase in the granulocytes. Granulocytic sarcoma may occur in patients with known AML, in those with a myeloproliferative disorder with an impending blast crisis, or in patients without any known hematologic disease.<sup>115</sup> At times leukemia cutis may precede the development of the systemic leukemia. This phenomenon is termed *aleukemic leukemia cutis*, and the cutaneous lesions can sometimes precede the systemic malignancy (most commonly AML) by years.<sup>121</sup>

## CONGENITAL LEUKEMIA CUTIS

Congenital leukemia is defined as leukemia presenting at birth or within the first month to 6 weeks of life. Congenital leukemia cutis, as compared with later-onset leukemia cutis, is believed to be quite common in the setting of this malignancy, with incidence estimates in the literature ranging between 25% and 30% of patients with congenital AML.<sup>122</sup> The cutaneous lesions range in size from a few millimeters to several centimeters and are usually red to brown to violaceous papules and nodules (Fig. 10-17). This latter clinical presentation in the neonate (with multiple violaceous papules and nodules) has been termed *blueberry-muffin baby*, and such skin findings may represent malignant cutaneous infiltrates or any of several possible causes of extramedullary hematopoiesis. Box 10-6 lists the various causes of blueberry-muffin skin lesions. As with noncongenital leukemia cutis, cutaneous infiltrates are more common with the myelogenous type of congenital leukemia.<sup>122</sup> Congenital leukemia cutis is felt to portend a poor prognosis, although some reports describe spontaneous remission.<sup>123,124</sup> However, because late relapses have been noted in some of these patients, they deserve close long-term follow-up observation. Occasionally infants with congenital leukemia cutis may have a solitary nodule.<sup>125,126</sup>

Transient myeloproliferative disorders:
with Down syndrome
without Down syndrome

Patients with Down syndrome have an increased risk of hematologic aberrations, including leukemia, leukemoid reaction, and transient myeloproliferative disorder. A leukemoid reaction is a temporary overproduction of leukocytes in response to infection, hemolysis, or other stress. Transient myeloproliferative disorder, which is also self-limited, is similar except that there is no identifiable trigger.<sup>127</sup> Patients with Down syndrome who have a leukemoid reaction or transient myeloproliferative disorder have been described with pustular or vesiculopustular skin eruptions, and smears or biopsies of these lesions have revealed immature myeloid forms.<sup>127,128</sup> This vesiculopustular presentation (Fig. 10-18) is quite distinct from the typical papules and nodules that occur with leukemia cutis. The significance of this eruption is unclear, and the findings resolve without therapy as the hematologic disorder subsides. However, true leukemia may develop months to years later, and therefore long-term follow-up monitoring is again indicated.

## Lymphoma Cutis

Lymphoma involving the skin is quite rare in children. The most common form of cutaneous lymphoma is cutaneous T-cell lymphoma (CTCL; mycosis fungoides; see below). Other forms of lymphoma cutis include subcutaneous panniculitic T-cell lymphoma (SPTCL), anaplastic large cell lymphoma (ALCL), cutaneous B-cell lymphoma, natural killer-cell lymphoma, angiocentric CTCL, and Hodgkin lymphoma. Some types of lymphoma that can also have skin involve-

**Figure 10-18** Vesiculopustular eruption in a patient with Down syndrome and a transient myeloproliferative disorder. (Courtesy of Beth Drolet, MD.)

ment but are not be discussed here include lymphoblastic lymphoma, marginal zone lymphoma, Burkitt lymphoma, and human T-lymphotropic virus (HTLV)-1-associated lymphoma. Lymphoma cutis may be a primary cutaneous process, or skin involvement may be associated with a systemic lymphoma. In patients with non-Hodgkin lymphoma overall, cutaneous involvement occurs in 1% to 5% of cases, and skin as the primary site (primary cutaneous lymphoma) is quite rare.<sup>129–131</sup>

Head and neck involvement is the most common pattern of cutaneous lymphoma in children.<sup>129–131</sup> The second most common site of involvement appears to be the abdomen.<sup>129</sup> Most patients present with solitary nodules in the skin, and less often multiple nodules are present. Papules or plaques are occasionally seen. The lesions are usually 5 to 10 cm in diameter, erythematous, and firm. SPTCL is a T-cell lymphoma that presents with subcutaneous nodules or nodular plaques and is most commonly seen in young adults (rarely in children). This tumor involves the subcutaneous fat in a manner similar to panniculitis and presents with multiple subcutaneous, inflammatory, poorly demarcated plaques and tender nodules, ranging in size from 0.5 to 10 cm. The lesions are most commonly localized to the lower extremities and occur less often on the trunk and upper extremities.<sup>132,133</sup> Ulceration may occasionally occur. The clinical presentation of SPTCL may mimic several processes, including lupus panniculitis and erythema nodosum, and hence this disorder may elude diagnosis.<sup>134</sup> SPTCL has been associated in some patients with hemophagocytic syndrome, and concomitant histiocytic cytophagic panniculitis has been observed.<sup>135,136</sup> Hence in any child with panniculitis and laboratory values suggestive of possible hemophagocytic syndrome, investigations for T-cell lymphoma should be performed.

Ki-1/CD30-positive ALCL is a form of lymphoma that may simulate a metastatic carcinoma or malignant histiocytosis.<sup>137,138</sup> A significant proportion of patients with ALCL are children or young adults. Patients show signs of fever, wasting, lymphadenopathy, and often cutaneous lesions. Skin involvement may consist of fleeting eruptions or more specific lesions, usually painful nodules, that occasionally undergo spontaneous involution.<sup>137,139</sup> In 36% of children in one series with peripheral lymph node involvement, lymphomatous infiltration of contiguous skin occurred and presented as erythematous, thickened, desquamating, and ulcerative plaques.<sup>140</sup> Primary cutaneous ALCL (C-ALCL) presents as a rapidly evolving cutaneous tumor, often with ulceration. It is most often solitary but may occur in regional or generalized forms.<sup>141</sup> ALCL is a high-grade non-Hodgkin

lymphoma that has a relatively good prognosis with early multiagent chemotherapy.<sup>138,140</sup> The primary cutaneous form is often treated with excision or radiation without chemotherapy, because some studies have shown that chemotherapy does not affect the rates of recurrence or survival.<sup>142,143</sup> Biopsies of affected skin reveal large, atypical lymphoid infiltrates that stain positive with the activation antigen Ki-1, also known as CD30.

The systemic form of ALCL (S-ALCL) has been further divided into anaplastic lymphoma kinase (ALK)-positive and ALK-negative types, based on staining for this fusion protein. ALK-positive S-ALCL tends to have a better prognosis than the ALK-negative subtype and is the primary type of this systemic lymphoma to occur in children. C-ALCL is typically ALK-negative, but primary cutaneous ALK-positive ALCL has been reported in children and may follow a relatively benign course.<sup>144</sup>

Cutaneous B-cell lymphoma is fairly rare, even though B-cell lymphomas represent the majority of non-Hodgkin lymphomas occurring in lymph nodes. As with T-cell lymphomas, B-cell lymphomas may involve the skin in a primary fashion or be secondary in relation to dissemination of nodal disease. Hence complete staging and evaluation is indicated for any patient diagnosed with a cutaneous B-cell lymphoma. This form of lymphoma cutis is notoriously rare in the pediatric population. The clinical presentation of B-cell lymphoma cutis includes papules, plaques, and tumors, occasionally with associated ulceration. The head, neck, upper trunk, and extremities seem to be sites of predilection in most patients, although some subtypes favor the lower extremities.

Natural killer-cell (CD56+ NK/T-cell) lymphoma is classically an aggressive nasal lymphoma, although patients can also have cutaneous plaques and subcutaneous nodules. This neoplasm may occur in a primary cutaneous or secondary form, and these two variants show considerable clinicopathologic differences with a more favorable prognosis associated with primary skin disease.<sup>145</sup> This neoplasm occurs primarily in older adults, seems to have an association with EBV infection, and usually is associated with a high mortality rate. Angiocentric CTCL is an unusual T-cell lymphoma of childhood that presents with a vesiculopapular eruption that may mimic hydroa vacciniforme (see Chapter 19).<sup>146</sup> It occurs mainly in children from Asia and Latin America and may be related to EBV infection.

Hodgkin lymphoma is a fairly common childhood lymphoma that often occurs before adolescence. It rarely occurs before the age of 5 years, and there is another peak of involvement later in adulthood. In the majority of cases, Hodgkin lymphoma, which is now classified as a B-cell lymphoma, is initially limited to the lymph nodes, with superficial lymph nodes more commonly initially involved than visceral lymph nodes. It presents as painless lymph node enlargement, usually in the neck. Hodgkin lymphoma is histologically characterized as one of several subtypes, and staging depends on the extent of lymph node involvement and the presence or absence of constitutional symptoms. Skin involvement resulting from infiltration of the malignant cells is quite rare (<1%), but nonspecific secondary findings may occur and include pruritus, purpura, ichthyosis, and pigmentary changes. When specific cutaneous lesions are present, they are usually pink to red-brown or violaceous papules or nodules that may coalesce to form larger plaques or tumors.

The treatment of cutaneous lymphomas can be planned only after thorough evaluation and staging for the extent of extracutaneous disease. Occasionally patients with low-grade neoplasms with limited involvement may be appropriately managed by watchful waiting. Therapeutic options otherwise include radiotherapy, chemotherapy, surgical excision (i.e., for localized primary cutaneous tumors), and newer cytokine and biologic therapies.

## Cutaneous T-cell Lymphoma

CTCL (mycosis fungoides) is a primary cutaneous lymphoma that occurs primarily in adults. Although approximately 75% of patients are diagnosed after the age of 50,<sup>147</sup> onset of the disease during childhood may occur in 0.5% to 5% of cases.<sup>147,148</sup> It has been diagnosed in patients as young as 22 months of age<sup>147</sup> and is suspected to have started in patients as young as 10 months of age.<sup>149</sup> Many factors may

contribute to the seemingly lower incidence of CTCL in children, including lack of recognition of its occurrence and hesitancy to perform skin biopsies in younger patients. Delay in diagnosis is most common in the youngest age group (0 to 3 years old).<sup>149</sup> The possibility of CTCL should be considered in the setting of chronic dermatoses recalcitrant to therapy, and serial skin biopsies may be necessary.<sup>150</sup> In general, patients who have CTCL during childhood are more likely to have limited disease and as a result seem to have a better disease-specific survival rate than older patients with CTCL.<sup>147,151</sup> Some studies, however, have found no statistically significant differences in the course between early childhood- and adult-onset disease.<sup>152</sup> Table 10-3 lists the staging and classification for CTCL.

The clinical presentation of CTCL is quite variable. Most pediatric patients have erythematous, scaly patches, papules, and plaques (Fig. 10-19) with variable degrees of pruritus. Thin, erythematous, atrophic patches on the trunk and buttocks are a classic presentation. At times, central clearing develops and the lesions assume serpiginous, arciform, horseshoe, or other bizarre shapes. The lesions of CTCL may simulate many other skin disorders, including atopic dermatitis, psoriasis, parapsoriasis, hypopigmenting or depigmenting disorders (i.e., vitiligo or pityriasis alba; see below), and pityriasis lichenoides.<sup>153,154</sup> Some patients show changes of poikiloderma characterized by the

BSA, Body surface area; TNMB, tumor, nodes, metastasis, blood.

\*Skin: T0, clinically suspicious lesions; T1, limited papules or plaques (<10% BSA); T2, generalized papules or plaques (>10% BSA); T3, tumors; T4, generalized erythroderma.

†Nodes: N0, none; N1, clinically abnormal nodes, negative pathology; N2, no clinically abnormal nodes, positive pathology; N3, clinically abnormal nodes and positive pathology.

‡Viscera: M0, no visceral involvement; M1, visceral involvement confirmed by pathology.

§Blood: B0, atypical circulating cells not present (<5%); B1, atypical circulating cells present (>5%).

**Figure 10-19** Cutaneous T-cell lymphoma. Erythematous macules, papules, plaques, and nodules in this 6-year-old male. Skin biopsy revealed an atypical T-cell infiltrate with similar circulating cells noted in the blood.

**Figure 10-20** Lymphomatoid papulosis in a patient with cutaneous T-cell lymphoma (CTCL). This 10-year-old male with a long history of patch- and plaque-stage CTCL developed intermittent self-healing ulcerative nodules that were noted to be CD30+ on histologic evaluation.

combination of hyperpigmentation and hypopigmentation, atrophy, and telangiectasia. Although the lesions themselves may not be pathognomonic for CTCL, their chronic nature and history of recalcitrance to therapy often prompt further diagnostic investigations. Skin nodules and tumors, which may grow aggressively and occasionally ulcerate, are an uncommon presentation of pediatric CTCL and are more often seen in adult and elderly patients. Occasionally, focal skin nodules may intermittently occur superimposed on a background of patch- or plaque-type CTCL, with CD30+ cells and a self-limited clinical course consistent with lymphomatoid papulosis<sup>155</sup> (Fig. 10-20) (see Chapter 4). Occasionally, patients exhibit skin findings suggestive of pigmented purpuric dermatosis.<sup>156,157</sup> In some patients, the entire cutaneous surface may become infiltrated, producing thickened red skin with or without scaling and with islands of normal skin often remaining for a time before the universal erythroderma becomes complete.

Hypopigmented CTCL is a variant of the disease that occurs most commonly in children. It tends to present most often in patients with black or darkly pigmented skin, although more fair-skinned individuals may also manifest these findings.<sup>158–160</sup> Patients with this form of CTCL show hypopigmented macules and patches (Fig. 10-21) that are usually asymptomatic. The clinical appearance most often simulates disseminated pityriasis alba, tinea versicolor, or postinflammatory hypopigmentation. Lesions may be round, arcuate, or gyrate, and often there is some subtle overlying scale.<sup>148</sup> Histologically, biopsies of hypopigmented lesions show the same features as the inflammatory lesions of CTCL, although on immunophenotyping, the infiltrate may be shown to be composed predominantly of CD8+ T cells rather than CD4+ T cells.<sup>161</sup>

Granulomatous slack skin is an extremely rare form of CTCL characterized by the insidious onset of papules and violet-colored plaques with progression to pendulous skin masses.<sup>162</sup> The lesions appear erythematous and wrinkled and are most commonly distributed in the axillary and inguinal regions. There is a male predominance in the literature.<sup>148</sup> Histologically, a granulomatous T-cell infiltrate is seen along with fragmentation of elastic fibers.<sup>163</sup>

Follicular mucinosis (alopecia mucinosa) (see Chapter 7) has also been seen as a feature of CTCL, primarily in adults. Although it occasionally occurs as a manifestation of the disorder in children, in the majority of patients (children and adults <40 years), it is generally regarded as a benign condition not associated with CTCL. In a series of 31 children with follicular mucinosis, 12 fulfilled criteria for CTCL, and the vast majority responded to treatment with mild- to moderate-potency topical corticosteroids.<sup>164</sup> In another series of 11 patients with the condition, three were found to have CTCL based on immunophenotyping and/or T-cell-receptor gene cell rearrangement.<sup>165</sup> Follicular mucinosis presents as well-demarcated flesh-colored to hypopigmented patches with prominent superimposed follicular

**Figure 10-21** Hypopigmented cutaneous T-cell lymphoma. Hypopigmented patch with mild scaling on the posterior axillary region in a boy with histologically confirmed cutaneous lymphoma.

**Figure 10-22** Follicular mucinosis. This hypopigmented patch with superimposed follicular erythematous papules was present on the leg of a young boy with a known history of cutaneous T-cell lymphoma.

papules (Fig. 10-22), often with associated hair loss. It occurs most commonly on the lower extremities, although it may also involve the trunk or face, and there are usually multiple lesions. Although most cases in childhood represent a benign self-limiting process, when lesions are persistent or other suggestive features are present, evaluation for possible CTCL should be considered. Pityriasis lichenoides-like CTCL presents with erythematous papules with scaling and crusting that simulate pityriasis lichenoides chronica or pityriasis lichenoides et varioliformis acuta (see Chapter 4).<sup>166,167</sup>

Sézary syndrome, which is characterized by erythroderma, lymphadenopathy, and circulating atypical lymphocytes (Sézary cells), is felt to be a systemic variant of CTCL. It is rare in children. The cutaneous eruption is scaly, pruritic, and resistant to multiple therapies. As with many forms of CTCL, repeat skin biopsies may be necessary to confirm the diagnosis.

The diagnosis of CTCL is established based on the histologic findings of skin biopsy tissue in conjunction with immunohistochemical

studies. Although there are characteristic histologic features in well-developed disease, biopsy findings in patients with early involvement may be difficult to distinguish from other, more benign processes such as inflammatory dermatoses.<sup>148</sup> Immunohistochemical studies usually reveal an infiltrate of CD4+ T cells with loss of CD7+ (leu-9) cells. Southern blot analysis and polymerase chain reaction (PCR) may be used to evaluate for T-cell receptor  $\gamma$  gene rearrangement, which is seen in many but not all CTCL specimens.<sup>168</sup> A more specific technique, combining PCR and denaturing gradient gel electrophoresis (DGGE), demonstrates more sensitivity for detecting clonality but poorer specificity, because it may detect rearrangements in a subset of patients with chronic dermatitis.<sup>169</sup>

There are a variety of treatment options for children with CTCL, but no standard protocols exist and the ideal therapy remains unclear. Potent topical corticosteroids are often sufficient for limited patch- or plaque-stage CTCL, but patients must be monitored for adrenal suppression and cutaneous atrophy.<sup>170</sup> Topical nitrogen mustard has demonstrated efficacy in adults with patch- or plaque-stage disease, and long-term follow-up studies have confirmed its safety.<sup>171</sup> Psoralen plus ultraviolet A (PUVA) photochemotherapy is effective but may be difficult and have limiting side-effects in children. Topical PUVA has been demonstrated useful in children with patch- and plaque-stage disease.<sup>172</sup> Other therapies used for CTCL include ultraviolet B (UVB) therapy, carmustine, imiquimod, tazarotene, electron-beam therapy, systemic chemotherapy, denileukin diftitox (a fusion toxin), interferon, photopheresis, and bexarotene (a systemic retinoid, a cousin of the retinoids). Narrow-band UVB therapy may offer similar results as those seen in adults and has the potential advantages of being well tolerated in children, having fewer unpredictable phototoxic reactions, and requiring shorter treatment sessions.<sup>173</sup> However, pediatric experience with many of these treatments is quite limited. Young patients with CTCL may have an increased risk of Hodgkin lymphoma and hence should be monitored on a long-term basis.

## Neuroblastoma

Neuroblastoma, a tumor derived from primitive cells of the sympathetic nervous system, is the most common malignant tumor affecting infants in the first month of life and accounts for 30% to 50% of all tumors occurring in the newborn period.<sup>174</sup> It is a tumor with large variability in its clinical presentation and natural history. Neuroblastoma may regress spontaneously (particularly in infants), mature into a benign ganglioneuroma, or result in extensive metastatic disease with a poor prognosis.<sup>175</sup> These tumors typically present as an abdominal mass because of liver infiltration with malignant cells and may originate in the adrenal medulla, visceral ganglia, or paravertebral sympathetic ganglia.

Cutaneous metastases of neuroblastoma are seen in around 2% of all patients and 32% of those with a neonatal presentation. These skin lesions, which may be the presenting sign of the disease, appear as firm, blue-purple papules and nodules (Fig. 10-23). When occurring in a neonate, they fall into the spectrum of blueberry-muffin lesions (see Box 10-6). The catecholamines produced by the tumor cells may result in the classic blanching and peripheral halo of erythema noted after firm stroking. Subcutaneous nodules mimicking deep infantile hemangiomas have also been observed.<sup>176</sup> When cutaneous metastases of neuroblastoma are encountered in the infantile period, it confers a more favorable prognosis than other patients with metastatic neuroblastoma, although tumor biology is the most critical prognostic consideration.<sup>174,177</sup> Very hard subcutaneous nodules arising from the skull and orbital ridges are caused by skeletal metastases. Orbital metastases may result in the classic presentation of periorbital ecchymoses, so-called "raccoon eyes." Another ocular finding is that of heterochromia irides, which is related to involvement of the ophthalmic sympathetic nerve.

Staging of neuroblastoma is based on clinical and radiographic extent of disease and surgical resectability. Tumor tissue is usually necessary to confirm the diagnosis, and when cutaneous lesions are present, skin biopsy with histologic evaluation, immunophenotyping, and genetic analysis may be indicated. Measurement of urine and serum catecholamines or metabolites, CT and/or MRI, bone marrow

**Figure 10-23** Neuroblastoma with cutaneous metastases. This male infant had numerous firm, blue subcutaneous nodules that revealed neuroblastoma on histologic examination. He was found to have a large retroperitoneal primary tumor with disseminated metastatic disease.

**Figure 10-24** Fibrosarcoma. This congenital, vascular, friable mass was initially thought to be an infantile hemangioma; it grew rapidly and ultimately required full excision with amputation.

aspirate and biopsies, and iodine-123 metaiodobenzylguanidine (MIBG) scintigraphy are recommended as part of the staging evaluation.<sup>178</sup>

## Rhabdomyosarcoma

Rhabdomyosarcoma is the most common soft-tissue sarcoma in children and adolescents, accounting for 50% of all soft-tissue sarcomas in those under 15 years of age.<sup>179,180</sup> It is a malignant soft-tissue neoplasm of skeletal muscle origin and is seen primarily in the first and second decades of life. Although rhabdomyosarcoma is not typically a primary skin tumor, it is included in this section, because it may simulate other cutaneous tumors, may extend or metastasize to the cutaneous surface, and may initially present to the pediatrician or other pediatric healthcare provider.

Rhabdomyosarcoma usually presents as an asymptomatic mass that is occasionally painful.<sup>181</sup> The head and neck, especially the nasal cavity and paranasal sinuses, are the most common sites of involvement in children. The genitourinary tract and extremities are other common sites of predilection. Patients may present with small to large nodules or rapidly expanding swellings. The surface may be flesh-colored to erythematous and at times may appear vascular with prominent vessel markings. The differential diagnosis may include infantile hemangioma, vascular malformation, fibrosarcoma (Fig. 10-24),

cyst, infection, or other inflammatory or neoplastic process. Perianal rhabdomyosarcoma may mimic perirectal abscess.<sup>182</sup> Primary cutaneous rhabdomyosarcoma refers to a tumor that arises in the dermis or subcutis with no other identifiable primary tumor elsewhere and that tends to display aggressive behavior in both adults and children.<sup>183</sup> Congenital alveolar rhabdomyosarcoma is a rare subtype, with more than 50% of patients presenting with multiple cutaneous metastases.<sup>184</sup> Tumor-specific translocations are detected in the majority of cases, and the disorder is invariably fatal.

Treatment of rhabdomyosarcoma consists primarily of surgery, radiotherapy, and chemotherapy. Although challenging, the overall 5-year survival rate of children and adolescents with both nonmetastatic and metastatic tumors approaches 80%.<sup>185</sup>

Although chiefly of cosmetic significance, disorders of pigmentation are among the most conspicuous and thus can have profound psychosocial implications for pediatric patients. The most important pigments in skin are melanin, reduced and oxygenated hemoglobin, and carotene. Melanin is a pigment produced by melanocytes, specialized dendritic cells derived from the neural crest that migrate to the basal layer of the epidermis during embryogenesis. Melanocytes synthesize and package melanin within discrete membrane-bound organelles called *melanosomes*, which are then transferred via melanocytic dendrites to surrounding keratinocytes of epidermis and hair follicles; on average, there is one melanocyte to every 36 surrounding keratinocytes.<sup>1-4</sup> Variations in skin color among different individuals reflect the number and size of mature melanosomes, not the number of melanocytes.

Four stages of melanosome maturation have been described and can be distinguished by ultrastructural examination:

1. Membrane vesicles that contain no visible pigment (stage I or premelanosomes)
2. More elongated vesicles with an ordered internal membrane but no pigment (stage II melanosome)
3. The presence of melanin on ordered internal fibers (stage III melanosome)
4. Structures so full of melanin that the luminal structures cannot be seen (mature or stage IV melanosomes).

Darkly pigmented individuals have more numerous, larger, singly dispersed melanosomes, whereas individuals with light pigmentation have fewer, smaller melanosomes that are aggregated into complexes and are more rapidly degraded.<sup>5</sup> The presence of melanin in the epidermis helps protect against ultraviolet (UV) radiation and associated cutaneous damage, including pigmented nevi,<sup>6</sup> actinic damage, and cutaneous neoplasia. Red hair color, usually associated with an inability to tan, increases the risk of developing melanoma fourfold and has been associated with polymorphisms in the melanocortin receptor 1 (MCR1).<sup>7</sup>

Melanin exists in two forms in human skin: brown-black eumelanin and yellow-red pheomelanin. Melanin biosynthesis is primarily regulated by tyrosinase, a copper-dependent enzyme that allows the initial conversion of tyrosine to dihydroxyphenylalanine (DOPA). Eumelanin synthesis involves increased levels of tyrosinase activity and additional melanogenic enzymes such as tyrosinase-related protein (TRYP)-1 and TRYP-2/dopachrome tautomerase, both regulators of distal steps in the pathway to melanin and/or stabilizers of tyrosinase. Pheomelanin synthesis, however, involves the addition of a cysteinyl group that accounts for the yellow-red color and is associated with reduced tyrosinase activity and absence of TRYP-1, TRYP-2, and a protein called pink-eyed dilution (P) protein.

The ratio of eumelanin to pheomelanin, as well as the total content of melanin, is higher in skin types V–VI (the darkest skin colors) than in skin types I and II (the lightest skin colors, most prone to burning with UV light exposure). Pheomelanin levels tend to be greatest in individuals with bright red hair, whereas eumelanin is the predominant pigment in individuals with brown or black hair.<sup>8</sup>

In all races the dorsal and extensor surfaces are relatively hyperpigmented, and the ventral surfaces are less pigmented. This is most evident in races with darker skin (African-Americans, Hispanics, and Asians). The separation of the dorsal and ventral pigmentation is most conspicuous on the extremities (Voigt–Futcher lines) (Fig. 11-1).<sup>9</sup> This differentiation of dorsal and ventral pigmentation is present from infancy and persists throughout adulthood. Approximately 75% of

African-Americans and 10% of whites have at least one line of pigmentary demarcation.

## Disorders of Abnormal Pigmentation

Disorders of decreased pigmentation may be classified as:

1. Genetic or developmentally controlled disorders, in which pigmentation tends to be abnormal from birth or early infancy
2. Disorders associated with depigmentation or loss of previously existing melanin.

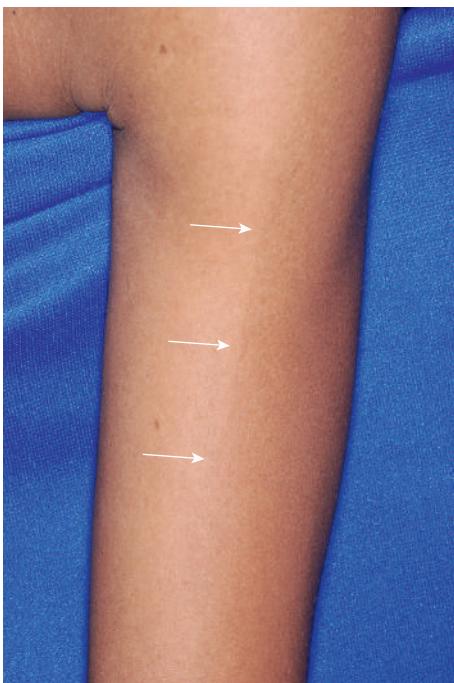

Genetic disorders of decreased pigmentation include tuberous sclerosis, piebaldism, Waardenburg syndrome (WS), and albinism. Acquired disorders of decreased pigmentation include vitiligo, postinflammatory hypopigmentation, pityriasis alba, and tinea versicolor. Hypopigmentary disorders may be further divided into patterned and unpatterned groups. Patterned forms of decreased pigmentation include pityriasis alba, cutaneous T-cell lymphoma, tinea versicolor, postinflammatory hypopigmentation, leprosy, pinta, tuberous sclerosis, pigmentary mosaicism, vitiligo, piebaldism, and the Waardenburg and Vogt–Koyanagi syndromes. Unpatterned decreases in pigmentation may be seen in albinism, phenylketonuria, and the silvery hair syndromes.

### VITILIGO

Vitiligo, an acquired form of patterned loss of pigmentation, is a polygenic, multifactorial disorder that involves at least 16 susceptibility genes,<sup>10,11</sup> encoding a variety of proteins involved in regulation of the immune system and tyrosinase, the principal vitiligo autoimmune antigen. Melanocytes are destroyed by antigen-specific cytotoxic T cells, resulting in patchy depigmentation. Both lesional and nonlesional skin show up regulation of markers of heightened innate immunity, although only lesional skin shows suppression or absence of melanocyte-specific genes.<sup>12</sup> Autoantibodies that can destroy melanocytes have been detected in serum samples of patients with vitiligo, further emphasizing that alterations are not limited to lesional skin.

Vitiligo affects approximately 1% of the population.<sup>13</sup> Although rarely congenital, its onset in about half of affected patients is before the age of 20 years and in one-quarter before 8 years of age.<sup>14–16</sup> The disorder has a prevalence of 7% to 12% among first-degree relatives, 6% among siblings, and 23% among monozygotic twins,<sup>17</sup> but a recent study suggested a family history of vitiligo in approximately 30% of patients.<sup>18</sup> Relative to postpubertal onset (after 12 years of age), prepubertal onset is associated with a greater likelihood of a family history of vitiligo and a personal history of atopic dermatitis.<sup>18</sup> Autoimmune disorders are seen with significantly increased incidence in immediate family members of affected individuals, most commonly vitiligo itself,<sup>14</sup> but other autoimmune disorders (particularly hypothyroidism and alopecia areata) occasionally occur in pediatric patients with vitiligo.<sup>19–21</sup> Thyroid autoimmune antibodies have been described in 11% of patients.<sup>19,22</sup>

The location, size, and shape of individual lesions vary considerably, yet the overall picture is characteristic. Lesions usually appear as partially or completely depigmented ivory-white macules or patches, usually with well-defined, sometimes hyperpigmented, convex borders<sup>23</sup> (Figs. 11-2 through 11-7). They tend to have an oval or linear contour and range in size from several millimeters to large patches. Rarely, extensive or near-total depigmentation of the body (universal

**Figure 11-1** Voigt–Futcher line. This persistent line of demarcation separates dorsal and ventral pigmentation.

**Figure 11-2** Vitiligo. Depigmented, usually well-defined, white macules or patches that tend to have an oval or linear contour.

or total vitiligo) occurs (see Fig. 11-4). Although usually considered to be a bilateral disorder, vitiligo may be asymmetric; segmental vitiligo, in which the depigmentation is confined to a localized, usually unilateral area, occurs more often in children than in adults (see Fig. 11-5). In 75% of affected individuals the first lesions occur as depigmented spots on exposed areas such as the dorsal surfaces of the hands, face, and neck. Other sites of predilection include the body folds (the axillae and groin), body orifices (the eyes, nostrils, mouth, navel, areolae, genitalia, and perianal regions (see Figs. 11-6 and 11-7), and areas over bony prominences such as the elbows, knees, knuckles, and

**Figure 11-3** Vitiligo. Symmetrical depigmentation of the knees and lower extremities. The dorsal aspect of the feet and hands are particularly hard to repigment.

**Figure 11-4** Vitiligo. Extensive depigmentation in this 13-year-old girl. Virtually all of her skin was depigmented, except for the pigmented areas on the back. After years of unsuccessfully trying to stimulate repigmentation, at 16 years of age this girl and her parents elected to initiate 20% monobenzyl ether of hydroquinone.

shins (see Fig. 11-3). Approximately 12% of patients show white hairs (leukotrichia or poliosis) (Fig. 11-8). Vitiligo has been divided into several subtypes based on the distribution of lesions. In descending order of incidence in pediatric patients, these include generalized, focal, segmental, acrofacial, mucosal, and universal. Patients with vitiligo, especially those with prepubertal onset,<sup>18</sup> commonly show halo nevi,<sup>24</sup> pigmented nevi surrounded by a zone of depigmentation (Fig. 11-9) (see Chapter 9, Fig. 9-26). The discovery of a halo nevus

**Figure 11-5** Segmental vitiligo. Segmental distribution of depigmentation on the right side of the philtrum and upper lip. Note the sharp midline demarcation.

**Figure 11-8** Vitiligo with poliosis. When the hair in the affected area is white, there is a decreased likelihood of repigmentation.

**Figure 11-6** Vitiligo. Periorbital depigmentation. Although eyebrows and eyelashes are occasionally affected as well (poliosis), in this boy the hair has retained its pigmentation. The perioral and perinasal areas are also commonly affected on the face.

**Figure 11-9** Vitiligo. Halo nevi are commonly seen in children with vitiligo and can partially or fully clear the nevus. Any patient with a halo nevus should be completely examined for the possibility of vitiligo elsewhere. The mechanism of clearance of pigmentation in vitiligo and halo nevi is thought to be the same.

**Figure 11-7** Vitiligo. The vitiligo was limited to the genital and perianal areas in this African-American boy.

and particularly multiple halo nevi<sup>25</sup> should prompt the search for vitiligo elsewhere.

The Koebner phenomenon (development of a lesion after trauma) has been described in approximately 15% of affected children with vitiligo, particularly related to sunburn. A recent study showed that skin friction induces melanocyte detachment in persons with vitiligo but not in individuals with normal skin, further emphasizing the role of trauma in triggering new lesions.<sup>26</sup> Other individuals associate the onset of vitiligo with periods of severe physical or emotional trauma.

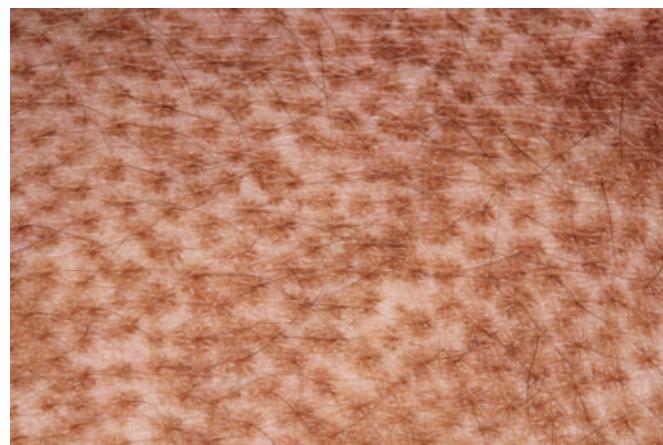

Ordinarily the diagnosis of vitiligo is not difficult, especially when there is symmetric depigmentation about the eyes, nostrils, mouth, nipples, umbilicus, or genitalia. In fair-skinned individuals it may be difficult to differentiate areas of vitiligo from the adjacent normal skin. In such cases examination under Wood light in a darkened room may help delineate a contrast between normal and depigmented skin. When the diagnosis is in doubt, the distribution of lesions, the age at onset, the presence of a convex hyperpigmented border, and the characteristic sites of predilection may help establish the correct diagnosis.

Lesions of postinflammatory hypopigmentation are hypopigmented, not depigmented, and patients usually provide a history of previous localized inflammation. However, it is not uncommon to see residual depigmentation in severe atopic dermatitis, especially in darker skinned patients and involving the wrists, hands, ankles, and feet. Nevus depigmentosus tends to be a well-defined, usually

hypopigmented patch that may be present at birth or appear during infancy as normal pigmentation increases but is subsequently stable (see Fig. 11-22). Pityriasis alba is a hypopigmentary disorder and may be further differentiated by its common distribution on the face, upper arms, neck, and shoulders and its occasional fine adherent scale (see Chapter 3, Fig. 3-33). Lesions of tinea versicolor may be differentiated by their discrete or confluent small, round hypopigmented macules; their fine scales; and their typical distribution on the trunk, neck, upper arms, or particularly in pediatric patients, the face (see Chapter 17, Figs. 17-33 and 17-34). The demonstration of hyphae on microscopic examination of epidermal scrapings is confirmatory (see Fig. 17-36). The diagnosis of cutaneous T-cell lymphoma of the hypopigmented type should be considered in adolescents with more extensive hypopigmented macules resembling pityriasis alba (see Chapter 10, Fig. 10-21).<sup>27</sup>

The presence of a white forelock and the pattern of depigmentation suggest a diagnosis of piebaldism or WS (see Figs. 11-17 and 11-19). Most individuals with WS show characteristic facial features. The diagnosis of albinism (see Oculocutaneous Albinism section) may be established by its presence at birth and by the facts that normal eye color is retained in vitiligo (but not in albinism); in addition, hair on glabrous skin in the patient with vitiligo, in contrast to that in the patient with albinism, often retains most of its pigment (see Fig. 11-11). Adolescents with GM3 synthase deficiency progressively develop depigmented patches as well as acral lentiginous.<sup>28</sup> The hypopigmented macules of tuberous sclerosis (see Fig. 11-21, A) usually lack the characteristic milk-white appearance of lesions of vitiligo, are present at birth or during the first years of life, do not change with age, and have a normal number of melanocytes (with reduction in size of melanosomes and melanin granules within them) in contrast to the absence or decrease in number of melanocytes in patients with vitiligo.

The course of vitiligo is variable. Long periods of quiescence may be interrupted by periods of extension or partial improvement. Complete spontaneous repigmentation is very rare, and in one study, more than 50% repigmentation occurred in only 2.4% of patients over 6 months.<sup>29</sup> At least partial repigmentation is more likely in children with lesions of recent onset and during the summer months because of increased exposure to UV light. Loss of pigmentation in lesions that have at least partially repigmented is common in temperate climates during the winter months. The repigmentation process proceeds slowly, although children tend to respond with more permanent and complete repigmentation than adults. Repigmentation most commonly appears as small, freckle-like spots of repigmentation, reflecting the migration of melanocytes from the hair follicle (Fig. 11-10). As such, the chance of repigmentation in a site is greater if pigmentation of regional hairs is retained. Diffuse repigmentation of lesions or repigmentation from the margins has also been described. The preferential tendency to repigment the face and neck versus other body sites has been attributed to the high density of hair follicles at these sites, as well as exposure to UV light. In contrast, sites lacking or poor in

**Figure 11-10** Vitiligo. Note the perifollicular pattern of repigmentation.

hair follicles, such as the dorsal surfaces of the fingers, hands, feet, and the volar aspect of the wrists, do not respond as well as other areas.

Quality-of-life studies have shown that children with vitiligo have impaired social development as young adults, stressing the importance of intervention.<sup>30</sup> Risk factors associated with the highest risk for quality-of-life impairment are age (15 to 17 years), location (face and legs), and greater extent of involvement.<sup>31</sup> In one study, anxiety was observed in 42% of caregivers of children with vitiligo, even higher than that in caregivers of children with atopic dermatitis or psoriasis, and was correlated with poor quality-of-life scores in the children.<sup>32</sup> Patients with vitiligo and their families can find support through the National Vitiligo Foundation ([www.vitiligofoundation.org](http://www.vitiligofoundation.org) or [www.nvfi.org](http://www.nvfi.org)).

Full repigmentation is challenging, especially in children with more extensive involvement and when vitiligo involves more recalcitrant areas. At least partial repigmentation can often be accomplished by the twice-daily application of mid-strength to potent topical corticosteroids or topical calcineurin inhibitors (tacrolimus ointment, pimecrolimus cream).<sup>33,34</sup> The skin of the head and neck responds best to both of these treatment modalities. Overall, 40% to 90% of pediatric patients show a response to these treatments, although moderate to high potency steroids can theoretically be associated with systemic absorption, especially if applied over large body-surface areas or on the head and neck continuously.<sup>21,35,36</sup> Application of a topical calcineurin inhibitor, especially for facial vitiligo, eliminates the risk of cutaneous atrophy and ocular toxicity carried by application of topical corticosteroids. However, hyperpigmentation in sun-exposed areas has been described after use of tacrolimus ointment.<sup>37</sup> Although topical anti-inflammatory therapy has been standard, one study described good to excellent repigmentation in 65% of 400 children treated with minipulses of oral methylprednisolone on 2 consecutive days weekly and fluticasone ointment twice daily.<sup>38</sup> Topical application of vitamin D<sub>3</sub> analogues (calcipotriene, calcipotriol) has also been used but has the potential to be more irritating.

The repigmentation of lesional skin can be stimulated most effectively by exposure to UV light, generally in combination with topically applied anti-inflammatory medications or vitamin D<sub>3</sub> analogues. Avoidance of burning with phototherapy is important, because cutaneous burning can lead to further depigmentation via the Koebner phenomenon. Most commonly narrow-band (nb) UVB is utilized, because it has been shown to be as effective as psoralen and UVA (PUVA) therapy,<sup>39-41</sup> which is now rarely used in children because of its toxicity. nbUVB phototherapy is largely reserved for older pediatric patients who are highly motivated and completely informed about their chances for improvement with these therapies. Treatment is traditionally 2 to 3 times weekly, beginning at a relatively low dose and increasing by about 20% each treatment until slight erythema is reached. Should there not be a good response within 6 months, nbUVB can be stopped.<sup>42</sup> The 308-nm monochromatic excimer laser (in the UVB range) is a painless therapy for more localized lesions.<sup>43</sup> The best responses to excimer laser are at sites that also respond best to nbUVB, with the dorsal aspect of the hands and feet, genital area, and suprapubic area the most difficult sites to repigment.<sup>44</sup> In one study of chronic stable vitiligo, more than 50% of patients showed more than 75% repigmentation.<sup>45</sup> Responses to the excimer laser may be improved by concurrently using anti-inflammatory therapy.<sup>46</sup> Treatment with the combination of topical tacalcitol (vitamin D derivative) and excimer laser for 12 sessions (over 12 weeks) was significantly more effective than the excimer laser treatments alone.<sup>47</sup> The use of antioxidants, particularly pseudocatalase, has been based on the demonstration of decreased enzymatic and nonenzymatic oxidants in the skin of patients with vitiligo.<sup>48</sup> Although in one retrospective uncontrolled study, twice-daily full-body application of pseudocatalase cream coupled with daily low-dose nbUVB stopped vitiligo progression and led to more than 75% repigmentation in 93% of treated children,<sup>49</sup> most experience with pseudocatalase cream has been disappointing. Oral antioxidants for vitiligo are under investigation.

Surgical modalities are based on the autologous grafting of nonlesional epidermis or cultured melanocytes from healthy skin sites to depigmented areas that have been deepithelialized by ablative procedures.<sup>50,51</sup> Chinese cupping has recently been shown to be a technique to induce blisters for capturing donor melanocytes.<sup>52</sup> Grafting has

been demonstrated to lead to at least 75% repigmentation in 30% to 90% of patients and is most successful for more localized lesions.<sup>53,54</sup> Although minigrafting with or without UV light exposure has shown success, especially in patients with facial grafts and with segmental and limited subtypes,<sup>55,56</sup> these approaches are time-consuming, costly, and can result in recurrence of vitiligo (including at the donor site), scarring, infection, and keloids in at-risk patients; grafting should only be considered for stable vitiligo in selected adolescents at sites that are resistant to medical treatment.

When treatment is unsatisfactory, lesions can be hidden by the use of camouflage therapy,<sup>57</sup> which has been shown to improve the quality of life in children with vitiligo.<sup>58</sup> Camouflage can be achieved most effectively with cosmetics (e.g., Cover FX, Dermablend, or Covermark), but aniline dye stains, such as Vitadye (Elder) and quick-tan preparations<sup>59</sup> have also been used.

In those few recalcitrant cases in which vitiligo has progressed to such an extent that more than 50% of the body is involved (particularly in those persons in whom only a few islands of normal skin remain), an attempt at depigmentation with 20% monobenzyl ether of hydroquinone (Benoquin) may be considered. Such patients should be reminded that the depigmentation is permanent, requiring lifelong vigilant use of sun protection. Owing to the permanence of depigmentation therapy, this treatment is not generally offered to preadolescent patients.

### VOGT-KOYANAGI-HARADA SYNDROME

Vogt–Koyanagi–Harada syndrome is a rare autoimmune disorder characterized by bilateral granulomatous uveitis, alopecia, vitiligo, poliosis, dysacusia (in which certain sounds produce discomfort), deafness, and sometimes meningeal irritation or encephalitic symptoms.<sup>60</sup> Usually seen in adults in the third and fourth decades of life,<sup>61</sup> the disorder also occurs in children and adolescents.<sup>62,63</sup>

The bilateral uveitis occurs in all patients and generally takes a year or more to clear. The uveitis is often accompanied by choroiditis and optic neuritis. As the uveitis begins to subside, poliosis (in 80% to 90%), usually bilateral vitiligo (in 50% to 60%), alopecia (in 50%), and temporary auditory impairment develop. A prodromal febrile episode with lymphocytosis, encephalitic or meningeal symptoms, and increased pressure of the cerebrospinal fluid may precede the bilateral uveitis. The poliosis may be limited to the eyebrows and eyelashes or may also involve the scalp and body hair. The pigmentary changes, which generally appear 3 weeks to 3 months after the onset of the uveitis, tend to be permanent. Although most patients show some recovery of visual acuity, the majority of children and adolescents have a residual visual defect related to the development of cataracts, glaucoma, choroidal neovascularization, and subretinal fibrosis.<sup>64</sup>

Early and aggressive systemic corticosteroids are the primary intervention, but refractory cases may respond to cyclosporine, methotrexate, or tumor necrosis factor (TNF) inhibitors.<sup>65,66</sup>

### ALEZZANDRINI SYNDROME

Alezzandrini syndrome is a rare disorder of unknown origin primarily seen in adolescents and young adults. Possibly related to Vogt–Koyanagi–Harada syndrome, it is characterized by unilateral degenerative retinitis with visual impairment followed after an interval of months or years by bilateral deafness and unilateral vitiligo and poliosis, which appear on the side of the retinitis.<sup>67,68</sup>

### OCULOCUTANEOUS ALBINISM

Albinism is a group of inherited disorders of melanin synthesis manifested by a congenital decrease of pigmentation of the skin, hair, and eyes.<sup>69,70</sup> Although some classifications include nonsyndromic and syndromic (e.g., silvery hair and Hermansky–Pudlak syndromes) forms, the pigmentary changes are very different among these disorders. Most albinism is oculocutaneous, but affected individuals may have ocular albinism, usually an X-linked recessive form caused by mutation in OA1/GPR143, with the abnormal pigmentation limited to the eye. An oculocerebral syndrome with hypopigmentation (Cross–

McKusick–Breen syndrome) is characterized by oculocutaneous albinism (OCA), microphthalmos, spasticity, and mental retardation.<sup>71</sup> Although albinism associated with immunodeficiency is primarily seen in the silvery hair syndromes (especially Chédiak–Higashi and Griscelli type 2), immunodeficiency is a feature of OCA associated with short stature (owing to mutations in LAMTOR2)<sup>72</sup> and in Hermansky–Pudlak syndrome (HPS) types 2 and 9, all related to the requirement for secretion of lysosomes and cytosolic granules for cytotoxic T- and natural killer cell function, antigen presentation to T cells, and neutrophil antimicrobial activity.<sup>73</sup>

### Nonsyndromic Oculocutaneous Albinism

Nonsyndromic oculocutaneous albinism (OCA) encompasses seven subtypes (Table 11-1) with decreased or absent melanin biosynthesis in the melanocytes of the skin, hair follicles, and eyes.<sup>74,75</sup>

OCA affects 1 in 17,000 persons in the United States. The highest prevalence (as high as 1% of the population) occurs in the indigenous Cuna tribe on the San Blas Islands off the coast of Panama. Affected Cuna children have been called *moon children* because they have marked photosensitivity and photophobia and prefer to go outdoors only at night. In some African tribes, the frequency is 1:1500. OCA is characterized by varying degrees of unpatterned reduction of pigment in the skin and hair, translucent irides, hypopigmented ocular fundi, and an associated nystagmus. Melanocytes and melanosomes are present in the affected skin and hair in normal numbers but fail to produce normal amounts of melanin. Regardless of subtype, affected individuals require vigorous sun protection of the skin and eyes and are at risk of adverse psychosocial effects because of the cosmetic aspects of albinism, especially in children from darker-skinned backgrounds. In addition to the stigma and potential social isolation, affected individuals in Africa have been maimed or killed because of the myths associated with albinism (contagion, body parts with magical and medicinal powers, intercourse with an affected woman will cure human immunodeficiency virus [HIV] infection).<sup>76</sup>

In the past, albinism was divided into tyrosinase-negative and tyrosinase-positive forms based on the ability (tyrosinase-positive) or inability (tyrosinase-negative) of plucked hair to become pigmented in the presence of tyrosine or DOPA. Tyrosinase-negative albinism, now called *type I albinism* (OCA1), results from absence (OCA1A) or partial reduction of the activity (OCA1B) of tyrosinase, the critical enzyme in melanin formation (see Table 11-1).<sup>77</sup> The underlying genetic bases for most forms of tyrosinase-positive albinism are also known. Type II albinism (OCA2) results from the absence of P protein,<sup>78</sup> OCA3 from absence of TRYP1,<sup>79,80</sup> and OCA4 from mutations in membrane-associated transporter protein (MATP).<sup>81</sup> Types OCA5–7 have been only been described in one to a few families (see Table 11-1).<sup>82–85</sup>

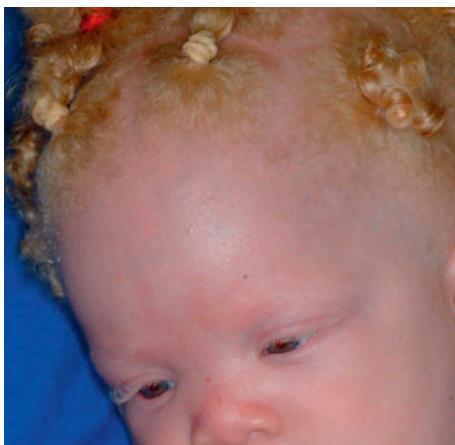

Individuals with OCA1A are unable to produce melanin at all and show white skin, white hair, and blue irides regardless of familial skin coloration.<sup>86</sup> Hair may show a slight yellow tint with advancing age because of denaturation of hair keratins. Similarly, ocular abnormalities are most severe with OCA1A. Eye findings include photophobia (with squinting), nystagmus (which typically develops at 6 to 8 weeks of age), strabismus, and decreased visual acuity; patients with OCA1A are often legally blind. The optic fibers are misrouted, resulting in monocular vision, which is usually not altered by surgical correction of the nystagmus or strabismus.<sup>87,88</sup> Although neurologic development is otherwise generally normal, an increased risk of attention-deficit/hyperactivity disorder (ADHD) has also been described.<sup>89</sup> Actinic damage (cutaneous atrophy, telangiectasia and wrinkling, actinic cheilitis, actinic keratoses) and malignant skin tumors (especially squamous cell carcinoma and nodular basal cell carcinoma but also melanoma) are almost always seen in affected young adults<sup>90</sup> but may present during childhood if the skin and eyes are not protected.

Patients with OCA1B have been divided into different phenotypic subgroups (see Table 11-1) that occur because of differences in degree of tyrosinase activity and the localization within the TYR gene of the mutation. In the yellow mutant form, the hair turns yellow in the first few years and a golden blond to light brown by the end of the second decade. Patients with platinum OCA develop small amounts of pigment with a metallic tinge in late childhood. Those with minimal-pigment OCA show darkening of the eyes with time, but the skin

**Table 11-1** Forms of Oculocutaneous Albinism

Type	Percentage of Patients Worldwide	Mutation	Function of Affected Gene	Comments
OCA1A	50%	TYR (absence) = tyrosinase negative	Critical enzyme in melanin formation	1:40,000; most severe cutaneous and ocular defects; highest risk of skin cancer; most common type in Caucasians
OCA1B		TYR (decreased)	Critical enzyme in melanin formation	Subtypes: yellow mutant (yellow hair); platinum (metallic tinge); minimal pigment (only eyes darken)
OCA1-TS		TYR (mutation site functions at higher temperatures)	Temperature-sensitive	Melanin at cooler sites (arms, legs)
OCA2	30%	P protein	Melanosome biogenesis and normal processing and transport of TYR and <i>TRYP1</i>	1:36,000 (whites); TYR-positive; includes Brown albinism (1:3900–1:10,000; most common form in patients of African origin; more pigment with advancing age)
OCA3 (Rufous)	3%	<i>TRYP1</i>	Catalyzes oxidation of 5, 6-dihydroxyindole-2-carboxylic acid monomers into melanin and stabilizes TYR so it can leave endoplasmic reticulum for incorporation into melanosomes	1:8500 Africans; reddish-bronze color to skin and hair
OCA4	17%	<i>MATP/SLC45A2</i>	Membrane transporter in melanosomes; mutations misroute TYR	Rare (whites); 1, 000 Japanese (27% of OCA in Japan); resembles OCA2
OCA5		Unknown (4q24)	–	One Pakistani family
OCA6		<i>SLC24A5</i>	Solute carrier protein involved in melanosome maturation and melanin biosynthesis	Heterogeneous extent of pigmentation
OCA7		<i>c10orf11</i>	Melanocyte differentiation	Rare

*MATP*, Membrane-associated transporter protein; OCA, oculocutaneous albinism; *P protein*, pink-eyed dilution protein; *TS*, temperature-sensitive; *TYR*, tyrosinase; *TRYP1*, tyrosinase-related protein 1.

**Figure 11-11** Albinism. This African-American girl has type II albinism (mutations in *P* gene) with light skin and yellow hair.

**Figure 11-12** In type II albinism, pigmentation can develop with time, including in pigmented nevi.

remains without pigmentation. Individuals with temperature-sensitive OCA1B are born with white skin and hair and blue eyes. Usually during the second decade of life, however, areas with lower temperature (especially hair at acral sites on the upper and lower extremities) are able to produce melanin, because the tyrosinase activity is only inactivated above 35 °C. This interesting phenotype is shared with that of the Siamese cat, a breed that also results from temperature-sensitive tyrosinase activity.

The OCA2 type of albinism, which includes tyrosinase-positive albinism and Brown OCA, is the most common form and is usually the type that occurs in African-American individuals (Fig. 11-11). The phenotype may vary from a slight to moderate decrease in pigmentation of the skin, hair, and eyes. With time, however, dark lentigines

and pigmented nevi usually develop at sun-exposed sites (Fig. 11-12). These individuals can also have problems with their eyes and an increased risk of cutaneous malignancy, but significantly less than that seen in individuals with tyrosinase-negative albinism. Although the degree of pigment dilution in affected individuals is variable, the diagnosis is usually easily established in those who have striking pigment loss or relative pigment dilution when compared with unaffected siblings or parents. Some patients with OCA2 have red hair, which has been shown to result from concomitant mutations in the melanocortin 1 receptor.<sup>91</sup> OCA2 has also been described in approximately 1% of patients with Angelman syndrome or Prader-Willi syndrome, disorders that result from deletion of the long arm of chromosome 15, the site of the *P* gene. Prader-Willi syndrome results

**Table 11-2** Clinical Features of Hermansky–Pudlak Syndrome

Type	Mutation	Underlying Cause	Findings Associated with the Cutaneous Pigment Dilution
HPS-1	<i>HPS1</i>	HPS1 and HPS4 associate in a complex (BLOC-3) that regulates biogenesis of melanosomes, platelet dense bodies, and the lung lamellar body	Nystagmus, decreased visual acuity; prolonged bleeding; pulmonary fibrosis; granulomatous colitis (up to $\frac{1}{3}$ of patients)
HPS-4	<i>HPS4</i>		
HPS-2	<i>AP3B1</i>	<i>AP3B1</i> encodes a subunit of AP-3, which mediates protein trafficking into transport vesicles of the lysosome (and is thus also involved in immune function)	Nystagmus, decreased visual acuity; prolonged bleeding; neutropenia; recurrent bacterial and viral infections; conductive hearing loss
HPS-3	<i>HPS3</i>	HPS3, HPS5, and HPS6 are associated in a complex (BLOC-2) that localizes tyrosinase and <i>TRYP1</i> , allowing them to function normally	Nystagmus, decreased visual acuity; mild extraocular manifestations: high cholesterol and slightly elevated triglycerides in HPS-5
HPS-5	<i>HPS5</i>		
HPS-6	<i>HPS6</i>		
HPS-7	<i>DTNBP1</i>	Dysbindin and BLOC1S3 are subunits of BLOC-1 and also involved in skin melanosome biogenesis and platelet function	Nystagmus, decreased visual acuity; prolonged bleeding
HPS-8	<i>BLOC1S</i>		
HPS-9	<i>HPS9/PLDN</i>	Subunits of BLOC-1	Nystagmus, immunodeficiency; may not have bleeding manifestations
Others		Subunits of BLOC-1 ( <i>MUTED</i> ; <i>CNO</i> ; <i>KXD1</i> ) and component of other subunits ( <i>AP3D</i> of AP-3; <i>VPS33A</i> , <i>RABGGTA</i> )	

BLOC, Biogenesis of lysosome-related organelles complex; *DTNBP1*, dystrobrevin binding protein 1.

from deletion of the paternal chromosome at 15q and is characterized by hyperphagia with obesity, hypogonadism, and mental retardation. In contrast, Angelman syndrome results from deletion of the maternal chromosome at 15q and is characterized by microcephaly, severe mental retardation, ataxia, and inappropriate laughter. Pigment dilution occurs when both copies of the *P* gene are mutated or deleted. Interestingly, duplication of the 15q chromosomal region has been associated with generalized skin hyperpigmentation.<sup>92</sup>

Rufous OCA or OCA3 presents as “ginger” red hair, a reddish-bronze color of skin, and blue or sometimes brown irides. This form may be underreported, because the decrease in pigmentation is slight and may be undetectable in lighter skinned patients. OCA4 is now considered one of the most common forms in Japan,<sup>93</sup> and affected individuals resemble patients with OCA2.<sup>81</sup>

Patients with albinism should be monitored by an ophthalmologist in addition to the dermatologist. Glasses may help the poor vision, and contact lenses and tinted glasses may ameliorate the photophobia. Nystagmus may be helped by surgery of the eye muscles or contact lenses; eye patching may be needed for the strabismus. High-contrast written material, large-type textbooks and computers that can enlarge text are all helpful for patients with poor visual acuity. Early actinic changes, keratoses, basal cell tumors, and particularly squamous cell carcinomas are common; the risk of melanoma (often amelanotic)<sup>94</sup> is also increased, even in children and adolescents. Thus individuals with cutaneous albinism must learn to avoid sunlight exposure, to wear sunglasses, and to use protective clothing and sunscreen preparations on exposed surfaces. The National Organization for Albinism and Hypopigmentation (NOAH) is a national support group for patients and their families ([www.albinism.org](http://www.albinism.org)).

### HERMANSKY–PUDLAK SYNDROME

Hermansky–Pudlak syndrome (HPS) is a group of at least 9 autosomal recessive disorders (HPS1–9) characterized by pigment dilution, a hemorrhagic diathesis secondary to a platelet storage pool defect, and ceroid-lipofuscin deposits within the reticuloendothelial system, oral and intestinal mucosae, lung, and urine.<sup>95–97</sup> HPS is a disorder of biogenesis of melanosomes and other lysosome-related organelles<sup>98–100</sup> including platelet dense granules (Table 11-2), and all of the mutations found are in genes encoding components of protein complexes (e.g., *BLOC-1*, *BLOC-2*, *BLOC-3*, and *AP-3*) that regulate vesicle trafficking in these organelle systems.<sup>101</sup> HPS is most commonly seen in Hispanics from Puerto Rico (1:1800 to 1:400 persons; HPS-1 and sometimes HPS-3), in persons of Dutch origin, and in East Indians from Madras. The platelet defect in patients with HPS does not produce a severe problem in children. Its expression, however, can be aggravated by ingestion of aspirin and other prostaglandin blockers.

**Figure 11-13** Hermansky–Pudlak syndrome. The legs of this baby show both the pigmentary abnormality and extensive ecchymoses as a sign of the bleeding diathesis.

Special precautions and sometimes platelet transfusions must be given to avoid excessive bleeding after minor trauma or dental surgery.

The diffuse pigmentary features of the skin and eyes of individuals with HPS include pigmentary dilution of the skin and often the irides with hair that has a peculiar sheen, although not as silvery as in Chédiak–Higashi syndrome (CHS), another syndrome of lysosome-related organelles. The degree of generalized pigment loss is quite variable in intensity, ranging from white skin to brown and light to brown eyes. Ocular pigmentation generally correlates with cutaneous pigmentation. Ocular findings include nystagmus, photophobia, and decreased visual acuity. Extensive ecchymoses are a common clinical manifestation (Fig. 11-13). The bleeding diathesis also commonly manifests as epistaxis and menometrorrhagia. Patients with both HPS and systemic lupus erythematosus have been described.<sup>102</sup> The life-threatening complications of HPS, other than the bleeding diathesis, have been described in certain subtypes and are unusual in most affected children. These include granulomatous colitis (including two patients with cutaneous granulomatous disease that resembled metastatic Crohn disease),<sup>103,104</sup> progressive pulmonary fibrosis,<sup>105</sup> and less

commonly, cardiomyopathy and renal failure. Immunodeficiency is a feature of HPS-2 and the newest described form, HPS-9, which to date has not been associated with a bleeding diathesis.<sup>106,107</sup> The life expectancy is 30 to 50 years of age. Glasses or contact lenses can help to correct the refractive errors. The bleeding from skin wounds may be stopped with thrombin-soaked Gelfoam, and desmopressin (DDAVP) has been administered for tooth extraction and other invasive procedures. Transfusions of platelets or erythrocytes are occasionally required. The pulmonary fibrosis and enterocolitis are most commonly seen in HPS-1 and are often recalcitrant to therapy; infliximab is sometimes helpful.<sup>108</sup> Gene testing is available for mutations of *HPS1* and *HSP3*.

### Phenylketonuria

Phenylketonuria results from deficiency in phenylalanine hydroxylase, the enzyme that converts phenylalanine to tyrosine. Although rarely an issue because of widespread perinatal Guthrie testing, untreated patients with phenylketonuria may develop generalized hypopigmentation of the hair, skin, and/or eyes in comparison with family members, related to the deficiency of tyrosine, the substrate for melanin. Neurologic features predominate (mental retardation, seizures, hyperreflexia), but patients may also show dermatitis and rarely, focal morphea-like skin lesions (see Chapter 22). Treatment is by avoidance of dietary phenylalanine.

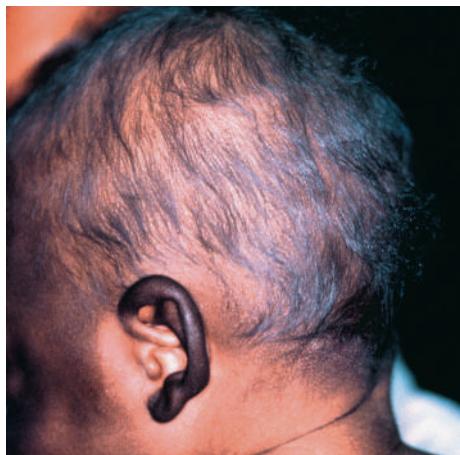

### SILVERY HAIR SYNDROMES

Three syndromes, CHS, Griscelli syndrome (GS), and Elejalde syndrome (probably a subset of GS), are autosomal recessive disorders characterized by an early silvery sheen to the hair, relative pigmentary dilution of skin with a grayish coloration, and in some patients ocular hypopigmentation.<sup>97</sup>

#### Chédiak–Higashi Syndrome

Patients with Chédiak–Higashi syndrome (CHS) usually have a characteristic silvery sheen to the hair and skin, with a skin color that may appear lighter than that of other family members.<sup>109,110</sup> In affected individuals of family backgrounds of darker skin, however, the skin of acral, sun-exposed areas (ears, nose) may become intensely hyperpigmented (Fig. 11-14) or show only speckled hypopigmentation.<sup>111,112</sup> Decreased iris pigmentation results in an increased red reflex and photophobia. Strabismus and nystagmus are common, but visual acuity is usually normal. Inflammation and ulceration of the oral mucosa, especially of the gingivae, have been described.

The immunodeficiency of patients with CHS leads to infectious episodes. These episodes are associated with fever and predominantly involve the skin, lungs, and upper respiratory tract. The most common organisms found are *Staphylococcus aureus*, *Streptococcus pyogenes* and

**Figure 11-14** Chédiak–Higashi syndrome. Note the silvery sheen to the hair and the intense pigmentation of the ear in this affected 8-month-old boy.

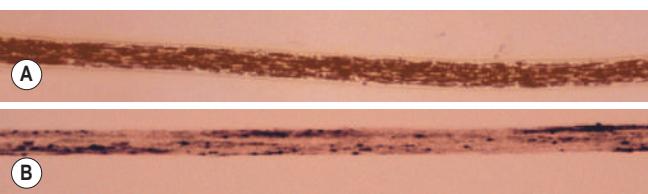

*pneumococcus*. The skin infections are primarily pyoderma, but infections with these organisms that result in deeper ulcerations resembling pyoderma gangrenosum have been reported.

Approximately 50% to 85% of patients with CHS undergo an “accelerated” lymphohistiocytic phase during the first decade of life, characterized by widespread visceral tissue infiltration with lymphoid and histiocytic cells that are sometimes atypical in appearance.<sup>113,114</sup> Hepatosplenomegaly, lymphadenopathy, pancytopenia, jaundice, a leukemia-like gingivitis, and pseudomembranous sloughing of the buccal mucosa are associated features. The thrombocytopenia, platelet dysfunction, and depletion of coagulation factors may lead to petechiae, bruising, and gingival bleeding. Granulocytopenia and anemia are found in 90% of patients during the accelerated phase. Neurologic manifestations may range from seizures to cranial nerve palsy to loss of consciousness. Viral infection, particularly from Epstein–Barr virus (EBV) infection, has been implicated in causing the accelerated lymphohistiocytic phase. The pigmentary changes that help to distinguish the CHS-related accelerated phase must be distinguished from autoimmune hemophagocytic syndromes and familial hemophagocytic lymphohistiocytosis (genetic defects in the cytolytic granule-dependent exocytosis pathway such as perforin). Neutropenia is common, and neutrophils are deficient in chemotactic and bactericidal capability. Selective deficiency of natural killer (NK) cells is characteristic. These immune abnormalities have been thought to cause the increased susceptibility to infections and the lymphohistiocytic phase.

Patients who survive into early adulthood may develop progressive neurologic deterioration, particularly with clumsiness, abnormal gait, paresthesias, and dysesthesias. Peripheral and cranial neuropathies and occasionally a form of spinocerebellar degeneration may occur.

CHS results from biallelic mutations in *LYST*, a lysosomal transport protein that regulates the fusion of primary lysosome-like structures. The skin pigmentary disorder has been attributed to the inability of melanosomal fusion and transfer to keratinocytes, leading to giant melanosomes within melanocytes. Giant granules are found in circulating leukocytes, melanocytes of skin and hair, renal tubular epithelial cells, central nervous system (CNS) neurons, and other tissues. In the hair shaft, these giant melanosomes are smaller than those of GS and regularly spaced (Fig. 11-15, A). The giant granules within phagocytic cells of affected children cannot discharge their lysosomal and peroxidative enzymes into phagocytic vacuoles. Of note, patients with leukemia may show granules that resemble those of CHS in leukocytes.

The mean age of death for patients with CHS without immune reconstitution is 6 years of age. Fatality usually results from overwhelming infection or hemorrhage during the accelerated phase. Approximately 10% to 15% of affected patients have a milder clinical phenotype and survive into adulthood but tend to develop the progressive neurologic dysfunction.<sup>115</sup> For all of the silvery hair syndromes, early bone marrow or stem-cell transplantation is the treatment of choice for patients with a human leukocyte antigen (HLA) match. Bone marrow transplantation reverses the immunodeficiency and prevents the often-fatal accelerated phase but has no effect on pigmentation or on neurologic deterioration. Otherwise, management of the disorder is largely supportive. Antibiotics help to control the recurrent infections, and immunoglobulin or immunosuppressive agents have been administered in an attempt to control the lymphohistiocytic or hemophagocytic phases. Splenectomy has been advocated in patients with the accelerated phase unresponsive to other forms of therapy.

**Figure 11-15** Silvery hair syndromes. The giant melanosomes are easily seen in the hair shaft of individuals with Chédiak–Higashi syndrome (CHS) (A) and Griscelli syndrome (B). Note the more regular spacing of the melanosomes in the hair from a patient with CHS.

### Griscelli Syndrome

Three subsets of patients with Griscelli syndrome (GS) have been described based on clinical manifestations and underlying gene defects. Two of these subsets are caused by mutations in genes close to each other on chromosome 15q21, *myosin Va* (type 1) and *RAB27A* (type 2). *Myosin Va* encodes a protein that binds organelles such as melanosomes to actin. *RAB27A* is a guanosine triphosphate (GTP)-binding protein involved in the movement of melanosomes. Melanocytes are unable to transfer melanosomes to epidermal cells, and ultrastructural examination of skin biopsies reveals accumulation of melanosomes in melanocytes but few in surrounding keratinocytes.

Patients who have uncontrolled activation of T lymphocytes and macrophages (hemophagocytic syndrome) and immune deficits (especially reduction in T-cell cytotoxicity and cytolytic granule exocytosis) have mutations in *RAB27A*,<sup>116</sup> whereas those patients with neurologic problems and without immune abnormalities or hemophagocytosis tend to have *myosin Va* mutations.<sup>117</sup> Elejalde syndrome (neuroectodermal melanolysosomal disease), characterized by similar abnormal pigmentation in the skin and hair and severe neurologic dysfunction (seizures, severe hypotonia, ocular abnormalities, and mental retardation) but no immunodeficiency or hemophagocytosis<sup>118,119</sup> is now considered a subset of GS type 1.<sup>120</sup> Rare patients with neurologic abnormalities with or without hemophagocytosis have shown a *RAB27A* mutation.<sup>118,121</sup> Type 3 GS shows a phenotype restricted to the pigmentary defects and results either from mutation in the gene that encodes melanophilin (*MLPH*) or from a deletion in the F-exon of *myosin Va*.<sup>122–124</sup>

Patients with GS, especially GS type 2, may be difficult to distinguish clinically from patients with CHS, because the silver-gray hair and skin color (Fig. 11-16), recurrent episodes of fever with or without infection, increasing hepatosplenomegaly owing to lymphohistiocytic infiltration, and progressive neurologic deterioration may be part of the clinical spectrum of both disorders.<sup>125</sup> In contrast to CHS, the lymphohistiocytic infiltration tends to occur in the first year of life. Blood smears show pancytopenia, but in contrast to the patients with CHS, no leukocyte inclusions. Microscopic examination of hair shows clumping of pigment in the hair shaft similar to that of CHS but with larger, more irregularly spaced macromelanosomes (see Fig. 11-15, B).

Intervention is similar to that of CHS, primarily through hematopoietic stem-cell transplantation. Given the lack of success of transplantation in patients with mutations in *myosin Va*,<sup>126</sup> restriction of transplantation to patients with *RAB27A* mutations has been

**Figure 11-16** Griscelli syndrome. The silvery hair suggests the reason for this child's hepatosplenomegaly and pancytopenia. The child died before bone marrow transplantation could be performed.

suggested. Early transplantation can prevent complications including the neurologic sequelae.<sup>127</sup>

### PIEBALDISM

Piebaldism is an autosomal dominant disorder characterized by congenital patterned areas of depigmentation, including a white lock of hair above the forehead (the white forelock) in most affected individuals.<sup>128,129</sup> The disorder usually results from mutations in the *KIT* protooncogene, which encodes a cell-surface receptor for the stem-cell/mast cell growth factor<sup>130</sup>; deletions in *SNAI2/SLUG* (encoding snail homolog of 2), a transcription factor, have also been described.<sup>131</sup> The clinical manifestations of piebaldism may be explained by the resultant defective migration of melanoblasts from the neural crest to the ventral midline and a defect in the differentiation of melanoblasts to melanocytes. The distinctive patterns of hypopigmentation or depigmentation usually persist unchanged throughout life, but affected individuals with progressive depigmentation,<sup>132</sup> response to UV light and partial repigmentation,<sup>133,134</sup> or forelock regression during infancy<sup>135</sup> have occasionally been described. The white forelock, with a depigmented triangular patch of the scalp and forehead (widest at the forehead with the apex pointing backward) occurs in 80% to 90% of individuals with piebaldism (Fig. 11-17). Depigmented areas on the forehead often include the whole or inner portions of the eyebrows and eyelashes and extend to the root of the nose. Hypopigmented or depigmented areas have also been noted commonly on the chin, anterior neck, anterior portion of the trunk and abdomen, and on the anterior and posterior aspects of the mid-arm to the wrist and the mid-thigh to mid-calf. Typical of the lesions of piebaldism are islands of normal and increased pigmentation within the hypomelanotic areas and sometimes hyperpigmented borders (Fig. 11-18). Intertriginous freckling and multiple café-au-lait (CAL) macules may occasionally be noted in patients and do not reflect the concurrence of piebaldism and neurofibromatosis (NF) 1 or Legius syndrome.<sup>136,137</sup>

The depigmentation of piebaldism can be differentiated from that of vitiligo by the usual presence at birth, lack of convex borders, and

**Figure 11-17** Piebaldism. This young girl shows the white forelock with depigmentation on the forehead as two triangular patches. The left cheek is also depigmented.

**Figure 11-18** Piebaldism. Note the sharply demarcated areas of depigmentation with the islands of normal pigmentation within the depigmented areas.

predisposition for ventral surfaces in contrast to the predilection on exposed areas, body orifices, areas of trauma, and intertriginous regions in vitiligo. The typical facial characteristics of type I WS are not seen in patients with piebaldism, although sensorineural deafness has rarely been described in piebaldism.<sup>138</sup> Biallelic homozygous mutations in *c-KIT* have been described from affected consanguineous parents; affected neonates show generalized depigmentation of the skin and hair, blue irides, and profound sensorineural deafness.<sup>139</sup> Incomplete penetrance has been described (e.g., a parent without evidence of piebaldism who has children with piebaldism and shares the *c-KIT* mutations).<sup>140</sup>

Treatment consists of cosmetic masking of areas of leukoderma<sup>59</sup> and vigorous sun protection. In the rare patients who show increased pigmentation after UV exposure, phototherapy may be considered. Reepithelialization by grafting from suction blisters and autologous cultured or noncultured epidermis, with or without laser, has provided permanent repigmentation.<sup>141,142</sup>

## WAARDENBURG SYNDROME

Waardenburg syndrome (WS) is a heterogeneous group of autosomal dominant disorders characterized by heterochromia irides, a white forelock, cutaneous depigmentation, and in many patients, congenital sensorineural deafness.<sup>143,144</sup> WS reportedly accounts for 2% to 5% of cases of congenital deafness.<sup>145</sup> Four major subtypes of WS have been described (Tables 11-3 and 11-4). Individuals with type I WS, the most common form, have characteristic facial features including a broad nasal root and lateral displacement of the medial canthi and lacrimal puncta of the lower eyelids (dystopia canthorum) (Fig. 11-19). For clinical diagnosis, an individual must have two major criteria or one major plus two minor criteria to be considered affected (see Table 11-3). Dystopia canthorum can be confirmed by a W index of greater than 1.95 (see Table 11-3).<sup>144</sup> Congenital, usually nonprogressive, sensorineural hearing loss occurs in 47% to 58% of affected individuals, whereas the white forelock and cutaneous depigmentation occur in approximately 45% and 30%, respectively. The white forelock may be present at birth, may appear later (typically during teenage years), or may become pigmented with time. The heterochromic irides and/or hypoplastic (often brilliant) blue eyes (Fig. 11-20) are less common than the hair or skin depigmentation. Type I WS results from loss-of-function mutations in *PAX3*, a gene critical for both melanocyte migration and facial embryogenesis.<sup>146,147</sup> Spina bifida has been described in several affected families, leading to the firm recommendation for folate supplementation during pregnancy.

Type II WS is a heterogeneous group of disorders that commonly shows the iris pigmentary changes (almost all patients, particularly the blue irides) and deafness (80%) of WS type I but not the facial

**Table 11-3** Diagnostic Criteria for Type I Waardenburg Syndrome

**Two Major Criteria or One Major Plus Two Minor Criteria Allows for the Diagnosis of WS Type I**

Major Criteria	Minor Criteria
White forelock, hair depigmentation	Skin depigmentation
Pigmentary abnormality of the iris	Synophrys/medial eyebrow flare
Dystopia canthorum, W index* >1.95	High/broad nasal root
Congenital sensorineural hearing loss	Hypoplastic alae nasi
Affected first-degree relative	Gray hair before 30 years old

WS, Waardenburg syndrome.

\*W index: The measurements necessary to calculate the W index (in mm) are as follows: the inner canthal distance (a), the interpupillary distance (b), and the outer canthal distance (c).

Calculate X = (2a - 0.2119c + 3.909)/c.

Calculate Y = (2a - 0.2479b + 3.909)/b.

Calculate W = X + Y + a/b.

**Table 11-4** Subtypes of Waardenburg Syndrome

Disorder	Inheritance	Gene	Other Comments
WS1	AD	<i>PAX3</i>	Most common form; dystopia canthorum
WS2A	AD	<i>MITF</i>	No facial dysmorphism; high risk of hearing loss; iris heterochromia
WS2B	AD	?	No facial dysmorphism; high risk of hearing loss; iris heterochromia
WS2C	AD	?	No facial dysmorphism; high risk of hearing loss; iris heterochromia
WS2D	AD	<i>SLUG</i>	No facial dysmorphism; high risk of hearing loss; iris heterochromia
WS2E	AD	<i>SOX10</i>	No facial dysmorphism; high risk of hearing loss; iris heterochromia
WS3	AD	<i>PAX3</i>	Associated limb abnormalities
WS4A	AD/AR	<i>EDNRB</i>	Aganglionic megacolon
WS4B	AD/AR	<i>EDN3</i>	Aganglionic megacolon
WS4C	AD	<i>SOX10</i>	Aganglionic megacolon
PCWH	AD	<i>SOX10</i>	Severe hypotonia with central nervous system and peripheral nerve abnormalities

AD, Autosomal dominant; AR, autosomal recessive; EDN, endothelin; EDNRB, endothelin receptor beta; PCWH, peripheral demyelinating neuropathy, central dysmyelination, Waardenburg syndrome, and Hirschsprung disease.

characteristics.<sup>148</sup> Mutations in the microphthalmia-associated transcription factor (*MITF*) gene have been described in 15% to 21% of patients with type II WS.<sup>149</sup> Tietze syndrome, also linked to *MITF* mutations on one allele, was originally characterized by generalized, albino-like pigmentary deficiency and hearing loss but no iris heterochromia; subsequent studies have shown clinical variability within families with heterozygous *MITF* mutations, ranging from a generalized decrease in pigmentation to patchy loss to no cutaneous manifestations in association with profound hearing loss and blue irides.<sup>148</sup> Patients with WS2 may have strabismus. Freckling in sun-exposed areas without depigmentation is common, especially among patients of Asian descent.<sup>148,149</sup> Other patients with type II WS have mutations in *SOX10* (~15%, encoding sex-determining region Y [SRY]-box10) or *SNAI2/SLUG* (as in piebaldism), transcription factors critical for the

**Figure 11-19** Waardenburg syndrome, type I. Note the white forelock, dappled skin, broad nasal root, and dystopia canthorum. This young woman also had an affected son.

**Figure 11-20** Waardenburg syndrome, type II. This affected individual shows iris heterochromia with the brilliant blue iris. She had sensorineural deafness but none of the facial features seen in type I Waardenburg syndrome.

migration and development of neural-crest cells. Type III WS is an extreme presentation of type I WS with musculoskeletal abnormalities and rarely associated neural-tube defects.<sup>150</sup> Some but not all patients with type III WS have homozygous mutations in *PAX3*. Type IV WS includes the pigmentary defects and sensorineuronal deafness in association with absence of enteric ganglia in the distal part of the intestine (Hirschsprung disease); presentation with chronic constipation beginning in the neonatal period is not unusual.<sup>151,152</sup> Facies are normal. Mutations have been described in three genes: *EDN3*, *EDNRB*, and *SOX10*, encoding endothelin 3,<sup>153</sup> endothelin B receptor,<sup>154</sup> and Sox 10, respectively.<sup>155</sup> Patients with Sox 10 mutations may also have severe hypotonicity with CNS and peripheral-nerve abnormalities because of the important role of Sox 10 in glial cell development.<sup>156</sup> All of the forms of WS show marked variability of clinical characteristics, even within families and in monozygotic twins,<sup>157</sup> and subtle features may be seen, especially in WS1. The white forelock may be a feature of several other genetic and acquired disorders, but most commonly piebaldism.<sup>158</sup> Iris heterochromia has also been described in HPS.<sup>159</sup>

## TUBEROUS SCLEROSIS COMPLEX

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder with variable expressivity that occurs in as many as 1 in 6000 to 1 in 10,000 persons.<sup>160-163</sup> Up to 70% of patients are thought to have new mutations. The disorder results from mutation in one of two different genes, *TSC1* (encoding hamartin; approximately 20% of patients) and

### Box 11-1 Features of Tuberous Sclerosis

Pathogenic mutation in *TSC1* or *TSC2* or two major features or 1 major feature + 2 minor features = definite tuberous sclerosis  
One major feature + 1 minor feature = probable tuberous sclerosis  
One major feature or two or more minor features = possible tuberous sclerosis

#### Major Features

- Hypopigmented macules  $\geq 5\text{ mm}$  across ( $\geq 3$ )
- Angiofibromas ( $>3$ ) or fibrous cephalic plaque
- Shagreen patch (connective tissue nevus)
- Ungual fibromas ( $\geq 2$ )
- Cortical dysplasias
- Subependymal nodules
- Subependymal giant-cell astrocytoma
- Cardiac rhabdomyoma
- Multiple retinal hamartomas
- Angiomyolipomas ( $\geq 2$ )
- Lymphangioleiomyomatosis
- Minor features
- "Confetti" skin lesions
- Intraoral fibromas ( $>2$ )
- Dental enamel pits ( $>3$ )
- Multiple renal cysts
- Nonrenal hamartomas
- Retinal achromic patch

*TSC2* (encoding tuberin; approximately 60% of patients); gene mutations have not been discovered in 10% to 25% of affected individuals. Tuberin and hamartin form a complex that suppresses cell growth through regulation of several signaling pathways, most importantly the mammalian target-of-rapamycin (mTOR) pathway signaling through switching Rheb from an active (GTP-bound) to inactive (guanosine diphosphate [GDP]-bound) state.<sup>162</sup> In general, patients with mutations in *TSC1* have milder disease.<sup>164</sup> The disorder is characterized by the development of hamartomas of the skin, brain, eye, heart, kidneys, lungs, and bone (Box 11-1).<sup>162</sup> A variety of cutaneous features, including hypopigmented macules, angiofibromas, fibrous tumors, and periungual and gingival fibromas, may be seen.

Three or more hypopigmented macules (white spots) of TSC are seen in 97% of patients at birth or shortly thereafter, although the appearance of additional lesions as late as 6 years of age has been described.<sup>165</sup> Once present, the hypopigmented macules tend to be persistent and stable in shape and relative size but may become less apparent during adulthood. Wood lamp examination in a completely darkened room may be useful in accentuating the macules in fair-skinned children. The white spots most commonly occur on the trunk, but hypopigmented tufts of scalp or eyelash hair meet the criterion for a hypopigmented macule. They range in size from a millimeter to several centimeters and number from a few to more than 75; 18% to 20% of individuals with TSC have 1 or 2 hypopigmented macules. The hypopigmented macules (Fig. 11-21) are often round ("thumbprint"), confetti-like hypopigmented macules (particularly over the pretibial areas), and oval or linear, but a lance-ovate shape ("ash leaf spots") is commonly described and is unusual in other disorders of localized decreased skin pigmentation such as nevus depigmentosus and vitiligo. Lesions of vitiligo tend to be depigmented and show a bright white coloration with Wood lamp examination. The hypopigmented white spots of TSC are most difficult to distinguish from nevus depigmentosus (also called *nevus achromicus*; Fig. 11-22), which occurs in 1.6% to 4.7% of children,<sup>166,167</sup> suggesting that the majority of young children with a white spot do not have TSC. *Nevus depigmentosus* may be present at birth or appear during early infancy as normal pigmentation increases and then persist. Despite its name, most *nevus depigmentosus* lesions are hypopigmented, not depigmented. Most individuals will have a solitary lesion of *nevus depigmentosus*, but multiple lesions and segmental forms of *nevus depigmentosus* have been described. *Nevus depigmentosus* and the hypomelanotic macules of TSC must also be distinguished from *nevus anemicus*, a developmental anomaly characterized by a circumscribed round or oval patch of pale or mottled skin<sup>168</sup> (see Chapter 12, Fig. 12-60).

**Figure 11-21** Tuberous sclerosis. **(A)** Several lance-ovate ("ash-leaf") and "thumbprint" white macules are noted on this infant's back. **(B)** Confetti-like macules on the lower extremities in a 13-year-old boy.

**Figure 11-22** Nevus depigmentosus. Well-demarcated patch of hypopigmentation that tends to be round or oval in configuration. Nevus depigmentosus, also known as *nevus achromicus*, may be noted at birth or may become apparent during infancy.

Cutaneous angiofibromas (adenoma sebaceum), which are hamartomas composed of fibrous and vascular tissue, appear in 75% of cases. They typically develop between 2 and 6 years of age and continue to increase in number thereafter but have been described at birth or as late as the mid-20s. These lesions characteristically are 1- to 4-mm, pink to red, dome-shaped papules with a smooth surface. They occur on the nasolabial folds, cheeks, and chin and sometimes more

**Figure 11-23** Tuberous sclerosis. Facial angiofibromas (adenoma sebaceum) are typically 1- to 4-mm, skin-colored to red, dome-shaped papules with a smooth surface. The facial angiofibromas largely involve the cheeks and nose with relative sparing of the upper lip.

**Figure 11-24** Tuberous sclerosis. The fibrous cephalic plaque may be present at birth and, together with the hypopigmented macules, may allow a definitive diagnosis of tuberous sclerosis.

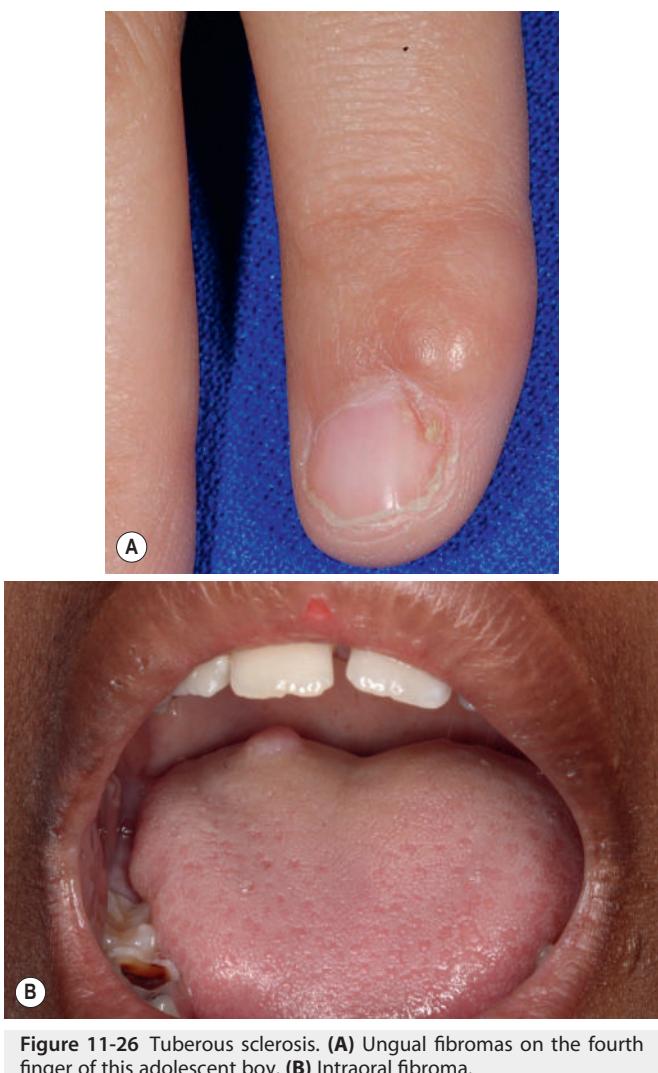

extensively on the face (Fig. 11-23). The upper lip is relatively spared, except immediately below the nose. The angiofibromas in affected adolescents may be masked by or misdiagnosed as acne. Their distribution is usually symmetrical but may be asymmetrical, especially in patients with a mosaic form of TSC.<sup>169</sup>

Large fibrotic plaques or nodules may occur on the forehead (fibrous cephalic plaque; Fig. 11-24), cheeks, or scalp in 25% of patients and are often present at birth. In 14% to 20% of patients, collagenomas also develop on the trunk, especially in the lumbosacral area, and most commonly during later childhood (shagreen patches or *peau de chagrin* lesions) (Fig. 11-25). They may be solitary or multiple and vary from smaller than 1 cm to palm-sized. Collagenomas are usually slightly raised with focal depression at follicular openings, leading to comparison with pigskin, elephant skin, orange peel, or gooseflesh. Fibromas under or around the nails of the fingers and especially the toes (ungual fibromas, sometimes called Koenen tumor; Fig. 11-26, A) and on the gums and other intraoral sites (intraoral fibromas) are also considered pathognomonic (Fig. 11-26, B). Seen in up to 80% of patients,<sup>170</sup> these fibromas do not tend to appear until after puberty but may be the only sign of TSC.<sup>171</sup>

Confetti-like hypopigmented macules have been noted in 6% of patients with multiple endocrine neoplasia (MEN) type 1<sup>172</sup> and multiple angiofibromas in 43% to 88% of adolescents and adults with MEN1.<sup>172,173</sup> Facial angiofibromas in patients with MEN1 tend to be fewer in number than in patients with TSC, may involve the upper lip or vermillion border, and fail to cluster in the nasolabial folds. Collagenomas have been observed in 72% of patients with MEN1.<sup>172</sup>

**Figure 11-25** Tuberous sclerosis. The shagreen patch is characteristically found at the lumbosacral area and has a *peau d'orange* texture.

**Figure 11-26** Tuberous sclerosis. (A) Ungual fibromas on the fourth finger of this adolescent boy. (B) Intraoral fibroma.

Patients with MEN1 are at high risk for the development of parathyroid, pituitary, pancreatic, and duodenal tumors.<sup>174</sup> Multiple facial angiofibromas with onset during adulthood have also been noted in patients with Birt–Hogg–Dube syndrome,<sup>175</sup> but facial fibrofolliculomas or trichodiscomas are more typical. Multiple biopsy-proven angiofibromas without other signs and with negative molecular testing have been described.<sup>176</sup> Having one to a few facial fibrous

papules is common in normal adults and may begin during adolescence; they resemble angiofibromas and have recently been shown to have activated mTOR signaling as well.<sup>177</sup>

The systemic lesions of TSC may produce severe symptoms and possibly death. Seizures, seen in 80% to 90% of patients with TSC, may begin as infantile spasms in which sudden repetitive myoclonic contractions of most of the body musculature are combined with flexion, extension, opisthotonus, and tremors. By 2 or 3 years of age, focal or generalized seizures and mental retardation may become evident. Extensive CNS involvement leads to hypsarrhythmia (salaam seizures) with electroencephalographic findings of multifocal high-voltage spikes and slow chaotic waves. Later in life the seizure pattern may change to a *petit mal* variety, and in less severe cases generalized or focal motor seizures may develop.

Retardation may be mild or severe and appears in 62% of affected individuals. The severity of mental retardation correlates well with the age of seizure onset. In approximately 90% of patients with TSC, the brain shows areas of cortical dysplasia (including cortical “tubers” and white-matter migrational abnormalities). These areas of cortical dysplasia can calcify and be visible on skull radiographs as curvilinear opacities. Periventricular or subependymal nodules may be seen by computed tomography (CT) or magnetic resonance imaging (MRI) scanning before calcification occurs.<sup>178,179</sup> Subependymal nodules are not malignant but may enlarge to cause obstructive hydrocephalus.

By the end of the first decade of life, 80% of patients show renal involvement. Renal hamartomas (angiomyolipomas) occur in about 70% of patients, and larger ones may lead to hemorrhage; of note, angiomyolipomas may be found in other organs as well, and having at least two angiomyolipoma without organ specificity is a major diagnostic feature. With advancing age, 20% to 30% of patients develop multiple bilateral renal cysts resembling those of polycystic kidney disease. These cysts can occur in individuals with *TSC1* or *TSC2* mutations, but a subset of individuals with aggressive renal cysts have deletions involving both *TSC2* and the contiguous polycystic kidney disease (*PKD1*) genes.<sup>180</sup> Abdominal ultrasound or scans are able to detect renal hamartomas or cysts in asymptomatic patients. Cardiac rhabdomyomas are most commonly present in the ventricles prenatally or in infancy and tend to regress spontaneously.<sup>181</sup> Although usually asymptomatic, rhabdomyomas may be associated with congestive heart failure, murmurs, cyanosis, arrhythmias, and sudden death, particularly during the first year of life. Two-dimensional echocardiography is a noninvasive technique that allows detection of asymptomatic cardiac rhabdomyomas.

The eyes may have characteristic retinal lesions (gliomas) referred to as *phakomas*. These retinal hamartomas have been described in 30% to 50% of patients. Funduscopy may show one of two types of lesions: multiple, raised, mulberry-like lesions on or adjacent to the optic nerve head; or flat, disk-like lesions in the periphery of the retina. Pulmonary lymphangioleiomyomatosis occurs overall in 2.3% of individuals with TSC, particularly in women between the ages of 20 and 40 years.<sup>182</sup> Affected individuals experience shortness of breath, hemoptysis, or pneumothorax and show diffuse interstitial infiltrates with cystic changes by CT examination. About 85% of patients with TSC have osseous manifestations with the bones, particularly those of the hands and feet, demonstrating cysts and periosteal thickenings. At least three dental pits (seen as punctate, round or oval, 1- to 2-mm randomly arranged enamel defects), particularly in the permanent teeth, are another marker of TSC and may be visualized better with use of dental disclosing solution.

The diagnosis of TSC may be difficult, because many affected individuals have subtle manifestations. However, the appearance of characteristic skin lesions in children with seizures, retardation, or both should establish a diagnosis of TSC (see Box 11-1).<sup>163,183</sup> Diagnosis depends on the cutaneous manifestations, family history (with careful clinical and sometimes imaging examination of family members), MRI of the brain, renal ultrasound, cardiac echocardiography in infants and young children, and in some cases ophthalmologic examination and chest radiography for honeycombing of the lungs.

The prognosis of TSC depends on the severity of the disorder and the presence of neurologic involvement.<sup>184</sup> The leading causes of premature death, status epilepticus and bronchopneumonia, are related to the associated neurologic issues. Seizures can be controlled by

anticonvulsant therapy in many patients, and prevention of seizures early in life has been shown to lower the risk of developmental delay and retardation. With routine MRI evaluations and the availability of microscopic surgery for neoplastic brain lesions, patients are surviving longer and have a better quality of life. Neurosurgical intervention may be required in patients with signs of increased intracranial pressure such as visual disturbances, papilledema, vomiting, or headaches. Sun protection is important for patients, not just at the sites of the hypopigmented macules, but also to prevent facial angiofibromas, which show second-hit mutations in TSC genes with a UV-signature mutation that is not seen in TSC germline mutations, in 50% of patients.<sup>185</sup>

The facial angiofibromas may be a cosmetic problem that responds to cryosurgical, surgical, or laser therapy.<sup>186</sup> However, a meta-analysis of 16 reports noted improvement in 94% of 84 patients with use of a variety of formulations of compounded topical rapamycin (ointment, gel, solution, cream; there is no commercially available formulation) with concentrations from 0.003% to 1%).<sup>187–190</sup> Recent-onset fibrous angiofibromas respond best, and topical rapamycin has also been used for maintenance after laser or surgical therapy. Local irritation is unusual but has been described with the use of rapamycin solution. Topical rapamycin has also led to improvement in early ungual fibromas.<sup>191</sup> Mammalian TOR inhibitors such as rapamycin and everolimus cause regression of astrocytomas, renal angiomyolipomas, and pulmonary lymphangioleiomyomas, as well as facial angiofibromas.<sup>192,193</sup> The Tuberous Sclerosis Alliance (at [www.tsalliance.org](http://www.tsalliance.org)) and the Tuberous Sclerosis Association (of the United Kingdom, at [www.tuberous-sclerosis.org](http://www.tuberous-sclerosis.org)) are among the groups that offer support for patients with TSC.

## CHEMICALLY INDUCED DEPIGMENTATION

A number of chemical agents are known to cause depigmentation after topical exposure. Among these compounds are the rubber antioxidant monobenzyl ether of hydroquinone, hydroquinone photographic developer, sulfhydryl compounds, azo dyes, diphenylcyclopropenone, phenolic germicidal agents (paratertiary butylphenol and amyłphenol), hydroxyanisole, and 4-tertiary butyl catechol (an additive to polyethylene film). The biochemical mechanism by which phenolic chemicals induce such hypopigmentation appears to be the competitive inhibition of tyrosinase or the release of toxic metabolites that produce injury to the melanocytes. Depigmentation has also occurred after topical exposure to paraphenylenediamine,<sup>194</sup> injections of triamcinolone, and in the periorbital area after injection of botulinum A toxin.<sup>195</sup> Oral ingestion of chloroquine,<sup>196</sup> arsenic, ST1571 (imatinib),<sup>197</sup> and dasatinib<sup>198</sup> have also led to depigmentation. A progressive generalized decrease in pigmentation has been reported after drug reaction to sulfonamide.<sup>199</sup>

## IDIOPATHIC GUTTATE HYPMELANOSIS

Idiopathic guttate hypomelanosis is a common disorder of adults, and its incidence increases with increasing age. It occasionally occurs in children and is more common in female individuals, although the latter may represent reporting bias. More striking in individuals with darker pigmentation, the lesions of idiopathic guttate hypomelanosis are characteristically 0.5- to 6-mm sharply defined, porcelain white macules. They are asymptomatic and once present do not tend to change. The macules most commonly occur on the extensor forearms and on the shins. The diagnosis is usually made clinically, and no treatment is effective. The underlying cause is unknown, although sun exposure is thought to be a trigger.

## POSTINFLAMMATORY HYPOPIGMENTATION

Postinflammatory hypopigmentation (or leukoderma) may be associated with a wide variety of inflammatory dermatoses or infections. This relative pigmentary deficiency may be noted after involution of certain inflammatory skin disorders, particularly burns, bullous disorders, infections, eczematous or psoriatic lesions, and pityriasis rosea (see Fig. 3-17). In the inflammatory dermatoses the intensity of the inflammatory reaction may bear little relationship to the development

of postinflammatory leukoderma. Postinflammatory hypopigmentation is generally self-limiting, clearing after months to years. It often becomes cosmetically obvious in individuals with darker skin, particularly during summer months, because the preferential darkening with UV light exposure of surrounding skin accentuates the hypopigmentation.

Although the pathophysiology of postinflammatory hypopigmentation is unclear, it is postulated that the hypopigmentation is caused when keratinocytes injured by the inflammatory process are temporarily unable to accept melanosomes from the melanocyte dendrites. No therapy is effective, but the condition tends to improve with time.

Pityriasis alba (see Chapter 3) is a common cutaneous disorder characterized by asymptomatic, sometimes scaly hypopigmented patches on the face, neck, upper trunk, arms, shoulders, and at times the lower aspect of the trunk and extremities of children and young adults (see Fig. 3-33). Seen predominantly in children 3 to 16 years of age, individual lesions vary from 1 to several centimeters in diameter and have sharply delineated margins and a fine, branny scale. Although the cause is unknown, this disorder appears to represent a nonspecific dermatitis. Postinflammatory hypopigmentation is commonly seen in children with atopic dermatitis, psoriasis (see Fig. 4-15, A), pityriasis lichenoides, and contact dermatitis; in the latter the pattern of the hypopigmentation may provide the clue to the contactant.<sup>200</sup>

Tinea versicolor ( pityriasis versicolor; see Chapter 17) is a common condition often found on the upper part of the trunk and neck of young adults. Caused by overgrowth of a yeast that normally inhabits skin, *Pityrosporum orbiculare* (*Malassezia furfur*), the condition is characterized by small, either hypopigmented or occasionally hyperpigmented macules, particularly on the trunk and upper arms. The round, individual lesions often coalesce. Facial involvement is more common in affected children than in older individuals. The hypopigmentation results from the production of azelaic acid, which inhibits tyrosinase; the hyperpigmentation is postinflammatory (see Figs. 17-33 through 17-34).

Sarcoidosis (see Chapter 25) is a granulomatous disorder of unknown origin with widespread manifestations involving the skin and many of the internal organs. In addition to the characteristic yellowish brown, flesh-colored, pink, red, and reddish brown to black or blue lesions, subcutaneous nodules, and infiltrated plaques, the spectrum of sarcoidal skin lesions includes hypomelanotic macules and papules. Measuring up to 1.5 cm in diameter, these hypopigmented lesions reveal sarcoid-type granulomas on cutaneous biopsy.

Leprosy (Hansen disease; see Chapter 14), a chronic infection in which the acid-fast bacillus *Mycobacterium leprae* has a special predilection for the skin and nervous system, can be divided into several types depending on the patient's cellular immune response to *M. leprae*. Tuberculoid leprosy shows characteristic well-defined anesthetic hypopigmented lesions and thickened and palpable peripheral nerves. Lepromatous leprosy, in contrast, more commonly shows nodules or diffuse infiltrates, especially on the eyebrows and ears, resulting in a leonine facies. A granulomatous infiltrate on microscopic examination of cutaneous lesions and particularly in the lepromatous lesions, demonstration of *M. leprae* on cutaneous smear or biopsy specimen generally confirm the diagnosis.

Pinta (see Chapter 14) is a treponemal infection caused by *Treponema carateum*. Seen almost exclusively among the dark-skinned population of Cuba and Central and South America, the disorder is commonly found in children of parents afflicted with this disorder. The cutaneous manifestations may be divided into primary, secondary, and tertiary stages. The late dyschromic stage takes several more years to develop. These lesions have an insidious onset and usually appear during adolescence or young adulthood. They consist of slate-blue hyperpigmented lesions that after a period of years become widespread and are replaced by depigmented macules resembling those seen in patients with vitiligo. Located chiefly on the face, waist, and areas close to bony prominences (elbows, knees, ankles, wrists, and the dorsal aspect of the hands), these depigmented lesions of pinta can be differentiated from those of other depigmented disorders by the presence of pigmented lesions, histologic examination of lesional specimens, identification of antibodies directed against *T. carateum* by serologic testing, and darkfield examination.

## Disorders of Both Hypopigmentation and Hyperpigmentation

### DYSCHROMATOSES

Two major forms of dyschromatoses have been described: dyschromatosis symmetrica hereditaria (DSH; reticulate acropigmentation of Dohi) and dyschromatosis universalis hereditaria (DUH), both of which are seen most commonly in Japanese and Chinese individuals (in about 2 per 100,000 individuals). These disorders show only pigmentary manifestations and affected individuals are almost always otherwise healthy. The reticulate hyperpigmentation of these disorders tends to appear more spotty than the more net-like reticulated

hyperpigmentation of disorders like dyskeratosis congenita (see Chapter 7), Rothmund–Thomson (see Chapter 19) and Kindler (see Chapter 13) syndromes. The differential diagnosis of these dyschromatoses includes other disorders with more or a macular pigmentation (such as xeroderma pigmentosum (see Chapter 19), Kitamura reticulate acropigmentation, and dyschromic amyloidosis (Table 11-5). Keratin disorders with hyperpigmentation also tend to have a more net-like reticulated pigmentation (e.g., EB simplex with mottled pigmentation [see Chapter 13], Dowling–Degos disease, Naegeli–Franceschetti–Jadassohn syndrome and dermatopathia pigmentosa reticularis).

DSH is an autosomal dominant disorder characterized by pinpoint to pea-sized hyperpigmented and hypopigmented macules on the dorsal aspects of the distal extremities and face.<sup>201</sup> Lesions first appear

**Table 11-5** Disorders with Reticulate Hyperpigmentation (and Sometimes Hypopigmentation)

Disorder	Inheritance	Gene	Onset	Features	Other Comments
Familial forms of amyloidosis		Unknown	Early childhood	Generalized hyperpigmentation with tiny generalized hypopigmented macules	AD form: focal subepidermal amyloid deposition in biopsies
Amyloidosis cutis dyschromica	AD			Carriers of X-linked form: along lines of Blaschko, resembling incontinentia pigmenti	
X-linked reticulate hyperpigmentation	XL			XL form: failure to thrive, developmental delay, seizures, hemiplegia, colitis, gastroesophageal reflux, inguinal hernia, urethral stricture, dental anomalies, hypohidrosis, photophobia, corneal clouding, skeletal changes	XL form: often no amyloid in biopsies of children
Dowling–Degos disease	AD	Keratin 5; <i>POFUT1</i> ; <i>POGLUT1</i>	Early adolescence	Reticulate pigmentation of flexures, neck, and sometimes generalized; sometimes pitted perioral scars and comedo-like follicular plugs	No acantholysis More generalized reticulated pigmentation in EBS with mottled pigmentation ( <i>KRT5</i> mutations; see Ch. 13)
Familial progressive hyperpigmentation and hypopigmentation	AD	<i>KITLG</i>	Birth or early infancy; increase in number with time	Face, neck, trunk, limbs with reticulate hyperpigmentation as well as diffuse background hyperpigmentation; café-au-lait macules and freckling; sometimes larger hypopigmented macules	Called familial progressive hyperpigmentation if no hypopigmentation; distinguish from NF1 and Legius syndrome
Dyschromatosis symmetrica hereditaria	AD	<i>ADAR1</i>	Infancy to early childhood	Hyperpigmented and hypopigmented small macules on dorsum of hands and feet	
Dyschromatosis universalis hereditaria	AD	<i>ABCB6</i>	First months of life (starts on trunk)	Generalized pigmented macules; may involve palms and soles, oral mucosa, and nails (dystrophy with pterygium)	
Galli–Galli disease	AD	Keratin 5	Early adolescence	Reticulate pigmentation of flexures	Moderate to severe suprabasal acantholysis in biopsies
Kitamura disease	AD	<i>ADAM10</i>	First to second decade	Acral reticular pigmentation with subtle atrophy, palmar pits, and rete ridge breaks	
Dyskeratosis congenita (see Ch. 7)	Esp. XL	Esp. <i>DCK1</i>	Late childhood	Net-like pigmentation, esp. in sun-exposed areas, often poikilodermatosus; associated with mucosal leukokeratosis, nail dystrophy, risk of bone marrow failure, mucosal squamous cell carcinomas	Nine known genes can be mutated; can be AD or AR
Naegeli–Franceschetti–Jadassohn syndrome	AD	<i>KRT14</i>	First 2 years	Reticulate hyperpigmentation, primarily of abdomen, perioral, and periocular areas; palmoplantar keratoderma, absence of dermatoglyphics, onychodystrophy, hypohidrosis, dental anomalies Pigmentation fades during adolescence	
Dermatopathia pigmentosa reticularis	AD	<i>KRT14</i>		Pigmentation primarily truncal distribution; nonscarring alopecia; palmoplantar keratoderma, absence of dermatoglyphics, onychodystrophy, hypohidrosis	

AD, Autosomal dominant; *ADAM10*, a disintegrin and metalloproteinase domain-containing protein 10; *ADAR1*, adenosine deaminase acting on RNA 1; AR, autosomal recessive; *DCK1*, dyskerin; *EBS*, epidermolysis bullosa simplex; *Esp.*, especially; *KITLG*, KIT ligand; *KRT*, keratin; *NF*, neurofibromatosis; *POFUT1*, protein O-fucosyltransferase 1; *POGLUT1*, protein O-glucosyltransferase 1; *XL*, X-linked.

**Figure 11-27** Dyschromatoses universalis hereditaria. Reticulated hyperpigmented and hypopigmented macules of various shapes and sizes on the trunk. (Courtesy of Drs. S. Worobec and S. Reddy.)

during infancy or early childhood, commonly spread until adolescence, and persist lifelong. Neurologic disease has been described in the minority of patients.<sup>202,203</sup> Molecular studies have uncovered mutations in ribonucleic acid (RNA)-specific adenosine deaminase (*ADAR1*, also called *DSRAD*).<sup>204–207</sup> Reticulate acropigmentation of Kitamura is another autosomal dominant disorder characterized by reticulated or lentiginous hyperpigmentation localized primarily to the dorsal areas of the hands and feet. It is caused by mutations in *ADAM10*.<sup>208</sup> The lesions have their onset during childhood and tend to be more atrophic than those of DSH. Pits on the palms, soles, and dorsal surface of the fingers and toes are associated.<sup>209</sup> DSH has recently been treated with miniature punch grafting and excimer light therapy.<sup>210</sup>

DUH is an autosomal dominant disorder (rarely recessive) in which patients show hyperpigmented and hypopigmented macules of various shapes and sizes with a mottled appearance (Fig. 11-27). In DUH skin lesions appear within the first months of life, predominantly on the trunk, and subsequently generalize, including the palms and soles in some cases. The oral mucosa may be involved, and nails may show dystrophy with pterygium formation. The numbers of melanosomes is normal, and the disorder presumably reflects increased melanocyte activity. DUH is caused by mutations in *ABCB6*.<sup>211</sup> Dyschromatoses resembling DUH may also be caused by heterozygous mutations in *KITLG*, encoding KIT ligand (familial progressive hyperpigmentation and hypopigmentation)<sup>212</sup> or *SASH1* (SAM and SH3 domain-containing protein 1), a tumor suppressor gene.<sup>213,214</sup> *SASH1* mutations on both alleles lead to the reticulate hypopigmentation and hyperpigmentation in association with alopecia, palmoplantar keratoderma, nail dystrophy, dental anomalies, skin ulcers, and recurrent squamous cell carcinoma.<sup>215</sup> The hyperpigmented lesions of DUH have been treated with Q-switched alexandrite laser.<sup>216</sup>

Reticulated hyperpigmentation is also seen in X-linked reticulate pigmentary disorder (also called Partington syndrome or familial cutaneous amyloidosis).<sup>217</sup> Affected boys show generalized reticulate hyperpigmentation in association with xerosis, failure to thrive, developmental delay, seizures, hemiplegia, colitis, gastroesophageal reflux, inguinal hernia, and urethral stricture. Dental anomalies, hypohidrosis, photophobia, and corneal clouding are also seen. Skeletal changes may include delayed bone age and shortened metacarpals. The amyloid found in skin biopsies of some affected adults has not been demonstrated in the skin of affected children. Pigmentation distributed along the lines of Blaschko in female carriers resembles the pigmented streaks and whorls of *incontinentia pigmenti*. Familial dyschromic amyloidosis with only the pigmentary abnormalities may be inherited in an autosomal dominant manner with incomplete penetrance.<sup>218,219</sup> The underlying genetic cause of these familial cutaneous amyloidoses is unknown.

Dowling–Degos disease and its acantholytic variant Galli–Galli disease are both autosomal dominant disorders usually caused by mutations in keratin 5.<sup>220</sup> Reticulated hyperpigmentation is localized to the intertriginous areas, primarily the axillae and the inguinal folds. Comedonal lesions and pitted acneiform facial scars are associated.<sup>221</sup> A more generalized form of Dowling–Degos disease has also been associated with mutations that affect glycoprotein synthesis, protein O-fucosyltransferase 1 and protein O-glucosyltransferase 1.<sup>222,223</sup> Naegeli–Franceschetti–Jadassohn syndrome and dermatopathia pigmentosa reticularis are autosomal dominant disorders with reticulate hyperpigmentation, palmoplantar keratoderma, absence of dermatoglyphics, onychodystrophy, and decreased sweating with lifelong heat intolerance. Both disorders result from heterozygous nonsense or frameshift mutations in keratin 14 that increase the susceptibility of keratinocytes to apoptosis.<sup>224,225</sup> In Naegeli–Franceschetti–Jadassohn syndrome, the reticulated hyperpigmentation is present during the first 2 years of life and primarily involves the abdomen, perioral, and periocular areas.<sup>226</sup> The pigmentation commonly fades during adolescence and may disappear altogether. Dental abnormalities are associated. The pigmentation in dermatopathia pigmentosa reticularis is primarily in a truncal distribution and is associated with nonscarring alopecia.<sup>227</sup>

The hyperpigmentation in all of these disorders is nonpalpable in contrast to the hyperpigmented papules and plaques of confluent and reticulated papillomatosis of Gougerot and Carteaud, an asymptomatic disorder of hyperkeratotic hyperpigmented papules in a reticulated pattern.<sup>228</sup> Seen primarily in adolescents and young adults, this disorder usually occurs on the upper anterior trunk, often in individuals with acanthosis nigricans (see Chapter 23, Figs. 23-26 through 23-28).

## POIKILODERMA

The term *poikiloderma* (*poikiloderma atrophicans vasculare*) is used to describe a triad of telangiectasia, atrophy, and reticulated dyschromia (hyperpigmentation and hypopigmentation). The disorder may be seen in patients with poikiloderma congenitale (Rothmund–Thomson syndrome), xeroderma pigmentosum, Bloom syndrome (see Chapter 19), dyskeratosis congenita (see Chapter 7), juvenile dermatomyositis (see Chapter 22), and cutaneous T-cell lymphoma (see Chapter 10). Actinic, thermal (see Erythema Ab Igne section, Chapter 20), and radiation damage can also leave poikilodermatous changes. Histopathologic examination of areas of poikiloderma reveals varying degrees of epidermal hyperkeratosis and atrophy, hydropic degeneration of the basal layer, varying numbers of pigment-laden melanophages, and a lymphocytic band-like or perivascular infiltration in the dermis. Management consists of early recognition, avoidance of sun exposure, and the use of protective clothing and topical sunscreen preparations in an attempt to arrest progression of the dermatosis.

## INCONTINENTIA PIGMENTI

*Incontinentia pigmenti* (Bloch–Sulzberger syndrome) is an X-linked disorder that predominantly affects the skin, teeth, CNS, and eyes.<sup>229–231</sup> The disorder results from mutations in nuclear factor-kappa B (NF-κB) essential modulator (*NEMO*; *IKBKG*), a gene localized to the X chromosome. In approximately 80% of patients, the mutation is a rearrangement in the *NEMO* gene that eliminates its activity.<sup>232,233</sup> Less commonly, affected girls (often with milder disease) have a missense mutation in the *NEMO* gene, particularly involving exon 10; these girls are at risk of having a son with hypohidrotic ectodermal dysplasia with immunodeficiency (see Chapter 7). *De novo* mutations occur in 65% of patients.<sup>234</sup> The mutation in *NEMO* prevents the activation of NF-κB, which is a regulator of cell proliferation, inflammation, and TNF-α-induced apoptosis. Approximately 97% of patients are female, suggesting that the disorder is lethal to affected hemizygous male individuals.<sup>235</sup> Male patients with Klinefelter syndrome (XXY genotype) or with *incontinentia pigmenti* as a mosaic condition have been described.<sup>236–240</sup> Affected girls show functional mosaicism because of the random inactivation early in embryologic development of one of the X chromosomes (lyonization). As such, the cutaneous lesions of *incontinentia pigmenti* tend to follow lines of

### Box 11-2 Manifestations of Incontinentia Pigmenti

X-linked dominant disorder; random X-chromosome inactivation dictates extent of disease  
 Mutations in NF- $\kappa$ B essential modulator (*NEMO*)  
 97% of patients are females; probably lethal in males; living males usually represent somatic mosaicism  
 Four cutaneous phases that may overlap  
 Inflammatory vesicles or bullae  
 Verrucous lesions  
 Streaks of hyperpigmentation  
 Streaks of atrophy/hypopigmentation  
 May have cicatricial alopecia and nail dystrophy

Blaschko, representing the clonal outgrowth of cells that express the affected allele. The variable severity and expression of clinical involvement in the eyes and brain reflect the random activation of the affected X allele in these tissues.

The disorder generally appears at birth or shortly thereafter (90% of patients have cutaneous lesions within the first 2 weeks of life; 96% have their onset before the age of 6 weeks). Although the cutaneous lesions have four distinct phases, their sequence is irregular and overlapping of stages is common (Box 11-2).

The first phase of incontinentia pigmenti begins with inflammatory vesicles or pustules that develop in crops over the trunk and extremities, often persisting for months. These may range from largely papular with scattered vesicles to pustules (Fig. 11-28). Biopsy of a blister during this vesicular stage reveals epidermal vesicles filled with eosinophils, and 74% of affected neonates show eosinophilia (from 18% to 89%). The vesicles clear spontaneously through cellular apoptosis and repopulation by continuous normal keratinocytes. However, the vesicular phase may be reactivated focally, especially in infants after infection, immunization, or physical trauma; less commonly erythematous whorls without vesication may occur in older individuals.<sup>241,242</sup>

In 70% of patients, the vesicular stage is followed by a verrucous phase characterized by irregular, linearly arrayed warty papules on one or more extremities and often on the hands and feet (Fig. 11-29). This stage resolves spontaneously, usually within a period of up to 2 years.

During or shortly after this verrucous stage, the highly characteristic pigmentary phase occurs in approximately 80% of patients. Lesions typically are thin bands of slate-brown to blue-gray coloration arranged in lines and swirls on the extremities and trunk (Fig. 11-29). These pigmentary bands may coalesce in areas and more closely resemble Chinese writing figures than linear streaks or whorls. When more linear, they must be distinguished from X-linked macular amyloidosis in carrier females.<sup>243,244</sup> Occasionally, these bands appear purpuric at onset (Fig. 11-30), and this appearance has raised the question of child abuse.<sup>245</sup> These pigmentary lesions progress until the patient's second year of life, then stabilize and persist for years. By adolescence they gradually fade and disappear in two-thirds of affected individuals. Biopsy sections from lesional skin show incontinence of pigment during this phase, leading to the name *incontinentia pigmenti*. Although the pigmentary changes were originally considered to be a postinflammatory phenomenon secondary to the vesiculobullous or verrucous stages, the pigment fails to follow the pattern, shape, or location of the vesicular or verrucous lesions.

A fourth phase is characterized by persistent atrophic streaks that are often hypopigmented (Fig. 11-31). Most commonly noted on the arms, thighs, trunk, and particularly the calves of affected individuals, these affected areas show diminished hair, eccrine glands, and sweat pores. These streaks are often subtle and may be accentuated by viewing with side lighting or by Wood lamp examination. Skin biopsy shows characteristic changes with scattered apoptotic cells, thickened

**Figure 11-28** Incontinentia pigmenti. (A) The lesions of incontinentia pigmenti tend to follow a curvilinear pattern along lines of Blaschko, lines of the embryological development of ectoderm, as a manifestation of functional mosaicism (i.e., the X chromosome with the mutation in the *NEMO* gene is the activated X chromosome in the skin at these sites). The lesions of the vesicular phase may range from largely papular with a minor vesicular component to vesiculopustular as shown here and occasionally to bullous. (B) Sometimes the lesions of incontinentia pigmenti do not show a linear pattern. Note the residual inflammation and scaling as the vesicular lesions clear.

dermis, and absence of hair follicles and sweat glands, allowing diagnosis in older individuals.<sup>246</sup>

Cicatricial alopecia is seen in 38% to 66% of patients (Fig. 11-32). It occurs most often near the vertex and does not necessarily relate to the previous presence of lesions at the site. Nail dystrophy is present in 7% to 51% of affected individuals. In addition, painful grayish-white verrucous or keratotic subungual tumors are seen in up to 10%, usually during the second or third decades of life<sup>247</sup> and rarely lead to squamous cell carcinomas.<sup>248</sup> Lytic defects on roentgenographic examination of the distal phalanges may be seen as well.

Noncutaneous manifestations occur in a high percentage of patients with incontinentia pigmenti. Some 70% to 95% of patients show

**Figure 11-29** Incontinentia pigmenti. Characteristic slate-brown lines on the legs may coalesce in areas and more closely resemble Chinese writing figures or a reticulated pattern than linear streaks. The hyperpigmentation usually fades by late in childhood. Note the warty papules of the verrucous phase, which are most commonly found on the hands and feet.

**Figure 11-30** Incontinentia pigmenti. The bands of brownish-gray pigmentation may initially appear purpuric, raising the question of child abuse.

dental anomalies (delayed dentition, partial anodontia, pegged or conical teeth)<sup>249,250</sup> (Fig. 11-33) reminiscent of those in boys with hypohidrotic ectodermal dysplasia (see Chapter 7). Ectodysplasin (which is usually mutated in boys with hypohidrotic ectodermal dysplasia), the ectodysplasin receptor, and *NEMO* all participate in NF- $\kappa$ B signaling, providing an explanation for these shared phenotypic features. In fact, boys with a form of ectodermal dysplasia with

**Figure 11-31** Incontinentia pigmenti. Atrophic streaks that are often hypopigmented can be found in the minority of affected individuals. Most commonly noted on the arms and legs, these affected areas show diminished hair, eccrine glands, and sweat pores. The atrophic, hypopigmented streaks are often subtle and may be accentuated by viewing with side lighting or by Wood lamp examination.

**Figure 11-32** Incontinentia pigmenti. Cicatricial alopecia most commonly appears near the vertex and does not necessarily relate to the previous presence of lesions at the site.

immunodeficiency (see Chapter 7) have mutations in *NEMO* that decrease its function but do not eliminate it.

Up to 30% of patients with incontinentia pigmenti demonstrate involvement of the CNS, most commonly seizures.<sup>251,252</sup> These seizures have been attributed to acute microvascular hemorrhagic infarcts,<sup>253</sup> although recurrent stroke has also been described.<sup>254</sup> Many such neonates are mistakenly thought to have neonatal herpes simplex infection because of the presence of vesiculopustular lesions and seizures. Overall, 7.5% have severe neurologic abnormalities including continuing seizures, retardation, and/or spastic abnormalities.<sup>251</sup> Seizures during the first week of life have been associated with the worst prognosis for normal development. Learning disabilities are common.<sup>255</sup>

Ophthalmic changes are present in 37% of patients; 18% have strabismus, and an equal number demonstrate more serious eye involvement (cataracts, optic atrophy, or retinal neovascularization or detachment). Bilateral blindness has been described in 4% to 8% of individuals with incontinentia pigmenti. Occasionally, cardiac anomalies and skeletal malformations (such as microcephaly, syndactyly, supernumerary ribs, hemiatrophy, or shortening of the arms or legs) may occur.

**Figure 11-33** Incontinentia pigmenti. Dental anomalies (delayed dentition, partial anodontia, pegged or conical teeth) occur in the majority of affected individuals. Interestingly, these dental changes mirror those of boys with hypohidrotic ectodermal dysplasia, a disorder that shares the NF- $\kappa$ B signaling pathway.

**Figure 11-34** Pigmentary mosaicism. Narrow to broad linear streaks of hypopigmentation following lines of Blaschko on the trunk of a patient with developmental delay (**A**) and on the face and neck of an otherwise normal baby (**B**). The term *pigmentary mosaicism* encompasses previous terms such as *incontinentia pigmenti achromians* and *hypomelanosis of Ito*. Most patients with pigmentary mosaicism are otherwise normal, but evidence of neurologic, ocular, and bony defects should be sought, especially with more extensive pigmentary changes.

The characteristic cutaneous lesions of incontinentia pigmenti allow early diagnosis and investigation for associated ocular and neurologic abnormalities. No special therapy is required for the skin lesions of incontinentia pigmenti, because they tend to clear spontaneously, but regular ophthalmologic evaluations are important.<sup>256</sup> If retinal involvement is discovered, early intervention with laser, cryotherapy, or intravitreal bevacizumab should be initiated.<sup>257</sup> If seizures or evidence of developmental delay appear, neurologic consultation is appropriate. High-dose glucocorticoids in the neonatal period have helped to control seizures recalcitrant to antiepileptics.<sup>258</sup> Dental evaluation by 2 years of age will allow investigation of missing or misshapen secondary teeth; prostheses can be made in patients with significant dental abnormalities.

Obtaining a history of cutaneous disorders during the neonatal and infantile periods and careful physical examination of mothers who may be carriers is important for genetic counseling. A mother of an affected individual who shows subtle manifestations is at increased risk for having another affected daughter (50% probability in daughters) and aborting a male fetus (50% probability in sons). Affected mothers may show subtle signs, most commonly hypopigmented, atrophic, hairless streaks along Blaschko lines (sometimes seen best by side lighting)<sup>259</sup> and sometimes a patch of cicatricial alopecia,<sup>260</sup> conical incisor, or nail dystrophy.<sup>261</sup> Sometimes carrier mothers show no signs, despite a history of a previous blistering disorder in the neonatal period. Prenatal diagnosis is possible, and preimplantation genetic diagnosis has been performed.<sup>262</sup> Treatment with topical corticosteroids<sup>263</sup> or tacrolimus<sup>264</sup> may halt the progression of the vesicular phase, although lesions ultimately clear spontaneously. The retinal neovascularization may regress with laser photocoagulation,<sup>265</sup> and preliminary studies of vascular endothelial growth factor (VEGF) inhibitors appear promising.<sup>266</sup> The Incontinentia Pigmenti International Foundation provides education and support (<http://www.ipif.org/>).

## PIGMENTARY MOSAICISM

The term *pigmentary mosaicism* is preferred for this heterogeneous group of disorders that includes hypomelanosis of Ito (incontinentia pigmenti achromians), linear and whorled nevoid hypermelanosis,<sup>267</sup> and the segmental form of nevus depigmentosus,<sup>268</sup> which is characterized by patterned streaks of hypopigmentation and/or hyperpigmentation (Figs. 11-34 and 11-35). The linear streaks and whorls tend to follow lines of mosaicism,<sup>269</sup> particularly the lines of Blaschko (lines of ectodermal embryologic development), or a phyllid pattern of mosaic distribution.<sup>270,271</sup> Both hypopigmented and hyperpigmented streaks may be seen in the same individual.

**Figure 11-35** Pigmentary mosaicism. Patterned hyperpigmented patches on the neck and trunk in a phyllid pattern. This child was otherwise normal.

The pigmentary mosaicism reflects gene mosaicism of affected areas. These mosaic conditions do not tend to be hereditary, although familial cases have rarely been reported.<sup>272</sup> Gross chromosomal abnormalities have been described in 60% of affected pediatric patients with more extensive pigmentary mosaicism and/or associated noncutaneous abnormalities when peripheral blood leukocytes and cultured fibroblasts or keratinocytes are evaluated.<sup>273–275</sup> In another study, an unselected patient population with pigment mosaicism showed an incidence of associated abnormalities (particularly of the bones, eyes, and/or CNS) in 30% of patients.<sup>276</sup> The majority of patients, however, do not have widespread involvement with pigmentary mosaicism and show no other problems by history and examination; these children require no further investigation.

The streaks of hypopigmentation or hyperpigmentation along Blaschko lines of embryologic development must be distinguished from the hypopigmented or hyperpigmented streaks of *incontinentia pigmenti*. The term *incontinentia pigmenti achromians* for the streaks of hypopigmentation has been abandoned to avoid confusion, because *incontinentia pigmenti* is unrelated. The lack of preceding vesicular or verrucous lesions of *incontinentia pigmenti* and the finding of increased melanin deposition at the basal cell layer in hyperpigmented streaks of pigment mosaicism (linear and whorled hypermelanosis) rather than the pigment incontinence of *incontinentia pigmenti* help to distinguish these disorders.<sup>277</sup> Epidermal nevi may present as flat brown streaks but more commonly are hyperkeratotic (see Chapter 9).

## Disorders of Hyperpigmentation

Pigmented nevi are among the most common hyperpigmented lesions and are reviewed in Chapter 9, as are streaks of pigmentation involving the nails (longitudinal melanonychia; see Chapter 7). Treatment of hyperpigmented lesions with topical agents has generally been unsuccessful. Sun protection is a critical aspect of management in preventing darkening. Lasers have been used to treat a variety of hyperpigmented disorders in children,<sup>278</sup> in particular CAL macules, nevus of Ota, and other forms of dermal melanocytosis, Becker nevi, and tattoos. Several therapeutic sessions are required, and results are rarely permanent.

### EPIDERMAL MELANOCYTE LESIONS

#### Freckles

Freckles (ephelides) are light brown, well-circumscribed macules, usually smaller than 3 mm in diameter, that appear in childhood, especially between 2 and 4 years of age and tend to fade during the winter and adult life. Their presence correlates with fair skin, red hair, and an increased risk of developing melanoma.<sup>279</sup> Freckles are most common on the sun-exposed areas of the face (especially the nose and cheeks), shoulders, and upper back.

Freckles become darker and more confluent after UV light exposure in the sunburn spectrum (290 to 320 nm) as well as in the long-wave UV (UVA) range (320 to 400 nm). UVA light is not blocked by window glass and sunscreen agents that filter out only the sunburn spectrum. They often become smaller, lighter, and fewer during the winter months. Histopathologic features of ephelides include increased melanin pigmentation of the basal layer without an increase in the number of melanocytes or elongation of the epidermal rete ridges.

Freckles bear cosmetic but no systemic significance. Treatment includes avoidance of sun exposure and appropriate covering makeup. Use of "full-spectrum" sunscreens that provide protection against both UVA and UVB light (e.g., with avobenzene or titanium dioxide) are more protective than sunscreens that only provide UVB protection. When desired, although seldom necessary, gentle chemical peels or laser may remove the superficial pigmentation and make many of the freckles less conspicuous.

#### Becker Nevus

Becker nevus (Becker melanosis), an irregular macular hyperpigmentation with hypertrichosis, is sometimes congenital, but more commonly starts during early adolescence. It occurs much more commonly

**Figure 11-36** Becker nevus. This light brown, irregularly bordered patch without hypertrichosis was recently noticed on the axillary area and shoulder of this 12-year-old boy.

**Figure 11-37** Becker nevus. Large patch of grayish-brown pigmentation on the back with associated coarse terminal hairs. These lesions usually appear during late childhood or early adolescence on the upper trunk.

in males than females, and affected individuals tend to be otherwise healthy. The first change generally appears as a brown pigmentation, most commonly on the chest, back, or upper arm, that expands to 10 to 15 cm in diameter (about the size of a hand or larger) (Fig. 11-36). The outline is irregular and sometimes surrounded by islands of blotchy pigmentation. Although characteristically seen unilaterally on the upper half of the trunk, especially around the shoulder, it has also been reported in other areas on the trunk, forehead, cheeks, supraclavicular region, abdomen, forearm, wrist, buttocks, and shins and may be bilateral.<sup>280,281</sup> After a period of time (often 1 or 2 years), coarse terminal hairs appear in the region of, but not necessarily coinciding with, the pigmented area (Fig. 11-37). The intensity of pigmentation may fade somewhat as the patient becomes older, but the hyperpigmentation and hypertrichosis tend to persist for life.

The etiology of Becker nevus is unknown, but a localized increase in androgen receptor sensitivity may explain the time of onset and clinical features seen in most individuals with this disorder.<sup>282</sup> Reports of familial cases<sup>283</sup> raise the question of a genetic influence in some patients, and the occasional association of significantly increased smooth muscle suggests that Becker nevus and smooth muscle hamartoma may perhaps represent two poles of the same hamartomatous change. Although most Becker nevi occur without other pathologic findings, association with a variety of other abnormalities (such as unilateral breast and areolar hypoplasia, focal acne, pectus

**Figure 11-38** Lentigines. This girl showed hundreds of lentigines, particularly on the face and extensor surfaces of the extremities. These sharply demarcated macules tend to be larger than a freckle but smaller than a café-au-lait spot and range in color from tan to black. Although one might consider LEOPARD syndrome or Carney complex in this girl, genetic testing showed no mutations in *PTPN11*, *RAF1*, *BRAF*, *MAP2K1*, or *PRKAR1A*.

**Figure 11-39** Speckled lentiginous nevus. This large patch of lentigines of different sizes overlying an increase in cutaneous pigmentation may represent a mosaic form of multiple lentiginosis syndrome.

carinatum, limb asymmetry, and spina bifida<sup>284,285</sup> has been called *Becker nevus syndrome*.<sup>283,286</sup>

Histopathologic features reveal epidermal thickening, elongation of the rete ridges, and hyperpigmentation of the basal layer with increased melanocytes.<sup>282</sup> Malignant transformation does not occur. Treatment of this disorder is purely cosmetic and is generally discouraged. Laser therapy or excision usually does not improve the appearance. The hypertrichosis may be treated with laser depilation<sup>287</sup> (see Chapter 7).

### Lentigines

Lentigines are small, tan, dark brown, or black flat, oval, or circular, sharply circumscribed lesions that usually appear in childhood and may increase in number until adult life. These may occur on sun-exposed areas (especially the face and dorsal aspect of the hands) as “lentigo simplex.” Lentigines usually measure 3 to 15 mm in diameter and may occur on any mucocutaneous surface (Fig. 11-38) including the lips or conjunctivae. The pigmentation is uniform and darker than that seen in ephelides (freckles) and CAL macules, and the color is unaffected by exposure to sunlight. Lentigines are typically larger than freckles and smaller than a typical CAL macule and can be distinguished from freckles and CAL macules histologically.<sup>288</sup> Multiple facial lentigines can be an early sign of xeroderma pigmentosum, especially in association with a history of sun burning after limited sun exposure. Lentigines have rarely been described after use of topical tacrolimus.<sup>289,290</sup>

Lentigines that appear early in life may fade or disappear; those appearing later in life tend to be permanent. Treatment other than for cosmetic purposes is ordinarily not indicated. When desired, however, excision by a small punch biopsy, cryosurgery, or laser may be beneficial. Interestingly, a patient with multiple lentigines shows marked lightening when treated with ST1571 (imatinib) for familial gastrointestinal stromal tumor syndrome.<sup>291</sup>

Patients with speckled lentiginous nevus or segmental lentiginosis show patches of lentigines, usually overlying a slight increase in cutaneous pigmentation (Fig. 11-39). Eruptive, agminated Spitz nevi may be seen within a segmental lentiginosis.<sup>292</sup> Eruptive lentiginosis is a disorder characterized by a widespread eruption of several hundred lentigines that may develop over a few months or years, usually in adolescents or young adults, without systemic manifestations. Inherited patterned lentiginosis is an autosomal dominant disorder of dark-skinned individuals with the onset of lentiginosis during early

**Figure 11-40** Bannayan–Zonana–Ruvalcaba syndrome. Lentigines of the penis are characteristic of Bannayan–Zonana–Ruvalcaba syndrome, an autosomal dominant disorder that also commonly features macrocephaly and lipomas.

childhood. Lentigines occur on the centrofacial area, lips, oral mucosae, buttocks, elbows, palms, and soles, and affected individuals are otherwise healthy.

Localized or extensive lentiginosis may also be a component of a multisystem disorder. Although they may occur in children without medical problems, lentigines of the penis are characteristic of Bannayan–Zonana (Bannayan–Zonana–Ruvalcaba) syndrome, an autosomal dominant disorder that results from mutations in the *PTEN* gene and is allelic with Cowden syndrome (Fig. 11-40) (see Chapter 9). Other major features are macrocephaly and lipomas. Lentigines of the hands, feet, and buccal mucosa may also be a feature of Cronkhite–Canada syndrome, in which nail dystrophy, hair loss, and intestinal polyposis are other characteristics. Centrofacial lentiginosis (also called *centrofacial neurodysraphic lentiginosis* or *Touraine syndrome*) is an autosomal dominant process in which lentigines are first noted in the

first year of life, particularly on the nose and cheeks. Patients with centrofacial lentiginosis may have associated mental retardation, congenital mitral valve stenosis, seizures, sacral hypertrichosis, coalescence of the eyebrows, high-arched palate, absent upper middle incisors, bony abnormalities, defective fusion of the neural tube (dysraphia), psychiatric disorders, dwarfism, and endocrine dysfunction.

The major lentiginous syndromes are Peutz–Jeghers syndrome, multiple lentiginosis/lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness (LEOPARD) syndrome, and Carney complex.

### Peutz–Jeghers Syndrome

The prevalence of this autosomal dominant disorder of mucocutaneous lentiginous macules and multiple hamartomatous intestinal polyps is approximately 1 in 100,000 individuals.<sup>293</sup> Mutations in the serine-threonine kinase *STK11/LKB1* gene have been found in 70% of familial cases and up to 67% of sporadic cases.<sup>293,294</sup>

Characteristic bluish-brown to black spots, often apparent at birth or in early infancy, represent the cutaneous marker of this syndrome. These discrete, flat pigmented lesions are irregularly oval and usually measure less than 5 mm in diameter. They are most commonly seen on the lips (Fig. 11-41), buccal mucosa, nasal and periorbital regions, elbows, dorsal aspects of the fingers and toes, palms, soles, and periumbilical, perianal, and labial regions; occasionally the gums and hard palate and on rare occasions, even the tongue may be involved. An umbilical lentigo has recently been described at birth in an affected neonate.<sup>295</sup> The pigmented lesions on the skin and lips often fade after puberty; those on the buccal mucosa, palate, and tongue, however, persist.

The hamartomatous gastrointestinal polyps seen in this disorder may be found from the stomach to the anal canal, although the small bowel represents the most commonly involved portion of the intestinal tract. Polyps vary from minute pinhead lesions to those measuring several centimeters in diameter. They may occur in early childhood, with one study showing a median age of presentation of 5 years; 50% of patients have symptoms in the first 2 decades of life, including abdominal pain, melena, or intussusception.<sup>296</sup> The most common symptom, recurrent attacks of colicky abdominal pain, is thought to result from recurring transient episodes of incomplete intussusception. A recent prospective multicenter study found a 15% risk of cumulative intussusception by age 10 years and 50% by age 20.<sup>297</sup> Hematemesis, although less common, may occur owing to involvement of the stomach, duodenum, or upper jejunum. Polyps of the nasal mucosae and gallbladder have occasionally been described, and rarely polyps involve the respiratory and urogenital tracts.<sup>298</sup>

Although the polyps of Peutz–Jeghers syndrome are generally benign, adenocarcinomas of the gastrointestinal tract (stomach, small intestine, colorectum, pancreas, and biliary tract), breast and uterine cervical carcinomas, and gonadal sex tumors (Sertoli cell tumors of the testis and sex-cord tumors of the ovary) have been

**Figure 11-41** Peutz–Jeghers syndrome. Characteristic bluish-brown to black spots were first noted in early childhood on the lips of this boy who later developed hamartomatous gastrointestinal polyps.

described.<sup>294,299</sup> Sertoli cell tumors can occur prepubertally and may present with gynecomastia.<sup>300</sup> However, most cancers occur during adulthood<sup>301</sup> with an 81% to 94% lifetime cumulative risk for all cancers (18-fold that of the general population) and an almost 70% risk for gastrointestinal cancer.

In the past, therapeutic management focused on relief of symptoms and recurrent resections with the risk of malabsorption. The recommendation now is to remove polyps if technically feasible (especially if larger than 5 mm).<sup>302,303</sup> Guidelines for initiating screening for polyps vary. Some suggest initially screening at 8 to 10 years with esophagogastroduodenoscopy (EGD) or capsule endoscopy and if these are negative, colonoscopy at age 18 unless a concern arises. In a case series of 14 children, however, the median age of polyp detection was 5 years,<sup>300</sup> leading to the suggestion that initial screening occur at 4 to 5 years of age. Sertoli cell tumors should be sought prepubertally, but yearly evaluation of other organs at risk of malignancy (breast, thyroid gland, pancreas, uterus, and ovaries) should begin by the end of adolescence. The lentigines of Peutz–Jeghers syndrome have responded to laser<sup>304</sup> and intense pulsed light<sup>305</sup> therapies, although the lentigines not uncommonly recur.<sup>306</sup>

Laugier–Hunziker syndrome is a benign pigmentary disorder that manifests as macular hyperpigmentation of the lips and buccal mucosa. Many patients also show long pigmented bands of the nails (melanonychia striata), but the visceral manifestations of Peutz–Jeghers syndrome are absent.<sup>306,307</sup>

### Carney Complex

Carney complex comprises an autosomal dominant disorder that features the pigmentary abnormalities of lentigines, epithelioid blue nevi, and pigmented schwannomas.<sup>308</sup> Nevi, atrial myxoma, and neurofibroma ephelides (NAME)<sup>309</sup> and lentigines, atrial myxoma, and blue nevi (LAMB)<sup>310</sup> syndromes are included in Carney complex.<sup>311–314</sup> Most cases are sporadic. The group of disorders is considered a form of MEN, in that endocrine abnormalities and tumors are common features, especially pituitary adenomas, ovarian tumors,<sup>315</sup> testicular (Sertoli cell) tumors, and pigmented nodular adrenocortical disease.<sup>316</sup>

Skin manifestations are seen in 80% of patients, most commonly lentigines that typically fade during adulthood in 70% to 75% of patients. The lentigines tend to appear peripubertally and most commonly involve the center of the face, especially the vermillion border of the lips, (leading to the misdiagnosis of Peutz–Jeghers syndrome,<sup>317</sup> as well as the conjunctivae and occasionally the intraoral area. Peutz–Jeghers and Carney syndromes share several other features including the occurrence of gynecomastia and growth acceleration, as well as Sertoli cell tumors and tumors of the breast and thyroid. The blue nevi, including epithelioid blue nevi, occur in 40% of Carney complex patients. They tend to be multiple, most commonly on the face, trunk and extremities, and characteristically are dome-shaped dark blue papules. The majority of epithelioid blue nevi in children are associated with Carney complex, but this form of blue nevus has also been described in children without other features of the syndrome.<sup>318</sup> The lentigines and blue nevi are often accompanied by CAL spots. Multiple cutaneous myxomas occur in 30% to 55% of studied patients and are most commonly seen on the eyelids, ears, nipples, and external genitalia. They are usually diagnosed during the late teen years but can occur as early as infancy.<sup>319,320</sup> Patients often show myxomas of the oropharynx, heart, and breast and may develop other neoplasia of mesenchymal and neural-crest origin. The typical psammomatous melanotic schwannomas occur in 10% of affected individuals and may involve the skin, posterior spinal nerve roots, gastrointestinal tract, and bone. Biopsies of the blue nevi and schwannomas show characteristic histologic features.<sup>321</sup> Patients have been described both with predominantly cutaneous features<sup>322</sup> and without cutaneous lentigines. The most common endocrine tumors or overactivity include primary pigmented nodular adrenocortical disease (25% of patients), growth hormone-producing pituitary adenoma (10% of patients), large cell calcifying Sertoli cell tumor, and thyroid adenoma (up to 75% of patients). Development of carcinoma is rare.

Mutations in the protein kinase A type I- $\alpha$  regulatory subunit (*PRKAR1A*)<sup>323</sup> occur in approximately 57% of patients. An additional 20% of families with Carney complex show linkage to 2p16 (gene not yet identified) and have a milder phenotype with later onset.

## Multiple Lentiginos/LEOPARD Syndrome

Multiple lentiginoses/LEOPARD syndrome (also called *Noonan syndrome with multiple lentigines [NSML]*) comprises a spectrum of patients who show manifestations ranging from generalized lentigines alone to the complete syndrome that characteristically shows lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness.<sup>324–327</sup>

Affected individuals typically are thin; show an elongated, marfanoid facies; and have CAL macules admixed within the myriad of lentigines (Fig. 11-42). The disorder is within the spectrum of “RASopathies,” and mutations in *PTPN11* have been found in 90% patients; genotyping may be required to confirm the diagnosis. Rarely, affected individuals have mutations in *RAF1* (3%), *BRAF*, or *MAP2K1*.<sup>328–331</sup> Variable expressivity is seen within families, so that some affected individuals show only the multiple lentigines, whereas others show a variety of the visceral manifestations. Nevertheless, the underlying mutation of a family with multiple lentigines without other features maps to chromosome 6q, a site that is distinct from *PTPN11* and *RAF1*.<sup>332</sup>

The dark, 1- to 5-mm lentigines that define the syndrome often first appear at 4 to 5 years of age but then increase dramatically (to thousands of lentigines) by puberty. The cutaneous lesions tend to be concentrated on the neck and upper trunk, but they may also appear on the skin of the face and scalp, arms, palms, soles, and genitalia. The lentigines characteristically spare the mucosa. Occasionally forms frustes of this disorder occur, in which the characteristic lentigines are absent. In most patients, the CAL macules are present before the onset of the lentigines, leading to consideration of the alternative diagnosis of NF type 1 or its allelic variant with CAL spots and pulmonary valve stenosis, Watson syndrome.

Cardiac abnormalities occur in about 85% of affected individuals—mostly hypertrophic cardiomyopathy (up to 75%), which usually appears during infancy and subsequently progresses. Pulmonary valve stenosis and conduction defects have been described in 10% and 7% of patients, respectively.<sup>330</sup> Skeletal aberrations may include retardation of growth (below the 25th percentile), hypertelorism, an elongated facies, pectus deformities (carinatum or excavatum), dorsal kyphosis, winged scapulae, and prognathism. Endocrine disorders include gonadal hypoplasia, hypospadias, undescended testes, hypo-

plastic ovaries, and delayed puberty. The hearing loss of LEOPARD syndrome is congenital and neurosensory and can be detected by early auditory evoked potentials.

## Café-au-Lait Spots

Café-au-lait (CAL) spots are large, round or oval, flat lesions of light brown pigmentation found in up to 33% of normal children; having a greater number of CAL spots is more common in children with darker skin color, but having more than five is rare other than in NF or Legius syndrome.<sup>333–336</sup> Commonly present at birth or developing soon thereafter, they vary from 1.5 cm or less in their smallest diameter to much larger lesions that may measure up to 15 to 20 cm or more in diameter (Fig. 11-43). CAL spots may rarely occur anywhere on the body. A recent study suggested that neonatal blue-light phototherapy increases CAL spots in preschool children.<sup>337</sup>

The CAL spots of McCune–Albright syndrome are seen in approximately 50% of patients. They tend to be present during infancy or early childhood, with a predilection for areas with particularly bony prominences (the forehead, nuchal area, thorax, sacral areas, and buttocks). However, CAL spots may be seen elsewhere, including on the oral mucosae.<sup>338</sup> They are commonly unilateral, stopping abruptly at the midline and following a dermatomal distribution. They tend to have irregularly jagged or serrated borders (described as resembling the coast of Maine, in contrast to the smooth-bordered CAL spots of NF, which have been compared to the coast of California). The McCune–Albright syndrome in its complete form is a triad characterized by CAL spots, polyostotic fibrous dysplasia, and endocrine dysfunction, often manifesting as precocious puberty (see Chapter 23, Fig. 23-23). McCune–Albright syndrome is a mosaic disorder resulting from activating mutations in *GNAS*, but next-generation sequencing techniques enable detection of the low-abundance mutations in blood samples.<sup>339</sup>

CAL spots are increased in number in Russell–Silver syndrome,<sup>340</sup> a disorder that also features short stature, musculoskeletal abnormalities, craniofacial dysmorphism, and genitourinary malformations, as well as in multiple lentiginoses/LEOPARD syndrome (see Multiple Lentiginos/LEOPARD Syndrome section and Fig. 11-42). Johnson–McMillin syndrome is an autosomal dominant disorder in which families show truncal CAL spots in association with facial nerve palsy and mild developmental delay.<sup>341</sup> Other disorders with increased numbers of CAL spots are ring chromosomes (chromosomes 7, 11, 12, 15, 17, 22), Cowden and Fanconi syndromes, TSC, and piebaldism.

**Figure 11-42** Multiple lentiginosis/LEOPARD syndrome. Myriad of lentigines with scattered café-au-lait macules overlying generalized hyperpigmentation in this adolescent with only cutaneous changes. In some individuals, the pigmentary changes are associated with a spectrum of visceral abnormalities, including lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness, leading to the term *LEOPARD syndrome*.

**Figure 11-43** Café-au-lait (CAL) spot. Round or oval patches of light brown pigmentation are common in children but usually are up to a few centimeters in diameter, in contrast to this larger CAL spot of the face. Although a rare disorder, the segmental distribution of the CAL spot should alert one to consider the possibility of McCune–Albright syndrome.

### Box 11-3 Diagnostic Criteria for Neurofibromatosis Type 2

Bilateral vestibular schwannomas seen by MRI scan  
or  
A first-degree relative with NF2  
AND  
Unilateral vestibular schwannoma  
or  
Two of the following criteria:  
Meningioma  
Glioma  
Schwannoma  
Juvenile posterior subcapsular cataract

Modified from Mulvihill JJ, Parry DM, Sherman JL, et al. NIH conference. Neurofibromatosis 1 (Recklinghausen disease) and neurofibromatosis 2 (bilateral acoustic neurofibromatosis): an update. Ann Intern Med 1990;113(1):39–52; and Nunes F, MacCollin M. Neurofibromatosis 2 in the pediatric population. J Child Neurol 2003;18(10):718–24.

*MRI*, Magnetic resonance imaging; *NF*, neurofibromatosis

Not uncommonly, infants may show what appears to be a CAL, but sometimes years later the CAL develops tiny more darkly hyperpigmented macules or papules. This lesion is called *nevus spilus* (see Chapter 9), and biopsy of the more darkly pigmented lesions will show typical features of pigmented nevi (see Fig. 9-28). Individuals with red hair or with parents of markedly different skin pigmentation may show hyperpigmented macules that resemble CAL spots. They can be differentiated by their often irregular shape, tendency to be less well defined than the CAL spots of NF, and the paler coloration of the hyperpigmentation. Observation of these CAL-like macules during the first 5 to 6 years of life should be performed, and annual ophthalmologic evaluations should be considered to be convinced that the macules merely represent a pigment variation. Lichen aureus, a form of pigmented purpuric eruption, can also be confused with a CAL but tends to show pinpoint petechiae and purpura on a hyperpigmented base<sup>342</sup> (see Chapter 12).

### Neurofibromatosis

Neurofibromatosis (NF) is an autosomal dominant disorder characterized by an increased propensity toward the development of tumors, particularly of the nerve sheath.<sup>343–345</sup> NF encompasses three distinct disorders: NF type 1 (NF1; von Recklinghausen disease), NF type 2 (NF2; bilateral acoustic or central NF),<sup>346</sup> and schwannomatosis. The latter is characterized by painful peripheral (nonvestibular, non-dermal) schwannomas and is largely diagnosed in adults.<sup>347</sup> More than 90% of cases of NF are NF1, which occurs in approximately 1 in 3000 births.<sup>348–351</sup> NF2 occurs in 1 in 25,000 to 40,000 individuals, and its diagnosis during childhood is unusual. Both disorders show variable expressivity; NF1 shows an approximately 50% rate of new mutations, whereas two-thirds of children with NF2 have an affected parent. Patients with NF1 have mutations in neurofibromin, a large gene that encodes a large GTPase-activating cytoplasmic protein that negatively regulates Ras activation.<sup>345</sup> The gene mutated in NF2, merlin or schwannomin, encodes a cytoskeletal protein that inhibits a serine/threonine kinase PAK1, which is essential for Ras transformation.<sup>352</sup>

The cutaneous manifestations of NF1 are of major importance, and thus most discussion of NF in this chapter will focus on NF1. However, skin tumors are an important diagnostic clue for patients with NF2 and are often present months to years before other features. These tumors, predominantly schwannomas or neurofibromas, are the presenting sign in 27% of individuals with NF2 and eventually occur in 59% of patients.<sup>353,354</sup> A higher number of skin tumors has been correlated with a worse prognosis. CAL spots are found in 33% of individuals with NF2, but only 2% have six or more CAL spots. Although NF2 is commonly considered a disorder of adults, approximately 15% of patients with NF2 are diagnosed before 18 years of age,<sup>355</sup> and onset during childhood predicts a worse prognosis. The major criteria for NF2 are shown in Box 11-3. NF2 in children most commonly presents with hearing impairment (one-third of children) or cranial-nerve dysfunction (one-third of children). Tumor load is often

### Box 11-4 Diagnostic Criteria for Neurofibromatosis Type 1

Must have two or more of the following:  
Six café-au-lait macules that measure  $\geq 0.5$  cm before puberty and  $\geq 1.5$  cm in diameter in adults\*  
Freckling of the axillary and/or inguinal areas\*  
A plexiform neurofibroma or two or more dermal neurofibromas  
Two or more Lisch nodules  
Optic nerve glioma  
Pathognomonic skeletal dysplasia; i.e., tibial or sphenoid wing dysplasia  
An affected first-degree relative

\*Given the recognition that Legius syndrome is distinct from neurofibromatosis type 1 (NF1) clinically and genetically but shares two of the major features, experts on NF1 have recently suggested that having the cutaneous pigmentary lesions alone (café-au-lait spots and freckling) is insufficient for a definitive diagnosis of NF1.

**Figure 11-44** Neurofibromatosis type 1 (NF1). The presence of six or more café-au-lait (CAL) spots larger than 0.5 cm in diameter in children and 1.5 cm in adolescents suggests the possibility of NF1, although having CAL spots alone does not allow for definitive diagnosis.

extensive in pediatric patients (especially vestibular and cranial schwannomas, cranial meningiomas, and spinal cord tumors). Overall, 75% of affected children develop hearing loss. Removal of vestibular schwannomas does not preserve hearing, although early detection and smaller tumors are associated with a better prognosis. Visual impairment owing to cataracts and amblyopia occurs in 83% of affected children. Treatment is primarily surgical. Auditory brainstem implants may partially restore hearing.<sup>356</sup>

Although NF1 is best known because of Joseph Merrick, the famed “Elephant Man” of the 1800s, he is now thought to have had Proteus syndrome, a disorder characterized by segmental overgrowth with asymmetry, macrocephaly, lipomas, linear verrucous epidermal nevi, and vascular malformations (see Chapter 12). The diagnostic criteria for NF1 (Box 11-4) have not been modified since 1988 and thus do not yet include having a pathogenic mutation in neurofibromin. These criteria are of limited value for young children who typically show only multiple CAL spots and in 50% of cases have no affected first-degree family member. As such, the diagnostic criterion of six or more CAL spots of greater than 5 mm in diameter prepubertally and more than 15 mm postpubertally probably indicates the presence of NF1 (Fig. 11-44)<sup>357</sup> but is not definitively diagnostic. About 95% of patients with NF1 meet these criteria by 8 years of age, and all meet it by age 20 years. There is marked variability in the overall severity and progression of NF. It can cause serious problems and even death in the newborn, or it may produce only mild or insignificant problems during the lifetime of the affected individual.

**Cutaneous Manifestations of Neurofibromatosis Type 1.** CAL spots and dermal and plexiform neurofibromas are the characteristic cutaneous findings of pediatric NF1. The severity of cutaneous involvement is not indicative of the extent of disease in other organs. In fact,

**Figure 11-45** Neurofibromatosis type 1 (NF1). Axillary freckling (Crowe sign) is present in 20% to 50% of individuals with NF1 and commonly appears between 3 and 5 years of age. Although the presence of both axillary freckling and multiple *café-au-lait* spots currently allows a definitive diagnosis of NF1, these features are also seen in Legius syndrome.

the number of CAL spots has recently been shown to be a function of germline sequence variants of other genes involved in pigment biology.<sup>358</sup>

CAL spots may occur anywhere on the body. They may be present at birth but often first appear during the first few months. They continue to increase in size and number during the first decade, especially the first 2 years of life. CAL spots in NF1 tend to have a greater melanocyte density and increased fibroblast secretion of stem-cell factor than CAL spots without associated NF1.<sup>359</sup> Large CAL spots may be a sign of an underlying plexiform neurofibroma.

Another form of pigmentation, termed *axillary freckling* (Crowe sign), also serves as a valuable diagnostic aid in the early recognition of NF (Fig. 11-45).<sup>360</sup> Axillary freckling appears as multiple 1- to 4-mm CAL spots in the axillary vault. These most commonly appear between 3 and 5 years of age. Lack of sun exposure in this area prevents confusion with true freckles. These freckles are also commonly seen in the inguinal region and may be more generalized. Overall almost 90% of affected children have intertriginous freckling by 7 years of age.

Multiple CAL spots and axillary and/or inguinal freckling are features of Legius syndrome (sometimes called NF type 1-like syndrome), which results from mutations in *SPRED1*. *SPRED1* interacts directly with Ras and is involved in its function. Although the clinical features during childhood generally do not allow Legius syndrome to be distinguished from NF1, distinction is important prognostically, because Legius syndrome has been associated with macrocephaly and learning disabilities but not with the cutaneous or plexiform neurofibromas, NF1 osseous lesions, or symptomatic optic-pathway gliomas.<sup>361</sup> Almost 2% of individuals with a previous diagnosis of NF1 are now thought to have Legius syndrome. Although CAL spots and freckling have been distinct criteria that, if both present, allow the definitive diagnosis of NF1, the discovery that Legius syndrome presents with these two criteria has led to the suggestion that multiple CAL spots and freckling be combined into a single criterion for diagnosis.<sup>362</sup>

NF1 is also characterized by dermal or subcutaneous neurofibromas that represent tumors primarily comprised of Schwann cells, mast cells, and fibroblasts. The Schwann cell has been shown to be the cell of origin, in which loss of the normal neurofibromin allele leads to uncontrolled growth in the setting of NF1 (loss of heterozygosity).<sup>363,364</sup> The dermal and subcutaneous neurofibromas usually occur in late childhood or adolescence; thus they are generally not found in affected children. Their appearance is commonly associated with puberty and pregnancy, and they have been noted in 84% of affected

**Figure 11-46** Neurofibromatosis type 1. Dermal and subcutaneous neurofibromas are rarely found before adolescence. These tumors, which originate from Schwann cells, increase in number progressively thereafter.

adults.<sup>365</sup> They are soft in consistency, may range in size from a millimeter to several centimeters in diameter, and often have an overlying violaceous, pink, or blue hue (Fig. 11-46). They may be sessile or pedunculated. With pressure from a finger, dermal neurofibromas may be invaginated, a sign called *buttonholing*. “Pseudoatrophic macules” and “red-blue macules” are unusual variants of dermal neurofibromas that show replacement of dermal collagen with neural tissue and thick-walled blood vessels in the superficial dermis overlying the neurofibroma, respectively. By adulthood, dermal neurofibromas may number from a few to hundreds, with a progressive increase in size and number as the patient becomes older. Neurofibromas may occur anywhere on the body with no specific site of predilection. Not uncommonly, patients complain of itchiness at the site of a dermal neurofibroma, perhaps related to the presence of mast cells.

Plexiform neurofibromas may be superficial or deep and occur in approximately 25% of children.<sup>366,367</sup> They often are oriented along the length of a nerve and involve several fascicles. They may be barely palpable, may be quite firm, or may become huge with a “bag of worms” consistency. Plexiform neurofibromas not uncommonly are present at birth and have a predilection to involve the extremities. Commonly, a large CAL spot, often with irregular borders, overlies the plexiform neurofibroma (Fig. 11-47); hypertrichosis maybe associated as well (Fig. 11-48). Underlying soft-tissue and bone hypertrophy (Fig. 11-49) or bone erosion may be seen. Plexiform neurofibromas may at times cause pain, muscle weakness, atrophy, or slight sensory loss. Given the hyperpigmentation and associated hypertrichosis, a plexiform neurofibroma may be confused with a congenital nevus, Becker nevus, or smooth muscle hamartoma. Orbital plexiform neurofibromas present with eyelid swelling and ptosis,<sup>368</sup> leading to amblyopia in 62% of affected children.<sup>369</sup> Isolated plexiform neurofibromas have been described in patients without NF1, although the possibility of mosaicism should be considered (Fig. 11-50).

Although a benign course for neurofibromas is usual, malignant peripheral nerve sheath tumors (MPNSTs) occur in 8% to 13% of affected individuals, peak in their occurrence during the second and third decades of life, and are the primary cause of early mortality. MPNSTs have been attributed to the occurrence of a second mutation within tumor cells, commonly a p53 mutation.<sup>370</sup> Malignant degeneration may be heralded by rapid enlargement, pain, change in texture, and neurologic deficit. Positron emission tomography (PET)-CT imaging of MPNSTs can distinguish benign neurofibromas from MPNSTs.

Two other skin changes in NF1 are juvenile xanthogranulomas (JXGs) and nevus anemicus. JXGs are discussed in Chapter 10, and these yellow dome-shaped papules (Fig. 11-51) are found overall in up to 37% of affected children with a mean age of onset of 24 months of age.<sup>366,371,372</sup> Most children have more than one JXG (mean  $\approx$ 3), and 90% clear by a mean age of 47 months. Nevus anemicus tends to be

**A****B**

**Figure 11-47** Neurofibromatosis type 1. **(A)** Plexiform neurofibromas are commonly present at birth and can resemble giant café-au-lait spots, although borders are often more irregular. **(B)** With advancing age, plexiform neurofibromas may enlarge and become more elevated with a firm or “bag of worms” consistency. **(A)** shows a plexiform neurofibroma in a 3-year-old boy, and **(B)** shows the same plexiform neurofibroma when the child is 11 years of age. This boy passed away as a teenager from a malignant peripheral nerve sheath tumor at a different site.

present at birth or infancy and has been described in 9% of children with NF<sup>373</sup> and 35% of those under 2 years of age.<sup>372</sup> These skin signs may add to the suspicion of NF1 in an infant (*nevus anemicus*) or young child (JXG) with only CAL spots and may become new criteria.

**Systemic Manifestations of Neurofibromatosis.** Other than the CAL spots, learning disability is the most common manifestation of NF1 in children.<sup>374,375</sup> Learning disability, which occurs in 30% to 70% of affected children, includes nonverbal and verbal disability as well as attention-deficit/hyperactivity disorder, which can lead to the poor development of social skills.<sup>376</sup> Diagnostic criteria for autism spectrum disorders have been found in 30% of children with NF1.<sup>377</sup> Another common sign is the occurrence of enhanced intensity of T2 signals in brain MRI examinations in the basal ganglia, brainstem, internal capsule, and cerebellum (unidentified bright objects) (43% to 93%).<sup>378</sup>

**Figure 11-48** Neurofibromatosis type 1. This plexiform neurofibroma is hypertrichotic and was misdiagnosed as a congenital nevus.

**Figure 11-49** Neurofibromatosis type 1. This plexiform neurofibroma of the tongue led to discomfort and difficulty with both speech and mastication. Note the cheek and neck involvement.

The ocular manifestations of NF1 include plexiform neurofibromas, Lisch nodules, optic gliomas, and the recently recognized choroidal nodules. Lisch nodules are asymptomatic yellowish-brown melanocytic hamartomas on the iris that cause no problem with vision. These Lisch nodules are found in more than 90% of affected adults but in only 43% of children under 12 years of age. They are best detected by slit-lamp examination, although larger ones may be seen without magnification as beige spots on a dark iris or darker spots on a light iris. Their presence virtually ensures the diagnosis of NF1, but their absence does not discount the diagnosis. Choroidal nodules are detectable in 71% to 79% of children with NF1 by near-infrared reflectance,<sup>379,380</sup> suggesting that they may be a better criterion for diagnosis in young children.<sup>381</sup> Optic gliomas occur in approximately 15% of children with NF1 and are more indolent than optic gliomas in

**Figure 11-50** Plexiform neurofibroma without neurofibromatosis type 1 (NF1). Occasionally typical plexiform neurofibromas occur in individuals without evidence of NF1; mosaicism should be considered.

**Figure 11-52** Neurofibromatosis type 1. Precocious puberty in a 5-year-old boy with an optic chiasm/hypothalamic glioma.

**Figure 11-53** Neurofibromatosis type 1. Bilateral tibial bowing without evidence of pseudoarthrosis in an affected infant.

**Figure 11-51** Juvenile xanthogranuloma (JXG) in neurofibromatosis type 1 (NF1). JXGs are seen in up to 37% of affected children, are usually multiple (mean of three per patient), occur with a mean age of onset of 24 months of age, and tend to clear about 2 years later. Some have suggested that having both JXGs and café-au-lait spots should allow a definitive diagnosis of NF1.

individuals without NF1. Precocious puberty has been described in up to 40% of patients with gliomas of the posterior chiasm and hypothalamic areas (Fig. 11-52).<sup>382</sup> Overall, only 33% of patients with optic gliomas develop symptoms or signs such as decreased visual acuity or visual-field defects, proptosis, strabismus, and/or optic-nerve pallor. A total of 35% of those with symptomatic optic gliomas eventually require treatment, specifically for their progressive loss of vision, gross disfigurement (e.g., from proptosis), or poor weight gain with diencephalic syndrome. Chemotherapy with carboplatin and vincristine is the treatment of choice. Surgical resection is used for cosmetic palliation, and radiation therapy is avoided because of the risk of second malignancy treatment.<sup>383,384</sup> Progression in optic gliomas usually occurs by 6 to 7 years of age, suggesting that annual eye examinations can thereafter be spaced to every 2 years until adulthood. Although

routine baseline MRIs are not necessary, imaging should be performed if abnormalities are found on ophthalmologic evaluation or in the face of signs of a problematic optic glioma.<sup>384</sup> Spontaneous regression of optic gliomas may occur.<sup>385</sup>

Brain tumors may lead to neurologic abnormalities. Other than optic pathway gliomas, brainstem gliomas (pilocytic astrocytomas) are the most common intracranial neoplasms<sup>386</sup> but usually behave less aggressively than histologically identical tumors patients who do not have NF1. Owing to the indolent nature of these tumors, conservative management with close follow-up monitoring is recommended. A total of 23% of meningiomas have been noted in individuals with NF1.<sup>387</sup> More severe developmental delay occurs in only 5% of patients and has been associated with total deletion of the neurofibromin gene<sup>388</sup>; these patients also have facial dysmorphisms and large numbers of neurofibromas.

Skeletal manifestations are most commonly bone dysplasias, pectus deformity, and scoliosis. Even without osseous abnormalities, children and adolescents with NF1 have decreased bone mineral density.<sup>389</sup> Although not among the diagnostic criteria, spinal deformities, particularly scoliosis or kyphosis, may occur in at least 10% of patients, and pectus deformities occur in approximately 24% of patients.<sup>390,391</sup> The dystrophic form of scoliosis almost always develops before 10 years of age and then progresses, usually involving the lower cervical and upper thoracic spine, and is associated with dysplastic changes of the vertebral bodies. Tibial dysplasia (congenital bowing), pathognomonic for NF1, presents as anteromedial bowing of the tibia (Fig. 11-53), usually during the first year of life and has been described in about 1% to 4% of affected children. The cortex of the bone is thinned,

and the medulla is sclerotic.<sup>392</sup> Fractures may occur at the site, leading to pseudoarthrosis. Sphenoid wing dysplasia occurs in 3% to 7% of children with NF1 and may manifest as pulsating exophthalmos. Nonossifying fibromas have also been described in association with multiple CAL spots (Jaffe–Campanacci syndrome); this group of patients has a high risk of recurrent fractures and significant resultant deformity and disability.<sup>393</sup>

Other features of NF1 that may be seen during childhood are short stature (10%), frequent headaches (30% to 40%), macrocephaly (24%), and rarely hypertension (1%). Short stature most often occurs without evidence of neuroendocrine problems.<sup>394,395</sup> The macrocephaly is usually not associated with hydrocephalus, although aqueductal stenosis has rarely been reported. In children, hypertension usually relates to renal artery stenosis, a form of NF1 vasculopathy<sup>396</sup>; in adults with hypertension and NF1, pheochromocytoma should be suspected. Stenosis or occlusion of several other arteries may occur, leading to cerebral vascular accidents, aneurysms, and even sudden cardiac death.<sup>397,398</sup> Small telangiectatic vessels often form around the stenotic area of the cerebral arteries, leading to a “puff of smoke” (moyamoya) on cerebral angiography. Watson syndrome is an allelic variant of NF1 with associated pulmonic stenosis, and NF1-Noonan syndrome combines the features of Noonan syndrome (ocular hypertelorism, low-set ears, downslanting palpebral fissures, webbed neck, and pulmonic stenosis) with NF1, usually with mutations in neurofibromin but not *PTPN11*, the gene usually associated with Noonan syndrome.

NF1 is associated with a 5% lifetime risk of developing malignancy. In addition to the development of MPNSTs, nonlymphocytic leukemias, rhabdomyosarcoma, and lymphoma are described with increased incidence in affected children. Although JXGs have been described in association with juvenile chronic myelogenous leukemia, few patients with NF1 and JXGs have leukemia.<sup>399</sup>

**Therapy of Neurofibromatosis Type 1.** The current management for most children with NF1 is anticipatory guidance, genetic counseling, and surveillance for potential complications. If available, referral to a multidisciplinary clinic that specializes in seeing individuals with NF1 is optimal. Baseline screening tests, except for ophthalmologic examinations, are not recommended. Monitoring and early intervention for learning disabilities is important. Complete physical examinations should be performed at least twice yearly, including measurements of height, weight, head circumference, and blood pressure; careful palpation for tumors; and assessment for scoliosis or other bony deformities. Methylphenidate has been shown to be helpful for the attention-deficit issues in children with NF1.<sup>400</sup>

Dermal neurofibromas may be excised, but plexiform neurofibromas usually cannot be removed in their entirety.<sup>401</sup> Surgical debulking may be undertaken for tumors that are disfiguring, interfere with function, or are subject to irritation, trauma, or infection. Mitogen-activated protein kinase kinase (MEK) inhibition has been shown to decrease both neurofibroma and MPNST size and prolong survival in preclinical studies<sup>402</sup>; decreased tumor size was noted in all 11 children treated with selumetinib, a MEK1/2 inhibitor.<sup>403</sup> Mast cells appear to play a critical role in the initiation and progression of plexiform neurofibromas, and imatinib has led to an at least 20% decrease in tumor size within 6 months in 26% of patients.<sup>404,405</sup> Treatment with sirolimus (mTOR inhibitor) improved pain associated with pediatric plexiform neurofibromas but caused no shrinkage.<sup>406</sup>

Genetic counseling is another important aspect of treatment, because there is a 50% chance of transmitting NF with each pregnancy. Mutations can be found by multistep mutation detection in more than 95% of individuals with NF1.<sup>345,407</sup> Mosaicism with postzygotic mutation in neurofibromin, however, is not uncommon.<sup>408,409</sup> Affected patients may show mosaic-generalized NF1, which is indistinguishable clinically from germ-line mutations with generalized manifestations or mosaic-localized NF1. Patients with mosaic-localized or “segmental NF1” show typical features of NF1 limited to a specific body segment. Although CAL spots are the most common manifestation of segmental NF1 in children, other cutaneous manifestations (freckling, dermal and plexiform neurofibromas) or noncutaneous manifestations (pseudoarthrosis, sphenoid wing dysplasia, optic glioma, Lisch nodules) in the localized area may also occur.<sup>410</sup>
