Individuals with mosaic forms of NF1 who also have germ-line involvement (more common with mosaic-generalized NF1) may have offspring with full NF1 with an up to 50% probability with each pregnancy. A national support group, the National Neurofibromatosis Foundation ([www.nfnetwork.org](http://www.nfnetwork.org) and [www.ctf.org](http://www.ctf.org)), offers patient information and support.

## ERYTHEMA DYSCHROMICUM PERSTANS

Erythema dyschromicum perstans (ashy dermatosis) is an acquired chronic, progressive bluish to ash-gray hyperpigmentation that can affect individuals of both sexes from childhood through adulthood. Although more common in darker-skinned individuals, several light-skinned affected children have been described.<sup>411,412</sup> The cause of erythema dyschromicum perstans remains unknown. Lesions usually begin as slate-gray macules (Fig. 11-54) but occasionally show a transient, slightly raised erythematous border. Generally seen on the trunk and upper limbs, lesions may also occur on other areas, with the exception of the scalp, mucous membranes, palms, and soles. Lesions vary from a few millimeters to many centimeters in diameter and often cover extensive areas. Lesions are usually distinct but can be confluent. Multiple linear lesions of erythema dyschromicum perstans have been described that follow the lines of Blaschko,<sup>413</sup> and lesions may be unilateral.<sup>414</sup>

This disorder must be differentiated from the postinflammatory hyperpigmented lesions of tinea versicolor, pityriasis rosea, and fixed-drug eruption, which usually show brown rather than grayish pigmentation. Idiopathic eruptive macular pigmentation is differentiated by the development of brown (rather than grayish) nonconfluent macules of the trunk, neck, and proximal extremities; the absence of preceding inflammation; the lack of exposure to a medication; and basal cell hyperpigmentation without damage to the keratinocytes and without dermal mast cells in biopsy sections. Histologic features of erythema dyschromicum perstans depend on the stage of the lesion. Older lesions show pigment incontinence, but early lesions may show hydropic degeneration of epidermal cells and a lichenoid infiltrate of lymphocytes.

**Figure 11-54** Erythema dyschromicum perstans. Oval slate-gray macules, all oriented along the same axis, on the trunk of this otherwise healthy boy. In children with erythema dyschromicum perstans, the hyperpigmented macules often clear spontaneously after years.

The dermatosis is asymptomatic but chronic. There are frequent exacerbations with extension into previously uninvolved areas. There is no known effective therapy, but most cases in children clear spontaneously within a few years.<sup>411,415</sup>

### POSTINFLAMMATORY HYPERPIGMENTATION

Post-inflammatory hyperpigmentation is one of the most common causes of hyperpigmentation, and is characterized by an increase in melanin formation following cutaneous inflammation.<sup>416,417</sup> Ordinary post-inflammatory hyperpigmentation is of relatively short duration and tends to persist for several months after the original cause has subsided. Examples include the pigmentation following physical trauma, friction, primary irritants, eczematous eruptions, lichen simplex chronicus, acne vulgaris and dermatoses such as pityriasis rosea, psoriasis, fixed drug eruptions, photodermatitis, and pyoderma. Individuals with dark complexions and those who tan easily following UV light exposure show the greatest degree and longest persistence of this form of post-inflammatory hyperpigmentation. In cases in which the dermal–epidermal junction and basal layer become disrupted (lupus erythematosus, lichen planus, lichenoid drug eruptions) melanin incontinence occurs (Figs. 4-43 and 4-51). The melanin tends to drop from its normal epidermal position and passes into melanophages of the dermis, leading to more pronounced and persistent discoloration. If areas of postinflammatory hyperpigmentation can be protected from further UV light exposure, fading gradually occurs over a period of months to years. Most patients do not respond to topical agents or resurfacing procedures as well as patients with melasma (see below).<sup>418,419</sup> Topical anti-inflammatory medications are appropriate if inflammation is ongoing.

### Retention Hyperkeratosis

Because melanin is transferred to epidermal cells, thickened epidermis often appears hyperpigmented. Focal patches of hyperpigmentation and mild skin thickening are not uncommonly seen at fold areas (such as the ankle) and on the neck and represent retention hyperkeratosis (sometimes called *scurf*) (Fig. 11-55). These persistent patches can be removed easily by gently scrubbing with an alcohol pad.

### MELASMA

*Melasma* is a term applied to a patchy dark-brown to black hyperpigmentation located primarily on the cheeks, the forehead, and occasionally the temples, upper lip, and neck.<sup>417,420</sup> Seen in up to 20% of women, including adolescents, who take anovulatory drugs or who are pregnant, this disorder has been termed the *mask of pregnancy*. Typical melasma also can occur in males and in females who are

**Figure 11-55** Retention hyperkeratosis. Persistent focal patches of hyperpigmentation and mild skin thickening, especially on the neck and near joints represent retained scale and can be removed easily by gently scrubbing with an alcohol pad. Parents often erroneously consider this a sign of inadequate cleansing.

neither pregnant nor taking oral contraceptives. Occasionally it may also appear in patients of both sexes taking phenytoin (Dilantin) or its derivatives. Overall 10% of affected individuals are male. Once melasma has developed, it tends to persist for a long time, and treatment is generally not very satisfactory. Melasma of pregnancy usually clears within a few months after delivery only to recur with subsequent pregnancies. Oral contraceptive-induced melasma may persist for up to 5 years after discontinuation of the medication.

Because sun exposure tends to trigger and intensify this hyperpigmentation, the disorder characteristically becomes more prominent in the summer months.<sup>421</sup> Both UVA and visible light have been implicated, emphasizing the need for physical sunscreen use and use of sun-protective clothing. In addition, treatment of melasma consists of discontinuation of potentially responsible medications and the use of bleaching agents.<sup>418,419</sup> Topically applied hydroquinones have been the gold standard of treatment, but their safety has recently been questioned, leading to the search for alternatives. Hydroquinones inhibit tyrosinase and are most effective when compounded with tretinoin (0.05% to 0.1%) and mild topical steroids. Twice-daily application of azelaic acid 15% to 20% is less efficacious but causes less irritation.<sup>422</sup> Other topical agents that have been used are tranexamic acid (also used orally), kojic acid, plant extracts (such as licorice or orchid extracts, soy, arbutin, and silymarin), ascorbic acid, N-acetylglucosamine, and niacinamide.<sup>419</sup> Chemical peels (e.g., with tretinoin or trichloroacetic acid) and laser therapy, especially with Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG), may also be helpful. These preparations often require 3 to 4 months before a therapeutic effect is achieved. Concurrent sun protection is critical to prevent further hyperpigmentation in patients using hydroquinones. Because continuous use of hydroquinone bleaching creams or lotions can result in excessive pigmentary loss or ochronosis-like hyperpigmentation, once the desired degree of depigmentation is achieved, hydroquinone therapy should be discontinued.

### METABOLIC CAUSES OF HYPERPIGMENTATION

Cutaneous changes often are helpful in the diagnosis of several endocrine disorders, including Addison disease (see Figs. 23-6, and 23-7), hyperthyroidism (see Fig. 23-2), hypothyroidism, acromegaly, and Cushing syndrome (see Chapter 23). More than two-thirds of patients with chronic hepatic disease (cirrhosis or prolonged bile-duct obstruction) also have some degree of cutaneous hyperpigmentation. Of these, diffuse darkening of the skin is perhaps the most common. Blotchy areas of brown hyperpigmentation occasionally may be seen, and accentuation of normal freckling and areolar hyperpigmentation may appear. Progressive, diffuse blotchy hyperpigmentation in addition to hair lightening has been described with cobalamin (vitamin B<sub>12</sub>) deficiency from homozygous mutations in *ABCD4*, which encodes a transporter involved in processing cobalamin.<sup>423</sup> Polycystic kidney disease and other chronic renal disease may be accompanied by diffuse yellowish-brown skin discoloration, especially on the face and hands. Although urinary chromogens and carotenemia may be present, melanin pigmentation also has been implicated.

### Hemochromatosis

Hemochromatosis is a familial iron storage disorder characterized by cutaneous hyperpigmentation that usually manifests between 40 and 60 years of age. However, type 2 or the juvenile form of hemochromatosis presents during childhood. An autosomal recessive disorder, the two subtypes are caused by mutations in *HJV*, encoding hemojuvelin (HFE2A), or *HAMP*, encoding hepcidin (HFE2B).<sup>424,425</sup> Hemojuvelin and hepcidin are involved in iron metabolism. Hyperpigmentation is seen in almost every patient with hemochromatosis and in conjunction with abdominal pain, is often the presenting sign. The increased pigmentation is produced by melanin and not by the deposition of iron in the skin. It appears initially in the exposed areas before it becomes diffuse and is most intense in the skin of the face, arms, body folds, and genitalia. Mucous membranes (the gums, palate, and buccal mucosa) and sometimes the conjunctivae are involved in 15% to 20% of affected persons. The skin is soft, dry, thin, shiny, and of fine texture. Spider angiomas are present in 60% to 80% of affected individuals, and palmar erythema is common. Facial, axillary, thoracic, and pubic

hairs are scant or absent. Cardiomyopathy, evidence of hypogonadism, and reduced glucose tolerance are seen by young adulthood. The hepatic cirrhosis characteristic of adult-onset hemochromatosis, however, is less clinically relevant in type 2 hemochromatosis, and icterus is unusual.<sup>426</sup>

Secondary hemochromatosis (hemosiderosis) with associated hyperpigmentation may be seen in patients with anemia who receive numerous blood transfusions. In such instances visceral fibrosis is unusual, diabetes mellitus is uncommon, and hypogonadism is not present.

The diagnosis of metabolic hemochromatosis is suggested by the presence of cutaneous hyperpigmentation in patients with hepatic cirrhosis and a history of diabetes mellitus. Elevated levels of serum ferritin and transferrin saturation confirm the diagnosis.<sup>427</sup> The demonstration of parenchymal iron distribution by skin, liver, and gastric biopsies and the presence of hemosiderin in urinary sediment are helpful. Skin biopsies show increased melanin in the basal layer and deposition of iron in the upper cutis (especially in macrophages, endothelial cells of capillaries, and the propria of eccrine glands).

The clinical course of untreated hemochromatosis is characterized by tissue destruction, malfunction of involved organs, and eventual death. Symptomatic treatment of the diabetes, liver dysfunction, and cardiac symptoms and quarterly phlebotomies, when initiated early, commonly result in clinical and pathologic improvement. Dietary restriction of iron is impractical, and chelating agents to date have been of little value.

### Ochronosis

Alkaptonuria (ochronosis) is an inborn error of tyrosine metabolism in which homogentisic acid, an intermediate product in the metabolism of phenylalanine and tyrosine, accumulates in the tissues and is excreted in the urine because of a lack of homogentisic acid oxidase. This autosomal recessive disorder usually first becomes manifest in the third decade with scleral blue-black pigmentation (Osler sign). Affected children rarely show Osler sign, and the characteristic dark urine is usually not noted because the color change only occurs with sitting for 1 to 2 h, especially in an alkaline environment.<sup>428,429</sup> Dark urine in the diaper may be the first sign in infants. Skin pigmentation first becomes visible around the fourth decade of life, especially on ear cartilage, eyelids and other facial areas, intertriginous areas, and over tendons. Nails may be stained brown. Around this time, the ochronotic arthropathy from pigment deposition also starts to develop and involves the weight-bearing joints (spine, knees) most commonly. The mean age of joint replacement is 55 years, of development of renal stones 64 years, of cardiac valve involvement 54 years, and of coronary artery calcification 59 years. The diagnosis can be confirmed by alkalinizing the urine (e.g., with sodium hydroxide), which leads to the typical black color; the homogentisic acid is detected by enzymatic spectrophotometry or gas liquid chromatography. Treatment with ascorbic acid twice daily may reduce the connective tissue damage, and affected children have also been placed on a low-protein diet. Nitrofurantoin therapy may decrease homogentisic acid production.<sup>430</sup> Endogenous ochronosis has recently been improved by erbium-doped YAG laser resurfacing and deep focal point treatment to remove areas of residual deep pigment.<sup>431</sup>

Exogenous ochronosis is clinically and histologically similar to its endogenous counterpart but is not hereditary and has no internal manifestations. The condition usually occurs in African-American patients from exposure to hydroquinones and is characterized by asymptomatic hyperpigmentation of the face, neck, back, and extensor surfaces of the extremities. Less commonly, exogenous ochronosis has been described after exposure to antimalarials or products containing resorcinol, phenol, mercury, or picric acid.<sup>432</sup>

### HYPERPIGMENTATION CAUSED BY HEAVY METALS

The systemic absorption of chemicals can also cause discoloration of the skin. Although the incidence of hyperpigmentation owing to exogenous heavy metals has decreased in recent years, limited exposure to such preparations still occurs, and metallic hyperpigmentation may still be seen in children as well as adults.

Argyria occurs after long-term ingestion or excessive application of silver preparations and presents as localized or widespread bluish-gray or slate-colored discoloration of the skin produced by the deposition of silver within the dermis. The condition is more pronounced on exposed parts of the body—namely the face, forearms, and hands—but may also occur in the sclerae, oral mucous membranes, and lunulae of the nails. Argyria has been increasingly described because of the promotion of colloidal silver-based products for their immunostimulant, antimicrobial, and anti-inflammatory properties. The antimicrobial properties are proportional to the bioactive silver ion released and its availability to interact with bacterial or fungal cell membranes.<sup>433</sup> These “health food” products deliver primarily inactive metallic silver, not the antimicrobial ionized form. Colloidal silver and silver sulfadiazine cream, for example, have high levels of silver release with relatively low levels of ionized silver.<sup>434</sup> Ionized silver dressings have more recently been introduced for wound care<sup>433</sup>; they occasionally cause local dermal argyria<sup>435</sup> but show very low local silver levels. On the other hand, temporary superficial silver staining of the stratum corneum is a common side effect of these dressings. An adolescent girl with osteosarcoma who had limb salvage and placement of a silver-coated megaprosthesis developed intense blue-gray pigmentation along the surgical incision line 1 year after surgery from slow release of the silver.<sup>436</sup>

Cases with more extensive hyperpigmentation have been described after chronic ingestion of silver-containing water<sup>437</sup> or colloidal silver<sup>438</sup> or widespread topical application of silver sulfadiazine<sup>439,440</sup> or colloidal silver. Localized staining can be seen periorbitally and on the eyes from ophthalmic preparations containing silver at acupuncture sites<sup>441,442</sup> or after exposure to silver earrings<sup>443,444</sup> but most commonly is now reported at burn or wound sites after use of silver sulfadiazine or colloidal silver when used as antibacterial agents, for example, for patients with burns or epidermolysis bullosa.<sup>440,445</sup>

The diagnosis of argyria is based on clinical examination and history of exposure and may be confirmed by cutaneous biopsy of affected areas, which shows fine, small round refractive silver granules throughout the dermis, especially around eccrine glands. Increased amounts of melanin may be seen in the basal layer of the epidermis and also within macrophages in the upper dermis. Treatment of argyria depends on recognition of the disorder, discontinuation of the use of the silver-containing preparation, and avoidance of sunlight exposure. The dermal hyperpigmentation is usually irreversible.

Chrysiasis (gold-induced hyperpigmentation) is a rare cutaneous disorder induced by the administration of gold salts followed by exposure to UV light.<sup>446,447</sup> The pigmentation is bluish gray or purplish and is similar to that seen in argyria except that the hyperpigmentation is more prominent around the eyes, is limited to areas of sunlight exposure, and does not affect the sclerae and oral mucous membranes. Hyperpigmentation may develop after treatment with a Q-switched laser after systemic gold treatment.<sup>448</sup> Other cutaneous manifestations are seen in up to 20% of individuals on gold therapy, which is most commonly administered for rheumatoid arthritis. These include morbilliform, eczematous, urticarial, bullous, purpuric, lichen planus-like, and pityriasis rosea-like eruptions. The histopathologic features of gold-induced hyperpigmentation consist of small, black, round or oval, irregularly shaped gold particles located in a perivascular distribution and in dermal histiocytes.

Chronic exposure to mercury systemically may result in acrodynia (pink disease), a disorder of infants and young children characterized by leg cramps; headaches; hypertension; excessive perspiration; itching; swelling; redness and peeling of the hands, feet, and nose; weakness of the pectoral and pelvic girdles; and nerve dysfunction in the lower extremities. However, exposure to topically applied mercury may lead to slate-gray pigmentation in areas of topical application. The discoloration is exaggerated in the areas of skin folds and is permanent.<sup>449</sup>

### DRUG-INDUCED HYPERPIGMENTATION

Hyperpigmentation may be induced by chronic exposure to medication and tends to be worsened by sun exposure. The diagnosis of a drug eruption is based almost entirely on history and physical

examination. The main drugs implicated in causing skin pigmentation are nonsteroidal anti-inflammatory drugs, minocycline, antimalarials,<sup>450</sup> amiodarone, diltiazem,<sup>451</sup> cytotoxic drugs, heavy metals (see Hyperpigmentation Caused by Heavy Metals section), clofazimine, imipramine,<sup>452,453</sup> and chlorpromazine. Clinical features are variable according to the triggering molecule and have a large range of patterns and shades. Bluish-gray discoloration is most common and especially prominent at sites of exposure to UV light. The condition is most commonly seen in the pediatric population in adolescents who have been taking minocycline for acne, with the blue discoloration usually notable at sites of acne scarring and on the oral mucosae and shins (Fig. 11-56).<sup>454</sup> Three subgroups have been described based on clinical appearance and histopathologic correlates: type I (blue-gray pigmentation in scars); type II (blue-gray pigmentation in previously normal skin, especially of the shins); and type III (brown discoloration at sun-exposed sites).<sup>455</sup> Biopsy specimens tend to show pigmentation within dermal macrophages, often localized to vessels and adnexal structures. Treatment involves interruption of therapy and sun avoidance, although laser, particularly the alexandrite 755 nm laser, may be useful.<sup>456,457</sup> These measures are often followed by fading of lesions, but pigmentation may persist for a long time or even be permanent.<sup>458</sup>

The plaques of fixed drug eruptions are circumscribed, usually round or oval, often edematous and sometimes bullous, usually pruritic, and reddish-purple. Drug-induced hyperpigmentation tends to recur in the same location after the readministration of certain drugs, particularly sulfonamides, tetracyclines, acetaminophen, phenolphthalein, barbiturate derivatives, and antineoplastic agents such as cyclophosphamide. Histopathologic examination of lesions of the hyperpigmented phase of fixed drug eruptions reveals an increase in the amount of melanin in the basal layer of the epidermis and within macrophages of the upper dermis and is helpful in confirming the diagnosis.

### Carotenemia

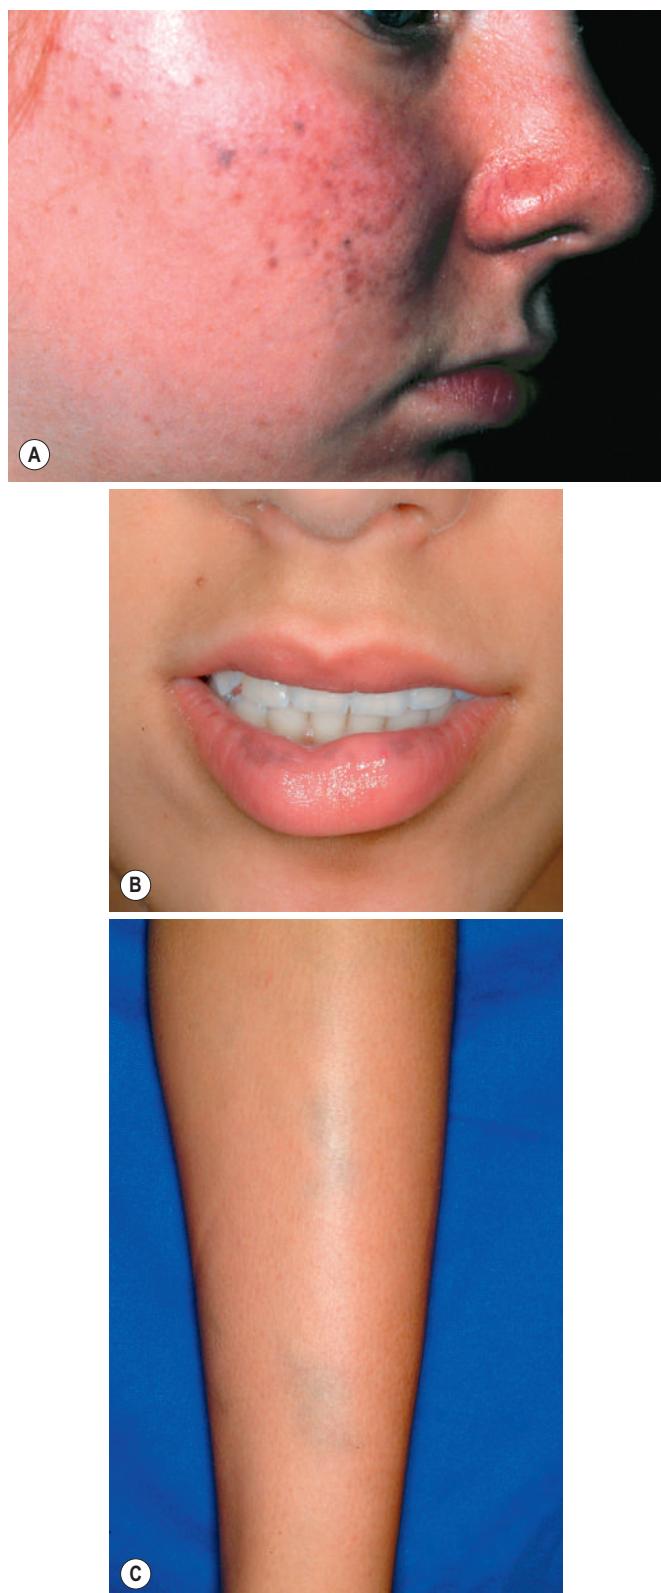

Carotenemia (sometimes called *carotenoderma*) is a yellowish-orange discoloration of skin caused by the ingestion of excessive quantities of carotene-containing foods, particularly carrots, squash, pumpkin, yellow turnips, sweet potatoes, peaches, apricots, papayas, mangos, egg yolk, and even green beans.<sup>459–461</sup> The condition is seen primarily in infants and occasionally in older children and adults.<sup>462</sup> The color is most prominent on the palms and soles, in the nasolabial grooves, on the forehead, chin, upper eyelids, postauricular areas, and anterior axillary folds, and over areas of pressure such as the elbows, knees, knuckles, and ankles (see Fig. 23-3). Lack of involvement of the sclerae and mucous membranes coupled with the absence of pruritus and lack of color change in the urine or stool helps rule out the presence of hepatic or biliary jaundice. Lycopene, a red-colored carotenoid pigment found in fruits and vegetables, especially ripened tomatoes, beets, chili beans, and various fruits and berries, may cause a reddish-yellow discoloration of the skin (lycopenemia).

Carotenemia is a benign disorder in infants, and no intervention is required. Rarely carotenemia may be a sign of systemic disease, especially hypothyroidism, weight-loss diets or anorexia, or diabetes. The diagnosis of carotenemia is confirmed by the presence of high carotene levels in the presence of normal serum bilirubin. If the coloration is problematic, reduction of dietary intake of carotene-containing foods to normal levels or correction of the underlying disorder usually results in gradual improvement within 4 to 6 weeks. Rarely children will show a genetic defect in the metabolism of carotenoids that is more recalcitrant to dietary intervention.<sup>463,464</sup>

### DERMAL MELANOCYTOSES

#### Mongolian Spots

Mongolian spots are flat, deep brown to slate gray or blue-black, often poorly circumscribed, large macular lesions generally located over the lumbosacral areas, buttocks (Fig. 11-57), and occasionally the lower limbs, back, flanks, and shoulders of normal infants. They are seen in 75% to 90% of individuals of African descent and Native-American babies; 62% to 86% of Asians<sup>465–468</sup>; 70% of the Hispanic population,

**Figure 11-56** Drug-induced hyperpigmentation. Bluish-gray discoloration on the cheeks at sites of acne scarring (**A**) on the oral mucosae (**B**) and on the shin (**C**) of adolescents administered minocycline for acne.

**Figure 11-57** Mongolian spots. Large blue-gray patches over the lumbosacral area and buttocks of an African-American baby. These spots often fade or clear within the first few years of life.

and 10% of Caucasian infants. Mongolian spots are present at birth, tend to fade during the first 2 to 3 years of life, and only occasionally persist into adulthood. Extrasacral location, multiple Mongolian spots, large size ( $>10$  cm in diameter), and darker color are associated with persistence beyond 1 year.

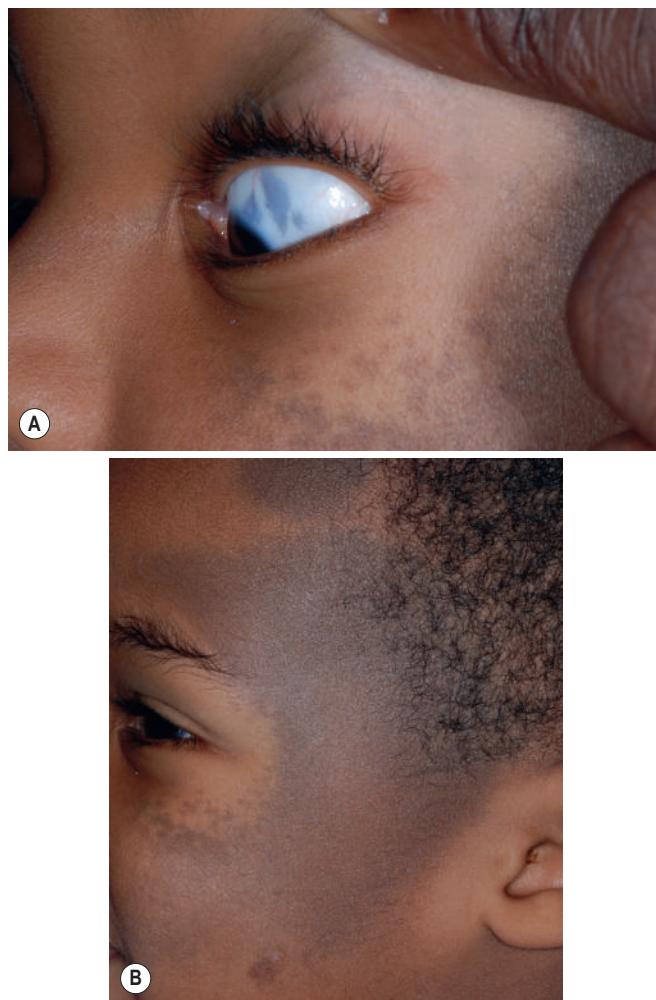

Mongolian spots may be single ( $\approx 50\%$  of babies) or multiple and vary from a few millimeters to 10 cm or more in diameter. They represent collections of spindle-shaped melanocytes located deep in the dermis, probably as the result of arrest during their embryonal migration from the neural crest to the epidermis. The slate blue to blue-black color depends on the Tyndall effect (a phenomenon in which light passing through a turbid medium such as the skin is scattered as it strikes particles of melanin). Long-wavelength light rays (red, orange, and yellow) tend to be less scattered and therefore continue to pass downward into the lower levels of the skin; colors of shorter wavelengths (blue, indigo, and violet) are scattered to the side and backward to the skin surface, thus creating the blue-black or slate-gray discoloredation.

Because Mongolian spots are benign, therapy is unnecessary. However, large and numerous Mongolian spots may be seen in lysosomal storage disorders, among them GM1 gangliosidosis type 1, Hunter syndrome, and Hurler syndrome.<sup>469-473</sup> In these children, the Mongolian spots often fade but not until at least the second decade of life.<sup>473</sup> Large and extensive Mongolian spots can be seen with phakomatoses pigmentovascularis and phakomatosis pigmentopigmentalis, on association with vascular malformations, and other pigmented lesions, respectively.<sup>474</sup>

### Nevus of Ota and Nevus of Ito

The nevus of Ota (nevus fuscoceruleus ophthalmomaxillaris) represents a usually unilateral, irregularly patchy, blue to bluish-gray to brown discoloredation of the skin of the face supplied by the first and second divisions of the trigeminal nerve.<sup>475,476</sup> It typically involves the periorbital region, the temple, the forehead, the malar area, and the nose (Fig. 11-58). About two-thirds of patients with this disorder have a patchy bluish discoloredation of the sclera of the ipsilateral eye (see Fig. 11-58) and occasionally, the conjunctiva, cornea, and retina. Palatal involvement has been described in up to 18% of affected individuals.<sup>477</sup> In about 5% of cases the nevus of Ota is bilateral rather than unilateral, and in rare instances the lips, pharynx, and nasal mucosa are similarly affected.

Although most commonly seen in Asians, nevus of Ota is not uncommonly seen in persons of African descent. Unlike Mongolian spots, which tend to disappear with time, the cutaneous coloration of nevus of Ota generally persists and often shows a speckled rather than a uniform discoloredation. Approximately 50% of lesions are congenital; the remainder usually appear during the second decade of life. Scleral

**Figure 11-58** Nevus of Ota. Unilateral, irregularly patchy, brownish-gray discoloredation of the sclera (A) and periorbital region (B) in an African-American boy.

melanocytosis alone is a much more common finding, which can progress and then recede with advancing age. In a study of Chinese children, only 4% to 5% were found to have scleral melanocytosis during the first year of life, but that number increased to 45% by 6 years of age with 78% of cases bilateral<sup>478</sup>; only 12% of the children continued to show evidence of scleral melanocytosis by 18 years of age.

The nevus of Ito (nevus fuscoceruleus acromiodeltoideus) has the same features as the nevus of Ota except that the pigmentary changes tend to involve the shoulder (Fig. 11-59), supraclavicular areas, sides of the neck, and upper arm, scapulae, and deltoid regions. It may occur alone or may be seen in conjunction with the nevus of Ota.

Similar to Mongolian spots, biopsy sections of the nevus of Ota and nevus of Ito show elongated dendritic melanocytes scattered among the collagen bundles. The melanocytes, however, often appear to be situated somewhat higher in the dermis than those seen in ordinary Mongolian spots.

Although these lesions do not disappear spontaneously, changes in color may occur. Darkening of lesions has been noted during and after puberty. These disorders are generally benign. However, glaucoma has been described in 10%<sup>479</sup> and melanoma, most commonly of the eye (choroid, orbit, iris, ciliary body, and/or optic nerve), but also of the skin, brain and meninges, has rarely been reported.<sup>479-483</sup> Long-term dermatologic and ophthalmologic follow-up monitoring is needed.

Laser therapy may improve the appearance of nevus of Ota, especially the Q-switched alexandrite laser and fractionated Nd:YAG.<sup>484,485</sup>

**Figure 11-59** Nevus of Ito. Blue patch on the shoulder.

**Figure 11-60** Blue nevus. Acquired navy blue papule on a girl's nose.

Multiple sessions are required, but resultant scarring is rare. One complication in individuals with darker skin types is postinflammatory hypopigmentation; vigorous sun protection is imperative, and pre-treatment with hydroquinone is sometimes used. Involvement on the zygomatic arch or frontal forehead regions responds better than peri-orbital pigmentation.<sup>486–488</sup> Cosmetic cover-up may also be used.

Nevus of Ota and nevus of Ito may be seen in association with vascular malformations (nevus flammeus or cutis marmorata telangiectatica congenita most commonly) in a disorder called *phakomatosis pigmentovascularis* (see Chapter 12).<sup>489</sup> The condition may be associated with Sturge–Weber syndrome or Klippel–Trénaunay syndrome when the nevus flammeus is on the forehead or limbs, respectively. Occasionally, a nevus spilus is seen in association as well.<sup>490</sup> Sturge–Weber syndrome has been shown to result from somatic mutations in *GNAQ*<sup>491</sup> and Klippel–Trénaunay syndrome in *PI3KCA* (phosphoinositide-3-kinase, catalytic, alpha), suggesting that these mutations, when occurring in melanocytes, may cause nevus of Ota or nevus of Ito.<sup>491,492</sup>

## BLUE NEVI

Blue nevi are a heterogeneous group of congenital and more often acquired melanocytic tumors.<sup>493</sup> Most often seen are common blue nevi and cellular blue nevi, although there may be histologic overlap between these types.<sup>494</sup> The nevi appear blue-gray clinically because of the deep (dermal) location of the melanin pigment and the Tyndall effect (selective absorption of longer wavelength components of light by melanin with reflection of the shorter blue components). Blue nevi are thought to result from the arrested embryonal migration of melanocytes bound for the dermal–epidermal junction. It is thus possible that the blue nevi, Mongolian spots, and the nevi of Ota and Ito are closely related and possibly represent different stages of the same physiologic process.

The common blue nevus (also called the *classic* or *dendritic blue nevus*) presents as a small, round or oval, dark blue or bluish-black, smooth-surfaced, sharply circumscribed, slightly elevated dome-shaped papule, nodule, or plaque (Fig. 11-60). Most common blue nevi range from 2 or 3 mm to 10 mm (<1 cm) in diameter. Although usually single, they may be multiple. Lesions may be present at birth but may appear at any age. Although common blue nevi may occur on any part of the body, areas of predilection include the buttocks, dorsal aspect of the hands and feet, scalp, and the extensor surfaces of the forearms. They also may occur on the face, bulbar conjunctiva, mucous membranes, and the hard and soft palates.

Once a common blue nevus appears, it usually remains static and persists throughout life. Although fading of color and some degree of flattening may occur with time, malignant degeneration of this form of blue nevus is rare. When a diagnosis of malignant melanoma is

considered, the common blue nevus can be differentiated from it by the presence of normal skin markings over the lesion, in contrast to the loss of such markings in lesions of malignant melanoma, the homogeneity of coloration and the smooth borders on routine examination, and the presence of a bluish-gray homogeneous lesion by dermoscopic evaluation.<sup>495</sup>

Cellular blue nevi tend to be larger and generally measure more than 1 cm in diameter. They are usually located on the scalp, buttocks, sacrococcygeal areas, and occasionally the dorsal aspect of the hands and feet. The plaque-type variant of blue nevus is a subset that is present at birth or develops during early childhood, occurs most commonly on the scalp, and may enlarge during puberty. The cellular blue nevus carries a higher risk of malignant transformation than the common blue nevus, but malignant transformation is still rare. Malignant blue nevi are locally aggressive but spread to regional lymph nodes in about 5% of individuals.

The classification of other forms of blue nevi is controversial.<sup>496</sup> Blue nevi may be hypochromic (sclerotic, hypomelanotic, and amelanotic forms), eruptive (particularly after sunburn on the upper central chest, shoulders, and “V” of the neck), or targetoid (preferentially on the back of the hands or feet, leading to a misdiagnosis of melanoma). Many show clinical and histologic features of more than one form, particularly combinations of variants of blue nevi with common and/or Spitz nevi (see Chapter 9). The deep penetrating nevus (usually has its onset after the first decade of life), epithelioid blue nevus (most commonly seen in individuals with Carney complex), and pigmented epithelioid melanocytoma show features of both blue nevi (intradermal location, pigmentation) and Spitz nevi (epithelioid morphology).<sup>497</sup> Molecular studies are likely to refine classification. *GNAQ* is mutated in about 83% of blue nevi.<sup>492</sup> However, deep penetrating nevi show *HRAS* mutations as seen in Spitz nevi rather than *GNAQ* or *GNA11* mutations,<sup>498</sup> suggesting reclassification of deep penetrating nevi with Spitz nevi.

Benign-appearing blue nevi do not require excision. If the diagnosis is in question, biopsy can be performed. Histopathologic examination of common blue nevi reveals greatly elongated spindle-shaped melanocytes, mainly in the middle and lower thirds of the dermis, which results in the blue coloration. In addition to spindle-shaped melanocytes, cellular blue nevi also have nodular islands of melanocytes.

## Classification of Vascular Lesions

Vascular birthmarks, or congenital vascular anomalies, are common lesions that may present in a variety of fashions. There has traditionally been a significant amount of confusion regarding the nomenclature of these lesions, and the term *hemangioma* has been widely used in the medical literature in reference to a variety of different vascular anomalies.<sup>1,2</sup> In 1982, Mulliken and Glowacki proposed a classification system for vascular birthmarks based on clinical and cellular features.<sup>3</sup> This classification was further refined 6 years later in a book,<sup>4</sup> and in 1996 it was adopted as the official classification system for vascular anomalies by the International Society for the Study of Vascular Anomalies (ISSVA). This nomenclature revolutionized the classification of vascular lesions, and is the basis for continued study into the causes of these lesions and their therapy.

According to this classification system (Box 12-1), vascular birthmarks are divided into the categories of tumors and malformations. Vascular tumors are neoplasms of the vasculature. This category includes hemangioma of infancy (the most common vascular tumor), kaposiform hemangioendothelioma (KHE), tufted angioma, and pyogenic granuloma (PG). Vascular malformations represent anomalous blood vessels without any endothelial proliferation or cellular turnover. In distinction to infantile hemangioma (IH), these lesions tend to be present immediately at birth and persist for a lifetime. Vascular malformations are further classified according to their predominant components, i.e., capillary malformation (port wine stain [PWS], salmon patch), venous malformation (VM), lymphatic malformation (LM), and arteriovenous malformation (AVM). Figure 12-1 pictorially demonstrates the different natural histories of IHs and vascular malformations.

This chapter includes discussion of vascular tumors and tumor syndromes, vascular malformations and malformation syndromes, disorders associated with vascular dilation, and a few miscellaneous disorders of the cutaneous vasculature.

## Vascular Tumors and Tumor Syndromes

### INFANTILE HEMANGIOMA

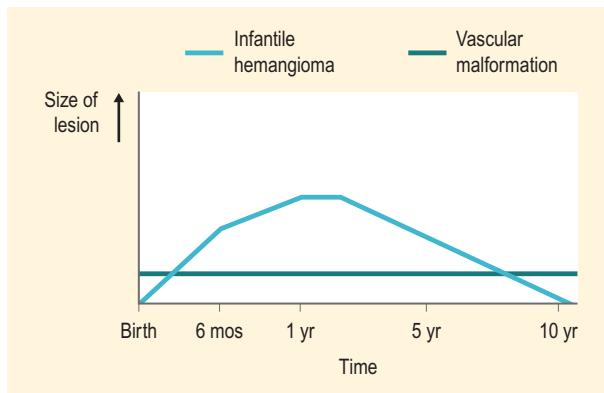

IH, or hemangioma of infancy, is the most common benign soft-tissue tumor of childhood. Although estimates vary, it occurs in around 2% to 12% of infants.<sup>5-9</sup> Female infants are three times more likely to have IHs than male infants, and the incidence is increased in premature neonates. Although they occur in all races, IHs appear to be less common in those of African or Asian descent.<sup>10</sup> Multiple gestation pregnancy, advanced maternal age, placenta previa and preeclampsia also appear to be risk factors for IH.<sup>11</sup> Although they are traditionally considered to be sporadic lesions, autosomal dominant segregation within families has been described.<sup>12</sup> These lesions vary considerably in their appearance and significance, related to their size, depth, location, growth pattern, and stage of evolution. Older descriptive terms for IH include *strawberry*, *cavernous*, and *capillary hemangiomas*. These terms are no longer useful and should not be used in the era of more specific vascular lesion nomenclature, as discussed earlier and shown in Box 12-1. Although IHs may occur on any part of the body, they most commonly involve the head and neck regions. Facial hemangiomas have been noted to have a nonrandom distribution, with the majority of lesions occurring on the central face at sites of development fusion.<sup>13</sup> Four primary segments of facial IH distribution have been identified, as shown in Table 12-1.<sup>14</sup>

The pathogenesis of IH is not yet completely understood. Positive endothelial-cell staining with erythrocyte-type glucose transporter (GLUT)-1 protein has been noted in lesions during all of the growth phases.<sup>15</sup> It is absent in other vascular lesions such as vascular malformations and hemangioendotheliomas. This protein is normally expressed in the microvascular endothelia of blood–tissue barriers such as the brain, retina, placenta, and endoneurium.<sup>16</sup> As such it has been suggested that IH may originate from invading angioblasts that have differentiated toward a placental cell type or from embolized placental cells, although some data refute a placental trophoblastic origin for these lesions.<sup>16</sup> Further evidence of a potential relationship between human placenta and IH includes the high level of transcriptome similarity between these tissues<sup>17</sup> and the higher incidence of pathologic placental findings observed from pregnancies resulting in a child with IH compared with those resulting in healthy infants without IH.<sup>18</sup> Other endothelial-cell markers shared between IH and placental tissue include Lewis Y antigen, FcγRII, and merosin. Recently, the Wilms tumor 1 (WT1) gene was found to also stain proliferative vascular tumors, including IH.<sup>19,20</sup> Aside from the placental embolization theory of pathogenesis, other hypothesized etiologies for IH development include a somatic mutation in a gene-mediating endothelial-cell proliferation or hypoxia-induced stimulation of endothelial progenitor cells.<sup>21</sup>

Hemangiomas may occur as superficial, deep, or mixed lesions representing their soft-tissue depth. The clinical appearance of the lesion depends on the type of hemangioma present. Superficial IHs, when well formed, present as bright red to scarlet, dome-shaped to plaque-like to lobulated papules, plaques, and nodules (Figs. 12-2 through 12-6). They may partially blanch with pressure and are rubbery or noncompressible on palpation. Deep IHs usually present as subcutaneous, partially compressible nodules and tumors, often with an overlying blue hue, prominent venous network, or telangiectasias (Figs. 12-7 through 12-9). These lesions may be warm to palpation. Combined IHs have both a superficial component and a deep component and occur in up to 25% to 30% of patients.<sup>22</sup> They present with both the superficial, bright red component and a deeper, blue nodular component (Figs. 12-10 and 12-11). Hemangiomas may also be divided into subtypes based on their anatomic configuration. Focal lesions are discrete, usually round lesions that appear to arise from a single focal point. Segmental lesions (see below) involve a more broad anatomic unit that may be determined by embryonic placodes. Indeterminate lesions are difficult to classify into one of the preceding two subtypes.

Hemangiomas may present with a variety of precursor lesions, and in up to 50% of affected infants these premonitory marks may be evident at birth.<sup>10</sup> They include areas of telangiectasias (Fig. 12-12), pallor, ecchymotic macules (Fig. 12-13), and even ulceration (Figs. 12-14 and 12-15).<sup>23</sup> Fully formed IHs may occasionally present at birth and are termed *congenital hemangiomas*. These lesions are discussed in more detail later.

The natural history of IH is characteristic. It is notable for a period of growth (the proliferative phase), a period of stability (the plateau phase), and a period of spontaneous regression (the involutorial phase). The majority of IHs first become evident at 2 to 3 weeks of life, with potential continued growth until around 9 to 12 months of age. The majority of growth, however, occurs during the first 5 months of age, and in those that continue to grow beyond this age, the growth rate is markedly slower.<sup>24</sup> Occasional lesions have a proliferative phase that lasts for longer than 1 year, sometimes as long as 18 to 24 months. Deep IHs tend to exhibit both a delayed onset of growth as

**Figure 12-4** Hemangioma, superficial. Note the patchy nature of this lesion, which eventually became confluent.

**Figure 12-5** Hemangioma, superficial: leg.

**Figure 12-6** Hemangioma, superficial. Note the early ulceration of the lateral inferior portion.

**Figure 12-7** Hemangioma, deep. Note the subtle blue hue and surface telangiectasias.

**Figure 12-8** Hemangioma, deep. This larger lesion shows the characteristic deep-blue hue and surface telangiectasia.

**Figure 12-9** Hemangioma, deep. This small, deep lesion resulted in mechanical ptosis, necessitating therapy out of concern for light-deprivation amblyopia. Note the overlying surface telangiectasias.

**Figure 12-10** Combined hemangioma. Note the larger, deep component and the bright red, superficial component of this combined lesion.

**Figure 12-11** Combined hemangioma. This lesion is predominantly deep, with studding of the surface with small, superficial components.

**Figure 12-14** Hemangioma precursor, ulceration. This 2-day-old newborn had this perianal ulceration; at 3 weeks of age, the ulceration was healing and the lesion had the classic appearance of a superficial hemangioma.

**Figure 12-12** Hemangioma precursor, telangiectasias. This lesion might initially be diagnosed as a port wine stain; within 4 weeks it was thickening, with eventual ulceration of the lip.

**Figure 12-15** Hemangioma precursor, ulceration. This perianal lesion presented at 1 week of age as a vascular plaque with ulceration.

**Figure 12-13** Hemangioma precursor, ecchymosis. This bruise-like appearance may be seen before hemangioma proliferation occurs.

well as a sustained, longer growth phase.<sup>24</sup> The onset of the involutional phase, which is difficult to predict in any given patient, is marked by a color change from bright red to dull red, purple, or gray (for superficial lesions) (Figs. 12-16 and 12-17). It may be more difficult to appreciate early involution in deep IH, but with time these lesions become smaller, more compressible, and less warm. It is estimated that completed involution of IH occurs at a rate of 10% per year, such that 30% have involuted by 3 years of age; 50% by 5 years of age; 70% by 7 years of age, and more than 90% by 9 or 10 years of age.<sup>10,22,25,26</sup> However, it should be remembered that involution does not necessarily imply totally normal skin. Possible residual changes after IH involution include telangiectasias (Fig. 12-18), atrophy (Fig. 12-19), scarring (Fig. 12-20), or fibrofatty masses (Figs. 12-21 and 12-22). These possibilities must be explained thoroughly to the parents of patients with IH.

Treatment decisions regarding an IH must incorporate many factors. These include the size and location of the lesion or lesions (see below), the age of the patient and growth phase of the hemangioma, associated findings, and the perceived potential for psychosocial distress both for parents and for the patient later in life. The latter is quite difficult to predict but must be seriously considered in the patient with a conspicuous IH, especially if it is facial. These lesions may be associated with parental disbelief, fear, mourning, and social stigmatization.<sup>27</sup> A hemangioma severity scale has been developed and validated and incorporates the factors above, as well as risk for

**Figure 12-16** Hemangioma, involution phase. Note the patchy vascular appearance in this involuting lesion in a 2-year-old boy.

**Figure 12-17** Hemangioma, involution phase. The redness has largely resolved and the lesion flattened in this 3-year-old female.

**Figure 12-18** Hemangioma, involuted. This lesion demonstrates the residual telangiectasias that may persist after involution of the hemangioma.

**Figure 12-19** Hemangioma, involuted. This hemangioma was very large with complete obstruction of the visual axis and secondary ulceration. After involution, atrophy and scarring are both evident.

**Figure 12-20** Hemangioma, involuted. Residual scarring and atrophy are evident in this fully involved lesion.

**Figure 12-21** Hemangioma, involuted. The cheek of this 4-year-old boy shows the residual fibrofatty tissue that may remain after involution.

**Figure 12-22** Hemangioma, involuted. This philtrum lesion has involuted, but fibrofatty residua remain.

associated structural anomalies, complications, pain, and likelihood of disfigurement.<sup>28</sup> The major goals of management should be to prevent or reverse life- or function-threatening complications; prevent disfigurement; minimize psychosocial stress; avoid overly aggressive procedures; and adequately prevent or treat ulceration in order to minimize infection, pain, and scarring.<sup>29</sup> Treatment decisions can be challenging and must include parental input and a thorough risk-to-benefit analysis. Hemangiomas for which further evaluation, referral to a specialist, and/or therapy should be considered are listed in **Box 12-2**. (These are discussed in more detail under Clinical Variants and Associated Syndromes.)

Treatment options for IH are listed in **Table 12-2**. Probably the most useful principle in the treatment of these lesions is that of active non-intervention. This term implies that the physician inquires about the parents' knowledge of the condition, offers education regarding natural history and therapeutic indications, and offers anticipatory guidance and support. Active nonintervention is an appropriate "therapy" for the majority of IHs, and can be offered by the pediatrician or primary care physician in most instances. Serial photography may be useful for parents of children with hemangiomas in order to document the gradual spontaneous involution, which may be subtle and underappreciated by them.<sup>22</sup> Referral to support groups and informational resources, such as the Hemangioma Investigator Group ([www.hemangiomaeducation.org](http://www.hemangiomaeducation.org)), Vascular Birthmarks Foundation ([www.birthmark.org](http://www.birthmark.org)), or the National Organization of Vascular Anomalies ([www.novanews.org](http://www.novanews.org)), is useful for parents of these children.

**Table 12-2** Treatments for Infantile Hemangioma\*

Treatment	Comment
Active nonintervention	Emotional support and guidance; distribution of patient education materials and referral to informational and support networks
Local wound care	When ulcerated: topical antibiotic, nonstick wound dressings, compresses, becaplermin gel
Oral antibiotics	When secondary infection present
Pain control	When ulcerated: may require temporary use of narcotic analgesics
Topical corticosteroids	Potent formulations; may be useful for localized, superficial IH
Intralesional corticosteroids	Usually triamcinolone; localized lesions; caution with periocular IH
Oral corticosteroids	Traditional gold standard for systemic therapy; prednisone or prednisolone, 2–4 mg/kg per day
Topical β-blockers	Most often timolol gel-forming ophthalmic solution, 0.1%–0.5%, applied 2–4 times daily; may be useful for smaller, localized and/or superficial IH
Oral β-blockers	Usually propranolol 2 mg/kg per day; risks include bradycardia, hypotension, hypoglycemia, bronchospasm, hypothermia, nightmares
Interferon α	Subcutaneous injection; severe, treatment-resistant, or life-threatening IH; risk of spastic diplegia
Laser therapy	Usually PDL; mainly useful for ulcerated IH or residual surface vascularity (i.e., telangiectasias) persisting after involution
Vincristine	Severe, treatment-resistant or life-threatening IH; requires venous access; risks include myelosuppression, peripheral neuropathy, extravasation necrosis
Surgical excision	Useful in select situations, i.e., incomplete resolution, disfiguring facial lesions, smaller complicated IH refractory to medical therapy

IH, Infantile hemangioma; PDL, pulsed-dye laser.

\*See text for more discussion.

Corticosteroids are the traditional mainstay of therapy for IHs requiring treatment. They are most often used in the oral form, although both intralesional and topical preparations may be useful. Intralesional corticosteroids are useful for localized lesions. Several injections may be necessary, and periocular lesions should be treated only by a physician experienced in their administration, given the possibility of embolization of corticosteroid particles and permanent vision loss.<sup>30,31</sup> Topical corticosteroid therapy with clobetasol (a potent, class 1 topical steroid) may be useful for localized IH.<sup>32,33</sup> In the authors' experience, this therapy is most useful for macular or very thin plaque hemangiomas in the early proliferative stage. This medication should be used cautiously with attention to the risks of atrophy, ocular toxicity, and adrenal suppression.

Oral corticosteroids were at one time considered the gold standard for treatment of complicated IHs, and their mechanism of action is poorly understood.<sup>6,34</sup> They are most useful during the proliferative phase and are generally administered in dosages ranging from 2 to 4 mg/kg per day of prednisolone or prednisone. Some authors advocate doses up to 5 mg/kg per day.<sup>22,34</sup> This therapy is usually continued for several months, with gradual tapering as tolerated. If corticosteroids are tapered too quickly, rebound growth and adrenal suppression may occur. The goals of decreased IH growth or partial shrinkage

must be balanced by the risks of long-term therapy. Common side effects include irritability, weight gain, hypertension, and gastrointestinal (GI) upset. Because the immune response is suppressed in patients receiving systemic corticosteroids, live-virus vaccinations should not be given during (or within 1 month after discontinuation of) therapy. Although decreased linear growth velocity may occur in treated patients, catch-up growth usually occurs after their discontinuation.<sup>6,10,35</sup> Adrenal axis suppression is rare, and when it occurs, tends to be reversible.<sup>35,36</sup> Many experts treat concomitantly with H2 blockers (i.e., ranitidine) to diminish the potential for symptomatic steroid-associated gastritis or worsening of gastroesophageal reflux. *Pneumocystis carinii* pneumonia has been rarely reported, which has prompted some experts to recommend trimethoprim-sulfamethoxazole prophylaxis during systemic steroid therapy.<sup>37,38</sup> In the more recent era of β-blocker therapy for IH, oral corticosteroids are used significantly less often.

Interferon α-2a or -2b, a potent inhibitor of angiogenesis, has been used successfully in patients with IH refractory to corticosteroid therapy.<sup>39</sup> This medication is administered as a daily subcutaneous injection, in a dose of 1 to 3 million units/m<sup>2</sup>. Common side effects include fever, irritability, and malaise. Neutropenia, anemia, and elevation of hepatic transaminases may also occur. However, the most concerning toxicity of this therapy is neurologic in origin, most notably spastic diplegia, which may occur in up to 20% of treated patients.<sup>40,41</sup> Because of this risk, interferon therapy should be reserved for patients with severe life- or function-threatening lesions that are recalcitrant to other therapies, and neurologic evaluation before and during therapy should be performed.<sup>42</sup> The chemotherapeutic agent vincristine is also occasionally used for steroid-resistant, life-threatening IHs.<sup>43-45</sup>

The current standard of care for IH requiring systemic therapy is propranolol. This nonselective β-blocker, which is traditionally used for cardiac indications such as hypertension or arrhythmia, was incidentally noted to result in marked shrinkage of IHs when administered in two children who had a cardiac indication and who also happened to have hemangiomas.<sup>46</sup> Subsequently these effects were confirmed in several more patients reported by the same authors as well as in several other open-label series, prospective studies, and retrospective reviews.<sup>47-53</sup> In the years after the initial report, propranolol has evolved to become the therapy of choice for most clinicians with expertise in the treatment of IH. A multicenter, prospective, international, placebo-controlled study of oral propranolol for IH has been completed and culminated in the recent approval of propranolol for treating IH by the US Food and Drug Administration as well as the European Medicines Agency.<sup>54</sup> The mechanism of action of propranolol in this setting is unclear, although most attribute the effects to some combination of vasoconstriction, inhibition of proangiogenic growth factors (including vascular endothelial growth factor, basic fibroblast growth factor, and matrix metalloproteinase-9), and induction of apoptosis.<sup>55</sup> It is most often started at around 0.5 to 1 mg/kg per day, with the dosage gradually titrated up to 2 to 3 mg/kg per day divided into two to three doses daily. Potential side effects include hypotension, bradycardia, bronchospasm, hypoglycemia, hypothermia, and nightmares, and this agent should be administered under close supervision with attention to these possible toxicities.<sup>56</sup> Rebound growth or recurrence of IH after propranolol therapy has been increasingly recognized and may occur in 6% to 19% of patients.<sup>57,58</sup> The time between cessation of therapy and notation of rebound is typically 3 to 6 months, and most lesions respond well to a second course of propranolol. Although propranolol therapy tends to be most effective during the early proliferative phase of IH (i.e., first 6 months), lesions in the post-proliferative phase may also respond to treatment.<sup>59</sup>

Hypoglycemia has surfaced as one of the most relevant (and preventable) potential toxicities of oral propranolol therapy, and the highest risk period for this effect is in the morning after the overnight fast that occurs during sleep.<sup>60</sup> The mechanism for the development of hypoglycemia is likely related to β-blocker-mediated inhibition of gluconeogenesis and glycogenolysis, mandatory components of physiologic glucose homeostasis. Measures to decrease this risk include always giving propranolol with food, holding therapy during periods of illness or decreased oral intake, and the avoidance of fasting for longer than 8 hours (which may require nighttime awakenings for

feeding).<sup>61,62</sup> Parents should be taught to recognize early warning signs of hypoglycemia, including shakiness, sweating, anxious appearance, and coldness. Table 12-3 list some guidelines for the use of propranolol in the treatment of IH.

After the discovery of propranolol's efficacy in treating IH, several investigators reported the use of a topical nonselective β-blocker timolol for small, uncomplicated superficial hemangiomas. Topical timolol maleate gel-forming ophthalmic solution is classically used for the treatment of glaucoma, but increasing reports have described its efficacy in subsets of patients with these smaller IH.<sup>63-67</sup> Most often used in concentrations of 0.1%, 0.25%, or 0.5%, it is applied two to four times daily to the surface of the IH and rubbed in well. Most small, superficial IHs and even some combined (superficial and deep) lesions respond to the treatment, which in general is very well tolerated. Systemic β-blocker side effects have been noted to occur only rarely, although adequate parent education about these potential toxicities (see previous discussion of propranolol) is warranted.<sup>68</sup> Topical timolol

**Table 12-3** Guidelines for Use of Propranolol in the Treatment of Infantile Hemangioma

Guideline	Comment
Consider contraindications	Cardiogenic shock, sinus bradycardia, hypotension, heart block (>1st degree), heart failure, bronchial asthma, hypersensitivity to propranolol
Perform ECG for patients at risk	At-risk category includes: HR below normal for age, family history of congenital heart conditions or arrhythmias, maternal history of connective tissue disease, personal history of arrhythmia or one noted during examination
Patients with PHACES syndrome: thorough imaging evaluation of head, neck, and cardiac arterial anatomy should be performed before initiation of therapy	If imaging findings place patient into higher risk for stroke, consult/comanage with neurologist during therapy; use lowest effective dose possible
Inpatient initiation of therapy recommended for infants ≤8 weeks' gestationally corrected age, with comorbid conditions, or with poor social support	Outpatient initiation of therapy appropriate for infants >8 weeks' gestationally corrected age, with adequate social support, and lack of comorbid conditions
Typical dosing is 1 mg/kg per day (initiation) and 2–3 mg/kg per day (maintenance), divided three times daily	BP and HR checks recommended at baseline, 1 and 2 hours after initial dose, and repeated with each dose increase of >0.5 mg/kg per day (until maintenance dose reached); dose may be increased every 3–7 days until goal dosage is reached
Always dose propranolol with food and avoid prolonged fasting	Discontinue during illness or periods of decreased oral intake; awaken baby to feed at night as needed to prevent sleeping longer than 8 hours without eating
Hold propranolol during illness that includes wheezing	β-blockers may worsen bronchospasm

Pediatr Dermatol 2013;30(1):155–9. BP, Blood pressure; ECG, electrocardiography; HR, heart rate; PHACES, posterior fossa malformations, hemangioma, arterial anomalies, cardiac defects, eye anomalies, and sternal defects.

**Figure 12-23** Hemangioma, ulcerated. This arm lesion, which was in the proliferative phase, reveals superficial ulceration with crusting.

**Figure 12-25** Hemangioma, ulcerated. This ulcerated labial hemangioma was very painful and responded to topical wound care and laser therapy.

**Figure 12-24** Hemangioma, ulcerated. This lower-lip lesion ulcerated with permanent scarring the result.

**Figure 12-26** Hemangioma, ulcerated. This anterior neck hemangioma ulcerated and healed with marked cribiform scarring.

ophthalmic solution is a reasonable consideration for small, primarily superficial, uncomplicated, and functionally insignificant IH.

Ulcerated IH deserves special mention, as this is the most common complication in these lesions, occurring in up to 16% of patients.<sup>69,70</sup> Ulceration usually occurs during the proliferative phase (Fig. 12-23) and is especially common in areas of recurrent trauma such as the lips (Fig. 12-24), genitals (Fig. 12-25), perineum/perianal region, or in moist intertriginous sites such as the neck (Fig. 12-26).<sup>70</sup> Tissue breakdown results in bleeding, secondary infection, pain, and permanent scarring. Local wound care with compresses, topical antibiotics (i.e., bacitracin, mupirocin, or metronidazole), and nonstick wound dressings (i.e., petrolatum-impregnated gauze) are useful. Oral antibiotics should be considered if persistent or deep ulceration, drainage, or exudate is present and should be guided by the results of culture and sensitivity testing. Pain management with acetaminophen or acetaminophen with codeine may be indicated. Topical lidocaine may be helpful for pain control but should be used with extreme caution given the risks of absorption and possible systemic toxicity. Bevacizumab gel, a recombinant human platelet-derived growth factor approved for topical therapy of lower-extremity diabetic neuropathic ulcers in patients 16 years of age and older, has been used off-label for the treatment of ulcerated IH with good success.<sup>71,72</sup> Ulcerated IHs that do not improve with the above treatments usually warrant systemic therapy.

Pulsed-dye laser (PDL; the word *laser* is an acronym for *light amplification by stimulated emission of radiation*) therapy may be useful in the

treatment of ulcerated IH. This laser emits a wavelength of light specific for oxyhemoglobin, thus imparting specificity for vascular structures (selective photothermolysis). Because the light penetrates only 1 mm of depth in the skin, this modality is generally not helpful for nonulcerated, elevated, or nodular lesions. With ulcerated lesions, though, it is useful in accentuating reepithelialization and decreasing pain.<sup>6,10,73</sup> The choice of PDL therapy must be individualized to the patient, and occasionally patients may show no response or even worsening with this modality.<sup>74</sup> PDL therapy may also be useful for residual surface vascularity after IH involution. Although PDL is the most commonly utilized form of laser therapy for IH, other lasers such as the neodymium-doped yttrium aluminum garnet (Nd:YAG) laser or the alexandrite laser may offer some benefit but carry a higher risk of scarring.<sup>21</sup>

### CLINICAL VARIANTS AND ASSOCIATED SYNDROMES

Hemangiomas in certain locations may suggest a higher probability of complications or associated findings. Hemangiomas involving various portions of the face may be quite problematic. Periorbital IHs may be relatively insignificant when small, but larger lesions (Fig. 12-27) may result in a variety of ocular complications. In addition, any periorbital IH may be indicative of deeper, retrobulbar involvement, which may or may not present with unilateral proptosis. Light-deprivation amblyopia may result from visual axis obstruction, most

**Figure 12-27** Hemangioma, periocular. This large hemangioma was obstructing the visual axis secondary to its size and location.

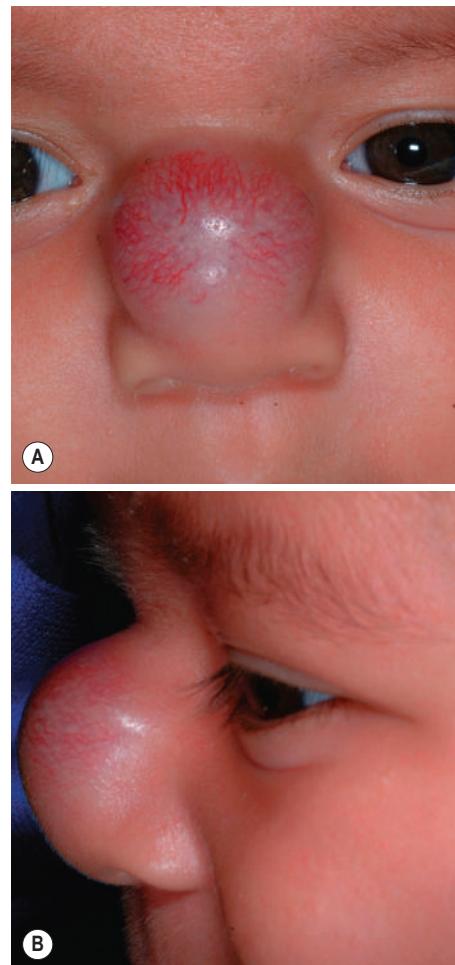

**Figure 12-28** Hemangioma, periocular. Superior eyelid hemangiomas may result in ptosis, with a risk for light-deprivation amblyopia.

commonly in the setting of significant upper eyelid lesions that result in mechanical ptosis (Fig. 12-28). Astigmatism may occur if the IH compresses the globe and may result in permanent amblyopia.<sup>10</sup> Rarely, IH situated near a tear duct may block the drainage system and result in matting and conjunctivitis.<sup>31</sup> Because of these concerns, any child with a periorbital IH should undergo ophthalmologic examination. If there are functional or anatomic ophthalmologic concerns, systemic therapy is usually indicated.

Nasal tip/bridge IHs (Fig. 12-29) often require specialist consultation because of their propensity to distort the nasal anatomy (Fig. 12-30), resulting in permanent disfigurement. Slow involution of these lesions may pose significant psychosocial distress to the older child, and the splaying of nasal cartilage combined with redundant fibrofatty tissue after involution may result in the "Cyrano" nasal deformity (Fig. 12-31). The nasal crease sign is a linear, gray atrophic crease in the inferior columella that may occur with segmental facial IH involving the nose (Fig. 12-32) and that may portend imminent cartilage destruction and nasal collapse.<sup>75</sup> It is for reasons such as these that therapy is often indicated for nasal IH.

Hemangiomas located on the lips tend to involute slowly and are more prone to ulceration and bleeding. These changes may in turn contribute to increased pain, feeding difficulties, and permanent

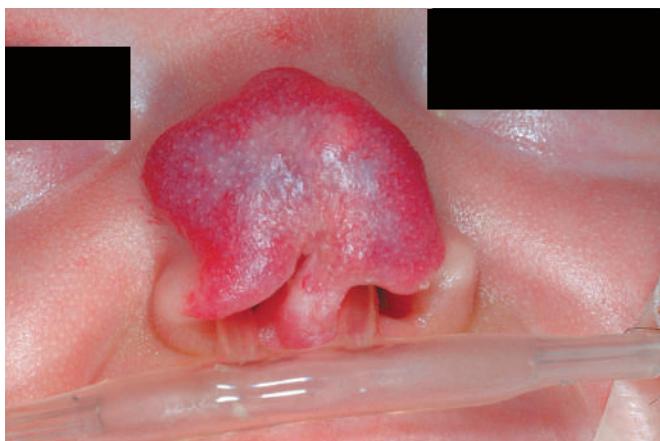

**Figure 12-29** Hemangioma, nasal bridge. This large lesion of the nasal bridge (**A**) results in significant bulbous distortion of the nose (**B**) and is likely to leave residual deformity.

scarring. Ear IHs may also be cosmetically disfiguring, and when large may obstruct the auditory canal and result in conductive hearing loss.

Hemangiomas that involve the neck, lower lip, chin, preauricular, and mandibular areas (beard lesions) (Fig. 12-33) are clinically important because of the increased risk of associated airway lesions in these patients. In one study, patients with more extensive IHs in this location had up to a 63% incidence of subglottic or upper-airway hemangiomatosis.<sup>76</sup> Airway IH may also occur in the absence of cutaneous IH. Infants with symptoms are usually brought for treatment within the first few months of life with croup-like cough, hoarseness, and biphasic stridor. Any infant with extensive IH in this distribution and/or symptoms of upper-airway obstruction should be immediately referred for direct visualization of the airway with laryngoscopy. Treatment options in this setting may include tracheotomy, propranolol, corticosteroids, interferon  $\alpha$ , surgical excision, and laser therapy.

Parotid IHs often present as mixed superficial and deep lesions with a prominent deep component of swelling with an overlying blue hue (Fig. 12-34). These lesions tend to grow significantly and may involute more slowly than IHs in other locations. They may have a poorer response to pharmacologic therapy, although propranolol has been demonstrated to be effective in many patients.<sup>77-80</sup> Genital (Fig. 12-35) and perineal IHs are problematic because of ulceration, with the concomitant risks of bleeding, infection, permanent scarring, and pain. When these lesions are larger and/or segmental, the possibility of associated developmental anomalies of the external genitalia, anorectal region, genitourinary tract, spine and spinal cord must be

**Figure 12-30** Hemangioma, nose. This large nasal lesion resulted in destruction of nasal cartilage and erosion of the columella in this extremely premature infant female.

**Figure 12-31** Hemangioma, nasal tip. Large nasal tip lesions like this one may leave significant fibrofatty residua, resulting in a "Cyrano" deformity.

considered (see PELVIS Syndrome). Hepatic IHs may be associated with significant morbidity and mortality and are discussed further in the Diffuse Neonatal Hemangiomatosis section.

Lumbosacral IHs (Fig. 12-36) are important, because they may signal underlying occult spinal dysraphism or spinal cord defects. Tethering of the spinal cord is one of the more common associations,<sup>81</sup> and this anomaly may result in permanent neurologic sequelae without release. Other common findings include spinal lipoma, intraspinal hemangioma, and sinus tracts.<sup>82</sup> In a prospective study of 41 patients with lumbosacral IHs who underwent magnetic resonance imaging (MRI) examination, intraspinal abnormalities were detected in 21 patients, with a positive predictive value of IH for spinal dysraphism of 51.2%. An increased risk for spinal anomalies correlated with IH ulceration and the presence of additional cutaneous anomalies (including gluteal cleft asymmetry or deviation, sacral dimple, skin appendage, lipoma, dermal melanocytosis, dermal sinus, and aplasia cutis). Importantly, 35% of patients with an isolated lumbosacral IH had spinal dysraphism. Also important, 42% of children with normal ultrasound scans who then underwent MRI evaluation had spinal anomalies, highlighting the potential risk of relying on ultrasonography as a screening tool for high-risk infants.<sup>83</sup> In addition to spinal anomalies, sacral IH may also be associated with various congenital anorectal or urogenital anomalies, as discussed with genital and perineal lesions.<sup>84</sup> This association is discussed in more detail below (see PELVIS syndrome). Any infant with a lumbosacral IH, especially when it is large or of the segmental type or when other cutaneous stigmata

**Figure 12-32** Hemangioma, nasal crease sign. This infant girl had a segmental facial hemangioma involving the left forehead, periorbital region, glabella, nasal bridge, and nose. At 11 days after noting this linear gray atrophic crease (A) she returned to clinic with complete destruction of the nasal septum and columella and nasal collapse (B).

**Figure 12-33** Hemangioma, beard distribution. Lesions involving the lower lip, chin, neck, or mandibular regions have a greater risk of airway involvement, as was seen in this female infant.

**Figure 12-34** Hemangioma, parotid. This large subcutaneous tumor with a blue hue and surface telangiectasias was characteristic for a parotid infantile hemangioma. These lesions tend to grow significantly and regress more slowly, and often require systemic therapy.

**Figure 12-36** Hemangioma, lumbosacral. This large segmental lesion would have an increased risk of association with underlying spinal dysraphism or spinal cord defects. MRI in this child was normal.

**Figure 12-37** Hemangioma, segmental. This superficial hemangioma occupied a large surface area of the distal arm and proximal forearm.

**Figure 12-35** Hemangioma, genital. This labial lesion is at increased risk for surface breakdown given its location.

are present, should be considered for MRI to assess for underlying abnormalities.

Segmental hemangiomas are lesions that involve a broad anatomic region (see Fig. 12-36; Fig. 12-37) or a recognized developmental unit.<sup>85</sup> They are often unilateral and sharply demarcated at the midline, although exceptions occur. Segmental IHs are most commonly located on the face. They seem to have a higher rate of complications and entail a greater risk for functional compromise and associated abnormalities such as urogenital anomalies or the posterior fossa malformations, hemangioma, arterial anomalies, cardiac defects, eye anomalies, and sternal defects (PHACES) syndrome (see the following paragraph).<sup>85</sup> In addition, they are more often complicated by ulceration.<sup>13</sup> The association of segmental IH with GI (typically lower GI) bleeding has been highlighted and appears to occur most often in the setting of PHACES syndrome with aortic dysplasia.<sup>86</sup>

The PHACES syndrome or PHACES association (Online Mendelian Inheritance in Man, 606519) is a constellation of clinical findings associated with extensive facial IH. Table 12-4 outlines the various

features seen in this syndrome. The majority of patients with PHACES syndrome are female.<sup>87,88</sup> Although the pathogenesis of this syndrome is unclear, it appears to be a developmental “field defect” that arises around the seventh to tenth week of gestation.<sup>89</sup> The facial IHs in patients with PHACES syndrome are usually large and segmental (Fig. 12-38) and may be unilateral or bilateral. They usually follow an aggressive growth pattern, and ulceration is common.<sup>87</sup> There may be a dermatomal distribution, although these dynamic lesions should not be confused with the static vascular malformations (PWSs) associated with Sturge–Weber syndrome (see below). When there is “beard” area involvement, airway hemangiomatosis should be considered. Hemangiomas may also occur in other nonfacial locations in the setting of PHACES syndrome, most notably the upper torso and extremities.<sup>90</sup> Patients with large facial IHs, especially in the presence of ventral developmental defects such as sternal clefting or abdominal raphe, should be screened for this syndrome with MRI of the brain, echocardiography, ophthalmologic examination, and close neurologic and head circumference examinations. Direct airway visualization should be considered if the infant has extensive involvement in the beard area or symptoms of upper airway obstruction.

Anomalies of the cervical and cerebral vasculature are commonly noted in PHACES syndrome, and these patients appear to have a progressive arterial vasculopathy with risk of arterial ischemic stroke (AIS).<sup>91</sup> Regressive changes in the vascular anomalies have also been noted in some patients.<sup>92</sup> Common central nervous system (CNS) structural abnormalities include Dandy–Walker malformation, cerebellar hemisphere hypoplasia (ipsilateral to the hemangioma), and arachnoid cysts.<sup>93,94</sup> Aortic arch anomalies, especially aortic coarctation, are the most commonly noted cardiac abnormalities in PHACES

**Table 12-4** PHACES Syndrome

Manifestation(s)	Comment
P Posterior fossa malformations	Dandy–Walker malformation; cerebellar atrophy; hypoplasia or agenesis of various CNS structures; may also have intracranial hemangioma, midline anomalies, neuronal migration disorder
H Hemangioma	Extensive facial; plaque-like; segmental; occasional airway involvement
A Arterial anomalies	Mainly head and neck; aneurysms, anomalous branches, aberrancy, hypoplasia, absence, stenosis, kinking, looping, tortuosity; increased risk of AIS
C Cardiac anomalies and aortic coarctation	PDA, VSD, ASD, PS, TF, others; in addition to aortic coarctation, may have dysplasia, aneurysm, aberrant origin of the subclavian artery with or without vascular ring
E Eye abnormalities	Microphtalmia, optic-nerve dysplasia, persistent fetal vasculature, morning-glory disc anomaly; also Horner syndrome, retinal vascular abnormality, cataract, coloboma
S Sternal clefting and supraumbilical abdominal raphe	Ventral midline developmental defects; may also include hypopituitarism, ectopic thyroid (with risk of hypothyroidism)

AIS, Arterial ischemic stroke; ASD, atrial septal defect; CNS, central nervous system; PDA, patent ductus arteriosus; PHACES, posterior fossa malformations, hemangioma, arterial anomalies, cardiac defects, eye anomalies, and sternal defects; PS, pulmonary stenosis; TF, tetralogy of Fallot; VSD, ventricular septal defect.

**Figure 12-38** Hemangioma, facial. Giant lesions like this one may be associated with the PHACES (posterior fossa malformations, hemangioma, arterial anomalies, cardiac defects, eye anomalies, and sternal defects) syndrome.

syndrome and tend to be complex and anatomically atypical. These anomalies may remain asymptomatic in the first days of life until the ductus arteriosus closes, at which time they may result in severe hemodynamic consequences.<sup>95</sup> Box 12-3 lists the recommended evaluation for the infant deemed to be at risk for PHACES syndrome. Diagnostic criteria for PHACES syndrome have been published.<sup>96</sup>

PELVIS syndrome has been used to describe infants with perineal IH in association with a variety of other malformations involving the genitourinary and GI tracts, lumbosacral spine, and spinal cord.<sup>97</sup> The acronym PELVIS stands for **p**erineal hemangioma, **e**xternal genitalia malformations, **I**lipomyelomeningocele, **v**esicorectal abnormalities, **i**mperforate anus, and **s**kin tag. This association has also been known as **SACRAL** syndrome, standing for **s**pinal dysraphism, **a**nogenital anomalies, **c**utaneous anomalies, and **r**enal and urologic anomalies

### Box 12-3 Recommended Evaluation of the Infant at Risk for PHACES Syndrome

#### Baseline

Thorough physical examination, including:

Cutaneous (including assessment for ventral developmental defects)

Cardiac (including pressure measurements in all four extremities)

Respiratory (i.e., for stridor, hoarseness of cry, tachypnea)

Neurologic (i.e., for hypotonia, developmental delay)

Abdominal (i.e., for hepatomegaly, abdominal bruit)

MRI/MRA of the brain and neck

Echocardiography

Ophthalmologic evaluation

Thyroid function testing

#### If Indicated

MRI/MRA of the chest

Other endocrine evaluations (i.e., for growth hormone deficiency, hypopituitarism, diabetes insipidus)

Airway evaluation/direct laryngoscopy

*MRI*, Magnetic resonance imaging; *MRA*, magnetic resonance angiography; PHACES, posterior fossa malformations, hemangioma, arterial anomalies, cardiac defects, eye anomalies, and sternal defects.

associated with **angioma** of **lumbosacral** localization.<sup>98</sup> More recently this phenotype has been expanded to include IHs involving not only the perineum but also the lumbosacral region, genitalia, and/or lower extremity by a group that suggested the terminology of **LUMBAR association**, for lower body IH and other cutaneous defects, **urogenital anomalies/ulceration**, **myelopathy**, **bony deformities**, **anorectal malformations/arterial anomalies**, and **renal anomalies**.<sup>99</sup> In this series, the IHs were noted to often be segmental as well as of the “minimal growth” phenotype (Fig. 12-39; also see below). Other cutaneous findings that may be present include lipoma, skin tag, caudal appendix, hair tuft, and sacral dimple. **PELVIS/SACRAL/LUMBAR** syndrome has been likened to PHACES syndrome, although it affects the lower half of the body and should be considered in any infant with a segmental IH (including those with minimal growth) affecting the anogenital, lumbosacral, or lower-extremity regions.

**Abortive hemangiomas** refers to IHs that exhibit very little (if any) proliferation during the period of expected growth. These lesions typically present as reticulated vascular patches, often with fine telangiectasias, occasionally as grouped telangiectases overlying normal-appearing skin, or as blue patches with a peripheral halo.<sup>100</sup> Small foci of typical bright red, superficial IH may be present around the periphery (Fig. 12-40). Other terms that have been used to describe these lesions include **plaque-telangiectatic hemangiomas**, **macular hemangioma with PWS-like appearance**, **reticular IH**, **minimal-growth hemangiomas**, and **IHs with minimal or arrested growth (IH-MAGs)**.<sup>101,102</sup> Several authors have confirmed these lesions to be IH in origin via positive GLUT-1 immunostaining of biopsies. IH-MAGs tend to present more commonly than typical IHs on the lower half of the body and may be associated with ulceration, especially when occurring in the anogenital area.<sup>102</sup>

Congenital IHs are lesions that are fully formed at birth. These lesions may follow the typical time course of IH, may have a more accelerated involution phase, or may persist unchanged. Noninvoluting congenital hemangioma (NICH) is a specific subtype of IH also known as a **congenital nonprogressive hemangioma**. These lesions may be diagnosed *in utero*, are fully formed at birth, and do not show the postnatal proliferation characteristic of IH.<sup>103</sup> Clinically NICH lesions are round to ovoid, pink to purple tumors with overlying prominent telangiectasias and peripheral pallor (Fig. 12-41).<sup>104</sup> Importantly, these lesions also do not undergo the spontaneous involution typical of IH and hence appear to be a distinctive type of vascular lesion. Interestingly, NICH lesions also have a different histologic appearance and are not immunoreactive for GLUT-1.<sup>103</sup>

**Rapidly involuting congenital hemangioma (RICH)** is the term used to describe a congenital IH that undergoes rapid involution early in life. These tumors may present similar to an NICH or they may have the appearance of a typical IH. They may also present as small to large

**Figure 12-39** PELVIS (perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag) syndrome. This infant has an infantile hemangioma with minimal growth involving the perineum (**A**) buttocks, and lumbosacral back (**B**). His history was also notable for imperforate anus, tethered spinal cord, and a filar lipoma. Note the midline lumbosacral scar related to his cord-untethering surgery.

**Figure 12-40** Abortive hemangioma (infantile hemangioma with minimal or arrested growth). This telangiectatic vascular patch presented on the medial calf of this 5-month-old boy. Note the scattered brighter red vascular macules and papules around the periphery, a classic feature in some of these lesions.

tumors with a red, violaceous, or gray appearance that may mimic other vascular (i.e., KHE, see [Kaposiform Hemangioendothelioma](#) section) or malignant (i.e., rhabdomyosarcoma, fibrosarcoma) neoplasms. They often involute completely by 12 to 15 months of age ([Fig. 12-42](#)) and may leave behind dermal and subcutaneous atrophy.<sup>105</sup>

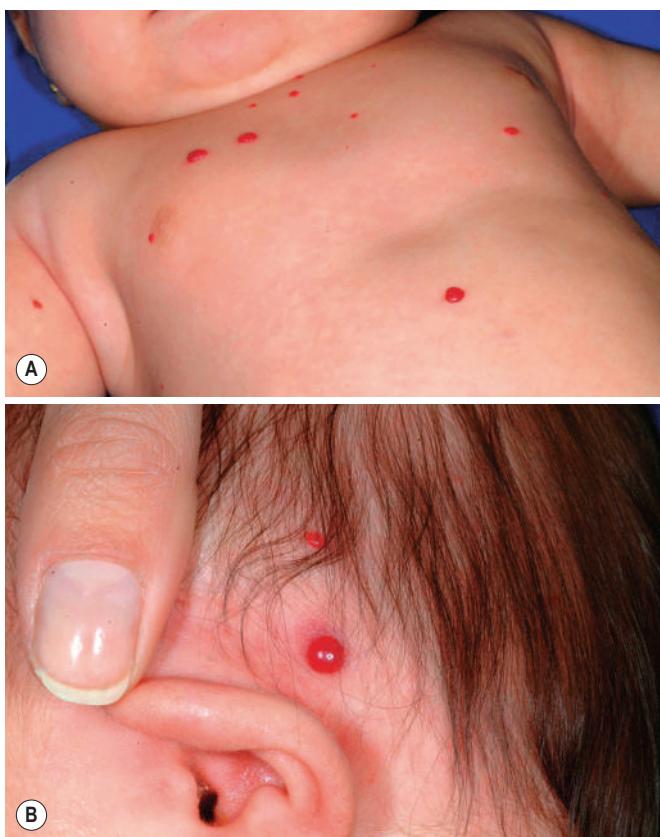

**Figure 12-41** Hemangioma, noninvolving congenital. Characteristic features include prominent surface telangiectasias and a peripheral rim of pallor.

**Figure 12-42** Hemangioma, rapidly involuting congenital. This hemangioma was fully formed at birth (**A**) and involuted completely by 1 year of age (**B**).

### Diffuse Neonatal Hemangiomatosis

Diffuse neonatal hemangiomatosis (disseminated neonatal hemangiomatosis) describes patients with multiple cutaneous lesions in conjunction with extracutaneous organ involvement. It must be differentiated from benign neonatal hemangiomatosis, in which the infant has multiple cutaneous lesions without any symptomatic visceral lesions or complications.<sup>106,107</sup> Patients with either type of hemangiomatosis may have only a few or up to hundreds of cutaneous IHs ([Figs. 12-43](#) and [12-44](#)). Some authors advocate for the terminology

**Figure 12-43** Hemangiomatosis, diffuse. This infant had multiple small lesions as shown on the trunk (**A**) and scalp (**B**) and no internal involvement.

**Figure 12-44** Hemangiomatosis, diffuse. This infant had variably sized lesions and liver hemangiomatosis.

*multipifocal IH with or without extracutaneous disease*, noting that many cases reported in the literature as diffuse neonatal hemangiomatosis may actually represent other entities such as multifocal lymphangioendotheliomatosis with thrombocytopenia (MLT) (see later this chapter).<sup>108</sup>

Although past data suggested that the risk of internal involvement could be predicted by the number of cutaneous IHs, the traditional

recommendation for internal imaging in patients with five or more lesions was more anecdotal than evidence-based. Recently, however, in a prospective study comparing 151 infants with five or more IHs to 50 infants with between one and four IHs, hepatic hemangiomas were identified on hepatic ultrasound in 16% (24) of the infants with five or more cutaneous IHs and in none of the control group with one to four cutaneous IHs. The study also revealed that preterm (<37 weeks' gestational age) delivery, multiple gestation, lower birth weight, *in vitro* fertilization, placental anomalies, and preeclampsia each occurred more often in infants with more than five cutaneous IHs, but on multivariate analysis only preterm delivery and lower birth weight were associated with having five or more cutaneous IHs. Of the 24 infants with hepatic hemangiomas, only two required therapy specifically for this finding.<sup>109</sup> This study helps to confirm that infants with five or more IHs are at greater risk for hepatic hemangiomas (and should be evaluated with liver ultrasound) and that the majority of those with hepatic involvement remain asymptomatic and do not require therapy.

Although the most common extracutaneous site for IH in patients with diffuse hemangiomatosis is the liver, multiple other organs can be involved, including the intestine, brain, eyes, spleen, oral mucosa, kidney, and lungs.<sup>110,111</sup> The diagnosis of hepatic hemangiomatosis is usually made clinically and radiographically, because liver biopsy is undesirable owing to the risk of bleeding. Liver lesions may be asymptomatic or present with hepatomegaly and congestive heart failure, the latter of which is believed to be the result of arteriovenous (AV) shunting, which leads to increased venous return and increased cardiac output. Occasionally anemia or thrombocytopenia is present.

Three patterns of liver hemangiomatosis have been proposed: focal, multifocal, and diffuse.<sup>112</sup> Focal lesions are well defined and solitary on imaging and are most often clinically asymptomatic. They usually are not accompanied by cutaneous lesions and tend to involute rapidly. Multifocal liver hemangiomas present as multiple spherical tumors, which may be asymptomatic or can result in high-output cardiac failure secondary to AV shunting. These lesions involute after the same course as seen with cutaneous IH. Diffuse lesions are extensive, may result in near-total replacement of hepatic parenchyma, and may be associated with serious complications including vessel compression, respiratory decompensation, abdominal compartment syndrome, and multiorgan system failure.<sup>112</sup> These lesions may also be associated with severe hypothyroidism.

Abdominal ultrasonography with Doppler studies is the diagnostic modality of choice, although MRI or computed tomography (CT) may occasionally be necessary. Treatment options may include optimization of cardiac function, corticosteroids, propranolol, interferon  $\alpha$ , vincristine, cyclophosphamide, embolization, hepatic artery ligation, hepatic resection, and liver transplantation.<sup>10,112</sup> Propranolol has been increasingly reported as an effective therapy for hepatic IH, and in most patients improvement in the liver lesions correlates with resolution of heart failure and improvement or resolution in the associated hypothyroidism, when present.<sup>113,114</sup> Infants with diffuse liver hemangiomas should undergo thyroid hormone monitoring and replacement as necessary. Most visceral hemangiomas, like the cutaneous lesions, grow during infancy and in surviving children regress during early childhood. Other evaluations that may be useful in the investigation for diffuse hemangiomatosis include complete blood cell counts, stool examinations for occult blood, liver function studies, urinalysis, echocardiography, electrocardiography, and CNS imaging when clinically indicated.

#### KASABACH–MERRITT PHENOMENON

Kasabach–Merritt phenomenon (KMP; also known as *Kasabach–Merritt syndrome*) is characterized by thrombocytopenia (owing to platelet trapping), coagulopathy, and microangiopathic hemolytic anemia in association with a rapidly enlarging vascular lesion. It was traditionally felt to be a complication of IH but is now known to be associated with vascular tumors other than IH, namely KHE and tufted angioma.<sup>115</sup> These lesions have characteristics that clinically distinguish them from hemangiomas (see below). KMP occurs most often within the first few weeks of life and presents with sudden enlargement of the vascular lesion, ecchymosis, prolonged bleeding,

**Figure 12-45** Kasabach–Merritt phenomenon. Note the deep purple color of this vascular tumor, which suddenly enlarged and became firm, with accompanying thrombocytopenia.

**Figure 12-47** Tufted angioma. This vascular plaque was mildly indurated to palpation. (Courtesy of Annette Wagner, MD.)

**Figure 12-46** Kaposiform hemangioendothelioma. These tumors are characteristically deep purple in color and may be associated with Kasabach–Merritt phenomenon.

epistaxis, hematuria, or hematochezia.<sup>116</sup> The cutaneous lesions show purpura, edema, induration, and an advancing ecchymotic margin (Fig. 12-45).<sup>117</sup> In addition to thrombocytopenia, other laboratory findings include anemia, hypofibrinogenemia, elevated D-dimers, fragmentation of erythrocytes on manual smear, and prolonged coagulation studies. The mortality rate is high, from 10% to 30%.

#### Kaposiform Hemangioendothelioma

Kaposiform hemangioendothelioma (KHE) is a locally aggressive vascular tumor, so named because of the histologic resemblance to Kaposi sarcoma. It presents as a firm, subcutaneous nodule or plaque that expands rapidly and often has a violaceous discoloration (Fig. 12-46).<sup>22,118</sup> Although KHE usually presents in infancy, it may appear months to years later.<sup>119</sup> In addition to involvement of the skin, KHE may involve the deep soft tissues and the bone.<sup>120</sup>

#### Tufted Angioma

Tufted angioma is actually named after its histologic appearance, which reveals groups of dermal capillary tufts. These lesions present clinically as erythematous, annular nodules, or plaques, often with induration (Fig. 12-47).<sup>121,122</sup> Although these lesions may spontaneously involute over years, they tend to persist or gradually progress in most patients. Both KHE and tufted angioma are usually easily distinguished clinically from IH, although in some patients either of the former two may mimic the latter.

Treatment for KMP is challenging. Multiple different regimens have been reported without randomized studies to support or refute their efficacy. It seems clear that a multidisciplinary approach is optimal, including medical and surgical components of diagnosis and therapy.<sup>117</sup> Hematologic therapies include red blood cell transfusions and administration of fresh frozen plasma and cryoprecipitate. Many experts recommend minimization of platelet transfusions given the risks of further platelet trapping and further expansion of the tumor. High-dose corticosteroids, antifibrinolytics, interferon  $\alpha$ , vincristine, sirolimus, cyclophosphamide and antithrombotics have been advocated.<sup>123–125</sup> Vincristine was demonstrated useful in a retrospective study of 15 patients with KMP based on increased platelet count and fibrinogen level and decreased size of the tumor.<sup>126</sup> Four of these patients had a relapse and were again treated successfully with the agent.<sup>126</sup> Vincristine in combination with corticosteroids is considered first-line treatment for many experts.<sup>123,125</sup> Combination vincristine and ticlopidine, without or with aspirin (vincristine-aspirin-ticlopidine [VAT] therapy), has been reported useful in several patients with KMP.<sup>127,128</sup> Early surgical intervention with full resection has been advocated for smaller lesions where this modality is feasible.<sup>116</sup> Other reported treatments include embolization, compression, and radiation therapy.<sup>129–133</sup> Propranolol was associated with clinical response in only 25% of patients with KMP in one series, suggesting the need for further study of this agent.<sup>134</sup>

#### PYOGENIC GRANULOMA

Pyogenic granuloma (PG) is a common acquired vascular lesion of the skin and mucous membranes in infants and children. It presents as a bright red to red-brown, raised, slightly pedunculated or sessile papulonodule (Figs. 12-48 and 12-49). The base of sessile lesions may reveal a peripheral collarette of scale (Fig. 12-50). Although its appearance is usually solitary, PG may occasionally present as several lesions. In addition, secondary PG-like proliferations may occasionally occur on the surface of an existing PWS (Fig. 12-51), usually in the older child or young adult. Multiple, or “agminated,” PG lesions have been reported in the setting of preexisting congenital vascular stains as well as in areas of preceding scalding burns.<sup>135,136</sup> PG is prone to superficial ulceration and bleeding, which usually brings the patient to medical attention. The pathogenesis of PG is unknown. Despite the name, the lesions are not considered infectious. Although they may occur on any skin surface, they most commonly appear in areas subject to trauma, especially the hands, fingers, forearms, face, and occasionally the mucosal surfaces of the mouth. They have been described on the penile shaft after circumcision.<sup>137</sup> Although histologic evaluation is usually not necessary for diagnosis, pathologic examination reveals changes similar to those of a well-circumscribed IH.

The traditional therapy for PG is simple shave excision followed by treatment of the base with electrodesiccation, which achieves hemostasis and seems to help prevent recurrence. PDL therapy may be useful for the treatment of smaller lesions,<sup>138</sup> and the continuous

**Figure 12-48** Pyogenic granuloma. An acquired, vascular papule.

**Figure 12-49** Pyogenic granuloma. This lesion is multilobulated.

**Figure 12-50** Pyogenic granuloma. This lesion demonstrates the calurette of skin around the base of the lesion.

wave/pulsed carbon dioxide ( $\text{CO}_2$ ) laser has also been demonstrated effective.<sup>139</sup> Topical imiquimod cream, an immune response modifier, may be helpful in some patients.<sup>140</sup>

### BACILLARY ANGIOMATOSIS

Bacillary angiomatosis (BA) is an exanthem characterized by cutaneous vascular lesions in association with *Bartonella* (previously *Rochalimaea*) infections. *Bartonella* species also cause cat-scratch disease, prolonged fever, hepatosplenomegaly, and ocular manifestations (includ-

**Figure 12-51** This young girl with Klippel-Trenaunay syndrome has multiple, pyogenic granuloma-like papules overlying a port wine stain of her lower extremity.

ing Parinaud oculoglandular syndrome), encephalopathy, hemolytic anemia, osteomyelitis, endocarditis, glomerulonephritis and pulmonary disease.<sup>141</sup> BA occurs primarily in immunocompromised individuals and was originally described (and once seen quite commonly) in patients with acquired immunodeficiency syndrome (AIDS).<sup>142</sup> It has been rarely documented in immunocompetent children.<sup>143,144</sup> BA is caused by *B. henselae* and *B. quintana*, and transmission is via the body louse, a cat scratch, or cat fleas. The lesions may involve various tissues, including brain, bone, lymph nodes, GI tract, respiratory tract, and bone marrow. Osseous lesions are most commonly seen with *B. quintana* infection, and visceral involvement is caused almost solely by *B. henselae*.<sup>145</sup> However, skin lesions are the most common manifestation, may be caused by both species, and present as disseminated red to purple papules generally no larger than 1 to 2 cm in diameter. The clinical differential diagnosis may include PG and Kaposi sarcoma. Occasionally, BA may present with ulcerative lesions.<sup>146</sup> Liver peliosis is a similar condition affecting the liver and lymph nodes and usually caused by *B. quintana*.

The diagnosis of BA is confirmed by tissue biopsy with histologic examination, which reveals vascular proliferation and plump endothelial cells with the infecting bacilli identified on Warthin-Starry stain. The possibility of human immunodeficiency virus (HIV) infection should be considered if BA is diagnosed. The disorder usually responds to antibiotic therapy with erythromycin, doxycycline, trimethoprim-sulfamethoxazole, or rifampin.

### GLOMUS TUMOR

Glomus tumor (glomangioma, glomuvenuous malformation) is a benign vascular lesion that usually presents as a blue papule or nodule. It represents a relatively uncommon hamartoma of the glomus body, which is a temperature-regulating AV shunt that bypasses the usual capillary bed of the dermis. The glomus cell, which proliferates in this disorder, is a modified smooth-muscle cell. Rarely seen in infants, these lesions may be solitary or multiple and occur in children as well as adults. Occasionally, nodular or plaque-like lesions may also occur.

Solitary glomus tumors, which represent 90% of all lesions,<sup>147</sup> do not appear to have a familial tendency. They are characterized by the clinical triad of paroxysmal pain, local tenderness, and cold sensitivity. Solitary lesions present as a blue-red nodule (Fig. 12-52) from 1 mm to several centimeters in size. They most often appear on the upper extremities, particularly the nailbeds, and occasionally on the lower extremities, head, neck, or penis. Although the etiology is unknown, some lesions appear to be associated with previous trauma. The differential diagnosis of a solitary glomus tumor includes VM, blue nevus, melanoma, dermatofibroma, and leiomyoma. If occurring in an infant, hemangioma of infancy may also be in the differential.

In contrast to the solitary type, multiple glomus tumors (often referred to as *glomuvenuous malformations*) are often dominantly transmitted, may be painful or painless, and vary from a few lesions to several hundred. The familial nature may not be obvious, because

**Figure 12-52** Solitary glomus tumor. (Courtesy of Sarah Chamlin, MD.)

**Figure 12-53** Multiple glomus tumors. This patient had multiple blue papules and papulonodules.

family members may have small lesions and never seek treatment.<sup>148</sup> They are relatively more common in children than adults, and although they can occur anywhere on the cutaneous surface, the majority involve the lower extremities. They may be regionally distributed or generalized, and segmental patterns of presentation have been reported.<sup>149,150</sup> Affected individuals usually have truncating mutations in the glomulin (*GLMN*) gene.<sup>151</sup> Multiple glomus tumors appear as blue-purple, flat to dome-shaped papules, plaques, and nodules (Fig. 12-53) that vary from a few millimeters to several centimeters in size. The differential diagnosis of multiple glomus tumors includes leiomyomas, diffuse hemangiomatosis, and blue rubber-bleb nevi. Multiple glomus tumors involving the fingers and toes have been reported in some individuals with neurofibromatosis type 1.<sup>152</sup>

A congenital variant of glomus tumor has been described and is characterized by a blue-red, nodular plaque that may be painful and tends to grow proportionate with the child's growth.<sup>147</sup> Congenital facial plaque-like glomus tumors may mimic VMs and can be quite disfiguring.<sup>153</sup>

Treatment of glomus tumors consists primarily of surgical excision, although this is not a feasible option for patients with multiple lesions and recurrence tends to be common. Sclerotherapy has been used with some success, as have CO<sub>2</sub> lasers.<sup>154</sup> Subungual glomus tumors are usually treated successfully with periungual or transungual surgical excision, although residual nail deformities may result.<sup>155</sup>

### HEMANGIOPERICYTOMA

Hemangiopericytoma is a rare tumor that occurs in both an adult and a childhood form, although children account for fewer than 10% of all cases.<sup>156</sup> Congenital lesions are occasionally observed.<sup>157,158</sup> This

tumor arises from pericytes, which are smooth-muscle cells that surround capillaries and postcapillary venules. Skin, subcutaneous, and muscular tissues maybe involved, and any part of the body can be affected, the most common location being the lower extremities. Some experts question whether a majority of lesions previously called *hemangiopericytomas* actually represent solitary fibrous tumors (originating from fibroblasts).<sup>159</sup>

Hemangiopericytoma may present in a variety of fashions without a distinctive or pathognomonic appearance. It often presents as a deep soft-tissue mass with slow growth. It may be flesh-colored or have a blue-red hue. Multicentric lesions have been described in infants and tend to behave in a fashion similar to their solitary counterparts.<sup>160</sup> The diagnosis of hemangiopericytoma is based on the cellular and architectural features on tissue histology.

The prognosis of this tumor in childhood is variable. It appears that children younger than 1 year of age (in which case, it is termed *infantile hemangiopericytoma* or the *congenital/infantile form of hemangiopericytoma*) have a better prognosis with a high response to chemotherapy. In children older than 1 year of age, the tumor behaves more similarly to those in adults and may be more aggressive.<sup>156</sup> Treatment consists of complete surgical resection when feasible, as well as radiotherapy and rarely chemotherapy.<sup>159</sup>

### ANGIOLYMPHOID HYPERPLASIA WITH EOSINOPHILIA

Angiolymphoid hyperplasia with eosinophilia (ALHE) is an uncommon vascular proliferation disorder occurring most commonly in young adult women and only rarely in children. It presents as a subcutaneous mass of the head and neck region, especially around the ears or on the scalp. Regional lymph node enlargement and eosinophilia may be present, and treatment is usually by surgical excision, although observation, cryotherapy, laser ablation, steroids, radiation, and chemotherapy have been reported.<sup>161</sup>

Kimura disease is a closely related, yet distinct, chronic inflammatory disorder that occurs primarily in young Asian males. It is characterized by the triad of painless subcutaneous nodules in the head or neck region, blood and tissue eosinophilia, and elevated serum immunoglobulin (Ig)E levels.<sup>162</sup> Clinically, the lesions of Kimura disease present as solitary or multiple, purple-red papules, nodules, or deep swellings. The parotid and submandibular glands may be involved,<sup>163</sup> as may the oral mucosa, scalp, ears, or orbit. Unilateral cervical lymphadenopathy is commonly present. Laboratory evaluation consistently reveals eosinophilia and increased IgE.<sup>164</sup> Pediatric Kimura disease may be associated nephritic syndrome, urticaria, and eczema.<sup>165</sup>

ALHE and Kimura disease may be confused with a variety of other entities, most commonly malignancies such as lymphoma, salivary gland tumors, or histiocytosis. These disorders histologically reveal vascular proliferation with eosinophils and mast cells, and their etiology remains unclear. Treatment options for Kimura disease include surgical excision (although recurrence is common), steroids, chemotherapy, and radiation.

### Vascular Malformations and Malformation Syndromes

#### SALMON PATCH

The salmon patch (nevus simplex) is the most common vascular lesion of infancy. It occurs in 30% to 40% of all newborns and appears as a flat, dull pink, macular lesion on the posterior neck and scalp (Fig. 12-54), glabella (Fig. 12-55), forehead, upper eyelids, and occasionally the nose or nasolabial regions. When seen on the nape of the neck, it is commonly referred to as a *stork bite* and when on the forehead/glabella, as the *angel kiss*. Although the salmon patch represents the most common form of capillary malformation, it is felt by many to be a form of persistent fetal circulation rather than a true malformation. Although older nomenclature may include salmon patch under the category of PWS, this terminology should not be used because these lesions have distinct natural histories and differing significance in

**Figure 12-54** Salmon patch. Faint, vascular macules of the occipital scalp.

**Figure 12-56** Inflammatory nuchal salmon patch. This young girl developed dermatitis overlying her congenital salmon patch. Note the central purulence, which represented secondary bacterial superinfection. The dermatitis resolved after treatment with topical steroids and oral antibiotics.

**Figure 12-55** Salmon patch. This blanchable vascular patch of the glabella and forehead becomes more prominent with crying or increased body temperature. Note the associated stain over the left superior eyelid.

**Figure 12-57** Port wine stain: arm/hand.

terms of potential syndrome associations. Salmon patches are usually isolated lesions without other associated findings. Nuchal or occipital stains may occasionally develop an associated overlying dermatitis (Fig. 12-56), which may respond to topical corticosteroids or PDL treatment, if necessary.<sup>166</sup>

No treatment is usually necessary for salmon patches, because 95% of facial lesions fade within the first 1 to 2 years of life. Lesions on the posterior neck or scalp (also known as *Unna nevus*) may fade, although some of these persist indefinitely. Since they are usually covered by hair, these lesions do not typically pose a cosmetic problem. Parents should be educated regarding the common finding of “reappearance” or accentuation of facial lesions during episodes of crying, breath-holding, straining with defecation, or physical exertion.

## NEVUS FLAMMEUS/PORT WINE STAIN

Nevus flammeus, or PWS, is a congenital capillary malformation that may occur as an isolated lesion or in association with a variety of syndromes. These lesions present as macular (nonpalpable) stains with a pink (Fig. 12-57) to dark red (Fig. 12-58) color. Although an early PWS may be indistinguishable from an IH, these lesions are usually distinguished by their congenital presence and their static nature without the rapid proliferation and thickening that characterizes hemangiomas during the first months of life. PWS may darken progressively over many years, and occasional lesions develop secondary proliferative (PG-like) vascular blebs on their surface (see Fig. 12-51). They may also become somewhat thickened and raised later in life. PWSs are often, but not always, unilateral and the most

**Figure 12-58** Port wine stain: face/scalp.

**CLOVES**, Congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and scoliosis/skeletal and spinal anomalies.

common site of involvement is the face, although they may occur on any cutaneous surface.

The significance of PWS is two-fold: the potential cosmetic impact of the lesion (especially facial PWS) on the developing child, and the potential for syndrome associations. **Box 12-4** lists the various congenital syndromes that may have PWS as a component. Several of these will be discussed later.

PWS lesions show little tendency toward spontaneous improvement or involution, and traditional therapy was limited to the use of tinted “cover-up” cosmetics (such as Covermark or Dermablend). Laser therapy has revolutionized the treatment of these lesions, and the flashlamp-pumped tunable PDL is the most accepted laser for PWS treatment.<sup>167</sup> PDL allows the targeting of short bursts of energy at intravascular hemoglobin (because of the specific wavelength of the emitted light) within the lesional vessels while sparing other tissue components and thus allowing for precise therapy. The absorbed light is converted into thermal energy, which leads to the coagulation of blood vessels. Treatment of PWS with PDL is usually performed in conjunction with local or general anesthesia, depending on the size and location of the lesion and the age of the patient. Some smaller lesions can be treated in the clinic setting without the need for anesthesia. PDL therapy is usually performed over several sessions separated in time by 6 to 8 weeks and can be quite effective in lightening these lesions, thereby minimizing their cosmetic and psychosocial significance. Although there may be psychological benefits of PDL therapy of facial PWS early in life,<sup>168</sup> studies evaluating efficacy as a function of patient age have yielded mixed results. Some authors have reported optimal treatment response in patients younger than 1 year of age, whereas others have found no evidence that treatment during

**Figure 12-59** Port wine stain. This lesion involves both the V1 and V2 trigeminal dermatomes in this infant with Sturge–Weber syndrome. (Courtesy of Annette Wagner, MD.)

early childhood is more effective than treatment at a later age.<sup>169,170</sup> In general, lesions over bony areas of the face (i.e., the forehead), lateral cheeks, chest, and proximal arms seem to respond best to PDL therapy, whereas those over the midface and distal extremities respond less well.<sup>167</sup> PWS of the central face may not respond as well, given the deeper vessels that may escape the effect of the PDL.<sup>171</sup> When PDL is being considered for PWS, it is important for the patient/parents to understand that complete clearance is rare, and 20% to 30% of PWSs are resistant to the treatment.<sup>172</sup>

#### Sturge–Weber Syndrome

Sturge–Weber syndrome (SWS; encephalofacial or encephalotrigeminal angiomas) is a neuroectodermal syndrome characterized by a PWS in the distribution of the first (ophthalmic) branch of the trigeminal nerve (V1) in association with leptomeningeal angiomas (presenting usually with seizures) and glaucoma. There are rare reports of patients with classic brain and ophthalmic findings of SWS in the absence of a facial PWS.<sup>173–176</sup> A somatic activating mutation in GNAQ (specifically, a single-nucleotide variant c.548G>A, p.Arg183Gln) was recently identified as the etiology behind SWS and has also been found in a significant number of individuals with non-syndromic PWS.<sup>177–179</sup>

Patients with SWS have a PWS in a V1 distribution (Fig. 12-59) and may also have multidermatomal or more extensive cutaneous involvement. Overall it appears that around 8% of patients with a trigeminal PWS have associated glaucoma and/or seizures.<sup>180</sup> Involvement of the V1 dermatome seems to be consistent in all patients.<sup>176</sup> Involvement of the other trigeminal dermatomes may be useful in predicting the risk of SWS. In one study, involvement of V1, V2, and V3 was associated with an increased incidence of SWS, as was bilateral trigeminal involvement.<sup>176,180</sup> Another study comparing unilateral to bilateral facial PWS found a higher incidence of glaucoma and leptomeningeal angiomas with bilateral involvement and greater risk of CNS involvement when there was complete (vs. incomplete) involvement of V1.<sup>181</sup> Although the exact innervation of the lower eyelid is controversial (V1 vs. V2), it seems that involvement of both upper and lower eyelids portends a significantly higher risk of SWS.<sup>176,180</sup> When PWS lesions are unilateral, there is usually a sharp demarcation at the midline.

CNS disease is another component of SWS. Seizures are the most common CNS feature and often have their onset during the first year of life. The seizures of SWS may be difficult to control, and both

early onset and increased seizure intensity are associated with future developmental and cognitive delay.<sup>176,182,183</sup> Headaches (including migraines), stroke-like episodes, focal neurologic impairments, cognitive deficits, and emotional and behavioral problems including depression, violent behavior, and self-inflicted injury are also more common in SWS.<sup>176,184</sup> Low self-esteem is common in relation to the facial PWS.

Leptomeningeal angiogenesis is a classic component of the syndrome, and lesions are commonly ipsilateral to the cutaneous vascular stain. Cerebral atrophy is a common radiologic finding, as is enlargement of the choroid plexus and venous abnormalities. MRI is the modality of choice for identifying these changes, although CT scans are better at detecting the classic cortical calcifications, which are also seen.<sup>185</sup> These calcifications follow the convolutions of the cerebral cortex and are characterized by double-contoured parallel streaks of calcification ("tram lines"). Intracerebral calcifications may be visible during early infancy and can often help confirm the diagnosis before other characteristic features are present. Diffusion MRI, postcontrast fluid-attenuated inversion recovery (FLAIR) imaging, and high-resolution blood oxygen level-dependent (BOLD) magnetic resonance venography may be useful in the imaging of suspected SWS.<sup>184</sup> Electroencephalography (EEG) is a good option for assessing abnormal brain activity in young children and may be useful in identifying patients at risk for future neurologic symptoms. However, a concerning EEG should always be followed by appropriate radiographic imaging.<sup>186</sup>

Ocular involvement occurs in around 60% of patients with SWS.<sup>176</sup> Glaucoma is the most common ocular finding, and it may present at any time between birth and the fourth decade. It may be unilateral or bilateral, with the latter being more common in patients with bilateral facial PWS. Vascular malformations of the eye in patients with SWS may involve the conjunctiva, episclera, choroid, and retina.<sup>187</sup> Other eye findings include nevus of Ota, buphthalmos, and blindness.<sup>188</sup>

Care of the child with SWS should be multidisciplinary. Dermatologic, neurologic, and ophthalmologic follow-up care is indicated, and the primary care provider must provide anticipatory guidance and support. Other specialty services may become necessary, including plastic surgery, neurosurgery, interventional radiology, and physical and occupational therapy. Referral to support organizations is useful. The Sturge-Weber Foundation ([www.sturge-weber.org](http://www.sturge-weber.org)) provides education and support to individuals with this condition and other disorders associated with PWS.

The primary aim of treatment in SWS is the minimization or elimination of seizure activity. Although the primary management for seizures is with pharmacologic agents, surgical therapy may become necessary. Visually guided lobectomy with excision of the angiomatic cortex is considered the primary surgical approach in a patient with focal lesions.<sup>189</sup> Hemispherectomy is often advised for patients with intractable seizures and unihemispheric involvement. This radical therapy is often successful, with decreased seizure activity and in some patients, cognitive and behavioral improvement.<sup>190,191</sup> Presymptomatic therapy with low-dose aspirin has been advocated by some for young children before the onset of seizures or strokes in an effort to decrease the incidence of these complications.<sup>186,192</sup> The modified Atkins diet and ketogenic diet have been used in some patients to help control seizures.<sup>186,193</sup>

### Phakomatosis Pigmentovascularis

*Phakomatosis pigmentovascularis* (PPV) is a term used to describe the association of a nevus flammeus (PWS) with a pigmented nevus or in some cases, a nevus anemicus. PPV has traditionally been classified into four types. More recently, a fifth type of PPV has been proposed as the concomitant findings of cutis marmorata telangiectatica congenita (CMTC) and mongolian spots.<sup>194</sup> The classification of PPV is shown in Table 12-5, and the cause of this disorder remains unclear. Nevus anemicus is a distinct vascular birthmark characterized by blanching of cutaneous blood vessels, hence presenting as a "white" (actually vasoconstricted) patch of skin (Fig. 12-60) that becomes unnoticeable when the surrounding skin is blanched with a glass slide (diascopy). These lesions may occur as part of PPV (types II, III, and IV) but may also be seen as sporadic lesions.

The most common form of PPV is type II, consisting of nevus flammeus and dermal melanocytosis (i.e., mongolian spots, nevus of Ota)

**Table 12-5** Classification of Phakomatosis Pigmentovascularis

Type*	Findings
I	Nevus flammeus + epidermal nevus
II	Nevus flammeus + dermal melanocytosis ± nevus anemicus
III	Nevus flammeus + nevus spilus ± nevus anemicus
IV	Nevus flammeus + dermal melanocytosis + nevus spilus ± nevus anemicus
V	Cutis marmorata telangiectatica congenita + dermal melanocytosis

\*Further subdivided into: *a*, skin abnormalities only; *b*, skin abnormalities and systemic abnormalities.

**Figure 12-60** Nevus anemicus. Note the well-demarcated patch of hypovascular blanching on this infant's upper chest. This area became more prominent with crying, as during this photograph.

**Figure 12-61** Phakomatosis pigmentovascularis type II. This infant has port wine stains in combination with dermal melanocytosis (mongolian spot, nevus of Ito).

(Fig. 12-61). Without extracutaneous involvement, the subtype designation *a* is used (i.e., PPV type IIa). When systemic involvement is present, the subtype designation *b* is used (i.e., PPV type IIb). Systemic involvement usually consists of similar changes to those seen in SWS or Klippel-Trénaunay (KT) syndrome.<sup>195</sup> This involvement is usually related to the body surface area affected by the vascular lesion.<sup>196</sup> In one series, nevus of Ota was a common associated finding.<sup>197</sup> Neurologic involvement in PPV may include psychomotor retardation,

**Figure 12-62** Klippel-Trénaunay syndrome. Lower extremity port wine stain with mild hemihypertrophy.

**Figure 12-63** Klippel-Trénaunay syndrome. This patient has the characteristic triad, including port wine stain, hemihypertrophy, and venous varicosities. (Courtesy of Sarah Chamlin, MD.)

seizures, cerebral atrophy, and hydrocephalus, and ophthalmologic associations include conjunctival melanocytosis, episcleral vascular malformations, and glaucoma.<sup>198,199</sup>

Therapy for the cutaneous lesions of PPV is generally not necessary, although PDL treatment may be useful for the nevus flammeus. Lesions of dermal melanocytosis may or may not fade spontaneously with time.

#### Klippel-Trénaunay and Parkes Weber Syndromes

Klippel-Trénaunay (KT) syndrome is a sporadic disorder characterized by the triad of vascular malformation, venous varicosity, and hyperplasia of soft tissue and bone. The vascular malformation is most often a capillary malformation of the Parkes Weber Syndromes (PWS) type. The various lesions of KT syndrome are usually distributed on the same extremity, although other areas may be involved. The lower extremity is the most common location affected. When AVMs are also present, patients have been invariably referred to as having Klippel-Trénaunay–Weber (KTW) syndrome or Parkes Weber syndrome.<sup>200</sup>

Patients with KT syndrome exhibit a capillary malformation that may vary from fairly localized, faint lesions to extensive, bright red or purple stains (Figs. 12-62 and 12-63). These lesions are usually present at birth or become evident during early infancy. Prominent superficial veins may be present, and venous varicosities often develop with aging, being present in nearly all patients over 12 years of age.<sup>200</sup> These lesions may become quite large and tortuous and may predispose patients to episodes of thrombophlebitis. Hypertrophy of the affected body part is another component of the syndrome and usually presents with increased limb girth and length (Fig. 12-64). The majority of this hypertrophy is related to soft-tissue and fat overgrowth, although bony hypertrophy is also observed.<sup>200</sup> Although the cause of this overgrowth is unknown, local hyperemia and augmented arterial flow related to the vascular abnormalities are hypothesized etiologic factors. Digital anomalies may also be present in patients with KT syndrome and include macrodactyly, syndactyly, ectrodactyly, clinodactyly, and camptodactyly.<sup>201</sup>

Lymphatic disease seems to be more common than originally thought in patients with KT syndrome. This component may be manifested as lymphangiectasia, large LMs, lymphedema, vascular blebs (Fig. 12-65), and pseudoverrucous papules. Patients with sharply demarcated and “geographic” vascular stains may have an increased likelihood of lymphatic involvement.<sup>202</sup>

Complications of KT syndrome, in addition to occasional thrombo-phlebitis as mentioned previously, include coagulopathy, congestive heart failure (in the presence of hemodynamically significant AVM), pulmonary embolism, stasis dermatitis, cutaneous ulcerations, and bleeding. Vascular malformations may occasionally involve the GI tract, liver, spleen, genitourinary tract, and heart, and life-threatening GI bleeding has been reported.<sup>203</sup> Orthopedic difficulties related to the overgrowth include compensatory scoliosis and hip dislocation. Facial involvement may result in premature dental eruption, facial asymmetry, and malocclusion.<sup>204</sup> Pain is a potentially debilitating problem for patients with KT syndrome and may be related to multiple causes including superficial or deep thrombosis, cellulitis, calcifications, arthritis, and neuropathic origins.<sup>205</sup> Treatments for KT syndrome are primarily supportive and may include compression garments, chronic pain therapy, laser therapy for the cutaneous stain, and vascular/orthopedic surgical procedures as needed. The clearest indication for surgical therapy is leg-length discrepancy, which is projected to exceed 2 cm at skeletal maturity and which can be treated with epiphysiodesis in the growing child.<sup>206</sup> Physical and occupational therapy should be considered, and referral to the Klippel-Trénaunay Support Group ([www.k-t.org](http://www.k-t.org)) is strongly encouraged. In addition, there are a variety of resources available for individuals who require different shoe sizes (including [www.oddshoe.org](http://www.oddshoe.org), [www.oddshoefinder.com](http://www.oddshoefinder.com), and the National Shoe Retailers Association at [www.nsra.org](http://www.nsra.org)).

#### Proteus and CLOVES Syndromes

Proteus syndrome is a rare and sporadic disorder characterized by postnatal segmental overgrowth of multiple tissues. This overgrowth may involve the skin and subcutis, connective tissues, CNS, and

**Figure 12-64** Klippel–Trénaunay syndrome. This young girl has massive hemihypertrophy, and her vascular malformation reveals multiple small thromboses, which are often quite painful. (Courtesy of Annette Wagner, MD.)

**Figure 12-65** Klippel–Trénaunay syndrome with vascular blebs. Note the purple, translucent papules overlying the vascular stain on the lower extremity of this young boy.

viscera.<sup>207</sup> The involvement characteristically occurs in a patchy (mosaic or segmental) and asymmetric pattern. Proteus syndrome was named after the Greek god Proteus, who had the ability to assume various forms to avoid capture.<sup>208</sup> Joseph Merrick, whose life was characterized in the story *The Elephant Man*, is believed to have had Proteus syndrome, although he was originally thought to have had neurofibromatosis type 1. A mosaic activating mutation in *AKT1*, which encodes the AKT1 kinase, has recently been identified in several individuals with Proteus syndrome.<sup>209</sup> Previously some reports suggested a potential association with somatic mutations in the tumor suppressor gene *PTEN* (see Chapter 9), although some now designate this cohort as having the segmental overgrowth, lipomatosis, AVM, and epidermal nevus (SOLAMEN) syndrome.<sup>210</sup> It is possible that both of these disorders are part of a related family of disorders that involve dysfunction of the PI3K-AKT pathway.

Cutaneous manifestations of Proteus syndrome include connective tissue hamartomas that primarily involve the palms and soles and result in cerebriform hyperplasia (Fig. 12-66). Lipomas and extensive fatty hyperplasia may be found in the subcutaneous tissues as well as more diffusely, at times involving body cavities, muscles, and limbs, and regional absence of fat may also occur. Epidermal nevi are common. A variety of cutaneous and subcutaneous vascular malformations may occur, including capillary, venous, and LMs. Patchy hypoplasia of the dermis may occur, resulting in prominent cutaneous venous structures.<sup>211</sup>

**Figure 12-66** Proteus syndrome, cerebriform palmar hyperplasia.

**Figure 12-67** Proteus syndrome, macrodactyly. Note overgrowth of the second toe.

Other features of Proteus syndrome include disproportionate overgrowth that may involve the extremities, hands, feet, digits (macrodactyly, Fig. 12-67), skull (macrocephaly exostoses), vertebrae, external auditory meatus, and viscera.<sup>212</sup> Dysmorphic facial features are occasionally present and include dolichocephaly, elongated facies, low nasal bridge, downslanting palpebral fissures, and wide or anteverted nares. Adenomas of the ovaries or parotid glands may occur with increased incidence in patients with Proteus syndrome. Hemimegalencephaly is the most common CNS finding, and ocular manifestations may include strabismus, nystagmus, high myopia, cataracts, and retinal pigmentary abnormalities.<sup>213,214</sup>

Diagnostic criteria for Proteus syndrome, which include general/nonspecific criteria (mosaic distribution of lesions, sporadic occurrence, and progressive course) as well as multiple specific criteria, may be useful both clinically and in the research arena.<sup>215</sup> Evaluation and management of the patient with Proteus syndrome may include skeletal survey, MRI of clinically affected areas, and consultation with dermatology, genetics, and orthopedic specialists when necessary. Both the medical and emotional aspects of the disorder must be considered. Supportive counseling and referral to the Proteus Syndrome Foundation ([www.proteus-syndrome.org](http://www.proteus-syndrome.org)) are useful.

*CLOVES* syndrome refers to an overgrowth syndrome characterized by congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and scoliosis/skeletal and spinal anomalies. Originally termed *CLOVE syndrome* by Sapp et al., the suggestion for expanding the acronym to *CLOVES* was made by Alomari 1 year later based on observations of associated spinal and skeletal involvement.<sup>216,217</sup> Patients with this disorder are often born with lipomatous masses

involving the thoracic and abdominal regions among other areas. They may have slow-flow vascular malformations but may also have spinal or paraspinal fast-flow lesions consistent with AVMs, and these lesions may result in spinal-cord injury including myelopathy.<sup>218</sup> Musculoskeletal defects often involve the hands and feet but may also include scoliosis, spina bifida, vertebral anomalies, congenital hip dysplasia, pectus excavatum, and rib defects. Neurologic manifestations may include tethering of the spinal cord, spasticity, paresis, and neural tube defects.<sup>219</sup> Although there is some significant overlap in the clinical features of CLOVES and Proteus syndromes, there are several distinguishing features, including the lack of cerebriform connective tissue hamartomas of the palms and soles, the progressive enlargement (and recurrence after resection) of the lipomatous masses, and the presence of paraspinal high-flow vascular lesions seen in the patients with CLOVES syndrome.<sup>219</sup> CLOVES syndrome has been ascribed to postzygotic mutations in PIK3CA, a gene involved in the PI3K-AKT growth-signaling pathway. Various segmental overgrowth disorders have been described in association with mutations in this gene and have been termed *PIK3CA-related overgrowth spectrum*.<sup>220</sup>

### **Macrocephaly-Capillary Malformation Syndrome**

The combination of CMTC-type skin changes and macrocephaly, occurring along with other findings such as abnormal somatic growth, craniofacial and skeletal anomalies, developmental delay, neurologic abnormalities with abnormal findings on neuroimaging, mental retardation, and connective tissue abnormalities, was originally termed *macrocephaly-CMTC*.<sup>221,222</sup> Subsequently, however, it was suggested that the vascular lesions seen in this setting are more consistent with reticulate PWSs and that this constellation is more appropriately termed *macrocephaly-capillary malformation (M-CM) syndrome*.<sup>223,224</sup> Centrofacial capillary malformations seem to be common in patients with this syndrome and most notably involve the nose, glabella, and philtrum.<sup>223,224</sup> The most common findings on neuroimaging include ventriculomegaly, cavum septum pellucidum, cerebellar tonsillar herniation, megalecephaly, and cerebral and/or cerebellar asymmetry.<sup>225,226</sup>

### **Capillary Malformation-Arteriovenous Malformation Syndrome**

Capillary malformations occurring in a familial fashion were demonstrated to be associated with the *CMC1* locus on chromosome 5q in 2002 and subsequently shown to be associated with inactivating mutations in the gene *RASA1*.<sup>227,228</sup> These individuals were also shown to have a predisposition toward the development of AVMs (see *Arteriovenous Malformation* section), AV fistulae, or Parkes Weber syndrome, and this autosomal dominant disorder was subsequently named *capillary malformation-arteriovenous malformation (CM-AVM) syndrome*. The hallmark skin lesions are capillary malformations that are typically multiple (Fig. 12-68); occur in a haphazard distribution; may reveal pink, red, brown or gray coloration; and occasionally have an associated white halo.<sup>229,230</sup> They are often present at birth but may continue to develop during childhood, a key feature that should suggest the need to consider this diagnosis.

The AVMs in CM-AVM syndrome may be cutaneous, subcutaneous, intramuscular, intraosseous, or cerebral, and arteriovenous fistulae (AVFs) may also be present. Occasionally one patient may have two or more AVMs or AVFs. Aneurysmal malformation of the vein of Galen has been described.<sup>230</sup> Spinal AVMs or AVFs have more recently been recognized in association with CM-AVM syndrome and *RASA1* mutation,<sup>231</sup> highlighting the importance of both brain and spine imaging (as well as mutation analysis) for patients in whom the disorder is suspected.<sup>232</sup>

### **Bannayan–Riley–Ruvalcaba Syndrome**

Bannayan–Riley–Ruvalcaba syndrome (BRRS) is an autosomal dominant, multiple hamartoma syndrome caused by mutations in the *PTEN* gene. This syndrome is one of the so-called *PTEN hamartoma tumor syndromes*, which also include Cowden syndrome (see Chapter 9), Lhermitte–Duclos syndrome, and some cases of Proteus syndrome. The hallmarks of BRRS are macrocephaly, lipomas, penile lentigines (involving the glans penis), developmental delay, and vascular malformations. The latter have been inconsistently described in the literature

as “hemangiomas” or “angiomas” but are actually vascular malformations usually of the capillary type. AVM has also been described in patients with BRSS.<sup>233</sup> Cowden syndrome and BRSS are considered allelic disorders and share several clinical features, possibly including the predisposition to malignant tumors known to exist in the former.<sup>234,235</sup> Some consider these two disorders to be one condition with variable expression and age-related penetrance.

### **Cobb Syndrome**

Cobb syndrome (cutaneomeningospinal angiomyomatosis) consists of the association of a cutaneous vascular malformation with a vascular malformation (often an AVM) involving the same metamere of the spinal cord. The cutaneous and spinal-cord lesions usually correspond within a segment or two of the involved dermatome.<sup>236</sup> The skin lesions present as a dermatomal capillary malformation with or without a deeper vascular component and occasionally with hyperkeratosis of the surface suggestive of an angiokeratoma. The importance of recognizing this cutaneous lesion lies in the resultant ability to image the spine and refer a patient for neurosurgical therapy before symptoms ensue. Neurologic symptoms related to the spinal-cord vascular malformation may include root pain, motor dysfunction, paresthesias, and spastic paralysis.<sup>236,237</sup>

Evaluation of the patient with a dermatomal capillary malformation should include MRI of the corresponding region of the spinal cord with consideration for spinal angiography. Treatment options may include surgery (when feasible), endovascular embolization, radiation, and steroid therapy, and the goal of therapy is to minimize neurologic sequelae by reducing mass effect, venous hypertension, and vascular steal.<sup>238</sup>

### **Beckwith–Wiedemann Syndrome**

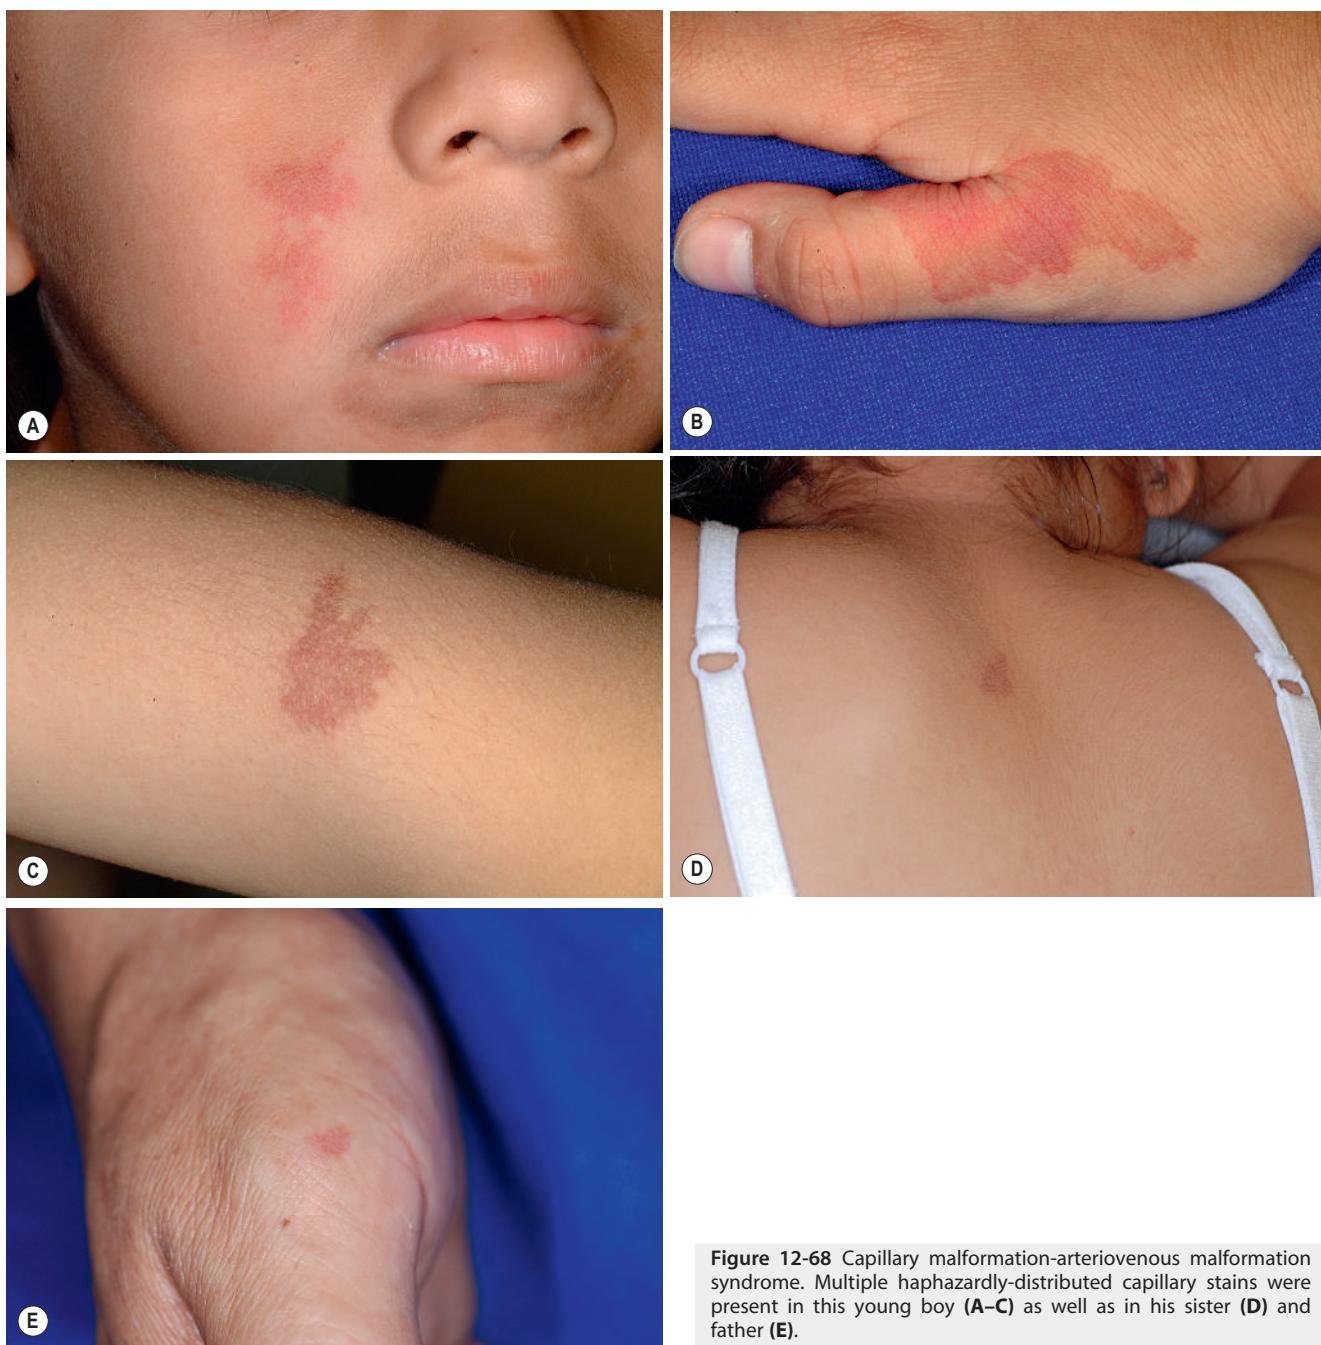

Beckwith–Wiedemann syndrome (BWS) is a genetic overgrowth syndrome characterized most classically by visceromegaly, macroglossia, various developmental defects, and neonatal hypoglycemia. It is the most common of the overgrowth syndromes.<sup>239</sup> BWS is a multigenic disorder with dysregulation of the expression of imprinted genes residing in the 11p15.5 region.<sup>240</sup> The inclusion of BWS in this section relates to the common occurrence of a facial capillary malformation involving the midforehead, glabella, and upper eyelids. This malformation may extend to involve the nose and upper lip in some patients.

Clinical features of BWS, which are variable, include omphalocele, macrosomia, and macroglossia. Overgrowth may be generalized or limited to specific body regions and may be associated with an advanced bone age. In addition to omphalocele, other abdominal-wall defects include umbilical hernia, prune-belly sequence, and inguinal hernia. Visceromegaly may involve the kidneys, liver, spleen, and pancreas. Hypoglycemia is the most common laboratory finding and tends to regress during early infancy. Patients with BWS have an increased risk of malignant tumors including Wilms tumor, adrenocortical carcinoma, and hepatoblastoma.<sup>241</sup> Perinatal features include prematurity, polyhydramnios, enlarged placenta, distended abdomen, and large fetal size.<sup>239</sup> Prenatal ultrasound may be useful in detecting the latter four features, enabling an early diagnosis of the syndrome.<sup>239</sup>

## **VENOUS MALFORMATION**

Venous malformation (VM) is a fairly common slow-flow type of vascular malformation present at birth. Various inaccurate names have been used to describe these lesions in the literature, including *venous angioma*, *cavernous angioma*, and *cavernous hemangioma*. It should be remembered that VM, like all vascular malformations, is a nonproliferative collection of abnormal vessels distinct from IH and other proliferative vascular tumors. They usually grow with the child. Although these lesions are present at birth, they occasionally may not become obvious until later in life. In addition, VM may rapidly enlarge after trauma, and occasionally this may be the initial presentation.

VM tends to present as blue to purple nodules in the skin (Fig. 12-69). Surrounding veins maybe prominent, and calcified phleboliths may be present within the lesion. These are the result of spontaneous local venous thrombosis within the malformation. Most VMs are asymptomatic, although they may occasionally become painful in association with their gradual enlargement and pressure on

**Figure 12-68** Capillary malformation-arteriovenous malformation syndrome. Multiple haphazardly-distributed capillary stains were present in this young boy (**A-C**) as well as in his sister (**D**) and father (**E**).

surrounding structures. Although most VMs are isolated, they may occur in association with other syndromic features such as in Maffucci syndrome and blue rubber bleb nevus syndrome (BRBNS) (see below). VM can occur in any body location, although head and neck lesions tend to be the most extensive.<sup>242</sup>

The diagnosis of VM can be confirmed with CT, MRI (with or without venography), or Doppler ultrasonography. Plain radiographs may reveal the calcifications associated with phleboliths (which present as painful, firm nodules). Other complications of VM (in addition to thromboses) include disfigurement with psychosocial distress (Fig. 12-70), pain, limitation of motion, bleeding coagulopathy (usually localized intravascular coagulopathy [LIC]), and functional compromise related to location of the lesion. LIC typically presents with pain, elevation of the D-dimer and variable fibrinogen levels.<sup>243</sup> Treatment for VM is difficult and may include compression with elastic stockings (which helps to limit swelling, decrease pain, and decrease the risk of coagulopathy in extremity lesions), surgery,

physical therapy, and percutaneous sclerotherapy. Low-dose aspirin therapy or low molecular-weight heparin may be useful in patients prone to thrombotic changes/LIC within the lesions. A multidisciplinary approach to therapy is desirable, with the goals of improving cosmesis, decreasing pain, limiting bony deformities, and maintaining function.

#### Maffucci Syndrome

Maffucci syndrome is a rare, congenital, nonhereditary disorder characterized by the combination of dyschondroplasia and vascular malformations. The cutaneous lesions in this disorder are compressible, red-blue papules and nodules most consistent with VMs. They may develop thrombi and phleboliths, with the associated calcifications visible on plain radiography.<sup>244</sup> These vascular malformations may occur anywhere on the skin surface but are often more extensive on one side of the body and have a preference for the hands and feet.<sup>245</sup> In addition to these lesions, LM<sup>246</sup> and spindle-cell

**Figure 12-69** Venous malformation. Note venous prominence of the medial and plantar surfaces and the swelling of the dorsal foot.

**Figure 12-71** Blue rubber bleb nevus syndrome. This patient has multiple blue-purple, compressible papules and papulonodules.

**Figure 12-70** Venous malformation. This blue nodular plaque involved the right medial cheek and lateral nose, and became more disfiguring as this young boy grew older, posing a psychosocial concern.

hemangioendothelioma<sup>247</sup> (a proliferative vascular tumor) are occasionally present. The vascular malformations of Maffucci syndrome may involve extracutaneous sites in some patients, including mucosal regions, bones, the respiratory tract, and the GI tract.

In addition to the vascular malformations, patients with Maffucci syndrome have enchondromas, which are the result of a developmental abnormality in cartilage formation (dyschondroplasia). These lesions start to develop during early infancy in conjunction with the vascular anomalies. They present as hard nodules over areas of long bones, hands, fingers, and feet. Occasionally they may enlarge and become so numerous as to result in grotesque deformity. Radiographically, enchondromas appear as irregular cystic lucencies. Other progressive skeletal abnormalities (marked bony deformities, pathologic fractures) may occur, as may neurologic deficits related to cerebral encroachment of skull enchondromas.

A significant risk in patients with Maffucci syndrome is that of malignancy, especially chondrosarcoma, which tends to arise from preexisting enchondroma lesions (up to 40% of which may transform into chondrosarcomas).<sup>248</sup> Other malignancies may also occur with increased incidence in these patients. Intracranial chondrosarcoma may rarely occur.<sup>249</sup> Maffucci syndrome has been shown to be caused by somatic mosaic mutations of *IDH1* and *IDH2*.<sup>250</sup>

#### Blue Rubber Bleb Nevus Syndrome

Blue rubber bleb nevus syndrome (BRBNS; also called *Bean syndrome*) is a rare disorder characterized by the presence of cutaneous and GI

VMs. Other visceral organs may occasionally be involved. Although usually a sporadic disorder, autosomal dominant inheritance has been reported.<sup>251</sup>

Patients with BRBNS have signs at birth or during early childhood of numerous blue to purple, soft, compressible nodules (Fig. 12-71). The lesions range in size from a few millimeters to 4 cm. Any area of the skin may be involved, as well as mucosal surfaces of the mouth and genitalia. With time, the lesions increase in both size and number. One of the diagnostic features is the ability to compress the nodules, leaving an empty wrinkled sac that then refills rapidly upon withdrawal of the pressure. GI involvement is characterized by hematemesis or melena with chronic anemia. The small bowel is the most common site of GI tract involvement, but lesions can occur anywhere from the mouth to the anus.<sup>251</sup> Blood loss may at times be severe, necessitating transfusion, and intestinal intussusception may occur.<sup>252</sup> Various orthopedic complications owing to adjacent VMs may occur and include bowing and pathologic fractures. CNS involvement with vascular malformations may also be a component of the syndrome.<sup>253,254</sup>

BRBNS may be diagnosed based on the clinical presentation, although other diagnostic studies may be necessary and may include CT, MRI, barium studies, skin biopsy, and upper and lower GI tract endoscopy. Capsule endoscopy and intraoperative enteroscopy have been reported as useful for thorough investigation of the small bowel.<sup>255</sup> Treatment of the condition is primarily supportive and may include iron replacement, transfusions, endoscopic sclerotherapy, band ligation or laser photocoagulation, and resection of severely involved portions of the GI tract. The response to pharmacologic agents is variable. Subcutaneous octreotide, a somatostatin analog used to decrease splanchnic blood flow in patients with GI bleeding, may be useful in decreasing the need for blood transfusion.<sup>256</sup> Other reported agents include corticosteroids, interferon  $\alpha$ , and vincristine.<sup>257</sup>

#### ARTERIOVENOUS MALFORMATION

Arteriovenous malformations (AVMs) are rare fast-flow vascular malformations consisting of both arterial and venous components with AV shunting. These lesions may vary in their clinical presentation, from macular erythema to thin vascular plaques to larger pulsating nodules or masses with an audible bruit. They typically range from stage I (pink patches or macules that may mimic a capillary malformation) to stage IV (larger lesions characterized by the presence of cardiac compromise). A bruit may be appreciated upon auscultation or with bedside Doppler ultrasonography and supports the diagnosis. AVMs may display aggressive growth patterns and result in functional or cosmetic deformity and in some patients, cardiovascular compromise related to increased blood flow. They are the most endangering type of vascular anomaly. Potential associations with AVMs include CM-AVM syndrome, Parkes Weber syndrome, Cobb syndrome, and

**Figure 12-72** Macrocytic lymphatic malformation.

hereditary hemorrhagic telangiectasia (HHT) (all are discussed elsewhere in this chapter). Diagnostic confirmation of an AVM may involve ultrasound with color Doppler study, CT or MRI evaluation, or arteriography. Treatment is notoriously challenging and includes surgical excision, embolization, and amputation. Multidisciplinary management is advisable when available.

## Disorders of Lymphatic Vessels

The lymphatic system is a complex network of thin-walled vessels responsible for carrying tissue fluid to the venous system.<sup>258</sup> Anomalies of the lymphatic system may include lymphedema and LMs. Lymphedema occurs as a result of aplasia or hypoplasia of lymphatic channels or obstruction of lymphatic pathways. LMs are slow-flow malformations that occur as a result of hyperplasia of the lymphatic network. Older terminologies for LMs are common in the literature, including *lymphangioma*, *cavernous lymphangioma*, *lymphangioma circumscriptum*, and *cystic hygroma*. These malformations are probably best described in accordance with the modern classification as LMs and further classified as macrocytic, microcystic, or combined.

LMs are composed of interconnected lymphatic channels and present differently depending on the size of these aberrant vessels. LMs may remain undiagnosed for years and may initially present after trauma with resultant enlargement, hemorrhage, or secondary infection.

Macrocytic LMs are composed of large interconnected lymphatic channels and cysts. They have been most commonly referred to as *cystic hygromas* or *cavernous lymphangiomas* in the literature. They may occur in any location, although the head, neck, axilla, and chest are the most common sites. Although macrocytic LM was once considered a diagnostic sign of Turner syndrome, it is now known that these lesions may be associated with other karyotypic abnormalities and malformation syndromes.<sup>258</sup> Other potential associations include Down syndrome, trisomy 18, trisomy 13, and Noonan syndrome. Teratogens may also be associated with macrocytic LM. These lesions are typically present at birth, and may be recognized antenatally on prenatal ultrasound.<sup>259</sup>

Macrocytic LM presents as a large, somewhat translucent mass lying under normal-appearing skin (Fig. 12-72). It enhances with transillumination. Acute hemorrhage within an LM may result in swelling, tenderness, and purple discoloration. Diagnostic confirmation can be made with ultrasound, CT, or MRI examination. Prenatal and neonatal complications include lymphedema, facial deformity, and effusions (pleural, pericardial, abdominal). Hydrops fetalis, heart failure, respiratory compromise, and intrauterine demise may occasionally occur. Treatment options for macrocytic LM include surgical excision; serial aspirations; and sclerosing therapy with bleomycin, OK-432 (Picibanil), ethanol, sodium tetradecyl sulfate (STS) or doxycycline.<sup>259–263</sup> Oral sildenafil, which selectively inhibits phosphodiesterase-5 and is normally utilized for pulmonary hyper-

**Figure 12-73** Microcystic lymphatic malformation. Note the multiple flesh-colored, translucent papules with hemorrhagic changes in some of the lesions.

**Figure 12-74** Combined microcystic/macrocytic lymphatic malformation with hemorrhage. There are numerous surface blebs (microcystic component), many of which reveal hemorrhage. This young boy also had a large underlying macrocytic lymphatic malformation. Note the surgical scars from past excisions.

tension and erectile dysfunction, resulted in marked reduction in size in three young children with large LMs and is being further studied.<sup>264</sup>

Microcystic LMs are a more common form of LM, representing microscopic aggregations of small lymphatic channels. These lesions usually present as cutaneous plaques or nodules with superimposed changes in the overlying skin. These surface changes consist of erythematous to flesh-colored papules that may be somewhat translucent (Fig. 12-73), accounting for the traditional analogy with frog spawn. The differential diagnosis of the superficial component of microcystic LM may include warts, molluscum contagiosum, herpes simplex, herpes zoster, and epidermal nevus. Perianal lesions may be misdiagnosed as anogenital condylomata.<sup>265</sup> Hemorrhage may occur within the superficial component (Fig. 12-74), and intermittent swelling or bruising may be a feature. Other complications include intermittent leakage of lymph fluid, inflammation, and secondary infection.

Microcystic LMs often present during infancy and may involve any area of the skin or mucosa. Oral lesions are quite common, most often involving the tongue (Fig. 12-75) or cheek. Microcystic LM is often (but not always) treatable by surgical excision.

## LYMPHEDEMA

*Lymphedema* refers to a set of conditions characterized by interstitial accumulation of lymphatic fluid and may be primary or secondary

**Figure 12-75** Microcystic lymphatic malformation of the tongue. This boy has extensive involvement of his tongue with translucent papules, several of which reveal hemorrhage. The white color of some lesions relates to maceration from the moist environment of the mouth.

**Figure 12-76** Congenital lymphedema. Note the fullness of the dorsal aspect of the foot in this infant male.

**Table 12-6** Classification of Lymphedema

Type	Comment
<b>PRIMARY</b>	
Congenital lymphedema	Single extremity or multiple limbs
Lymphedema praecox	Pubertal or postpubertal females
Lymphedema tarda	Usually after 35 years of age
Milroy disease	AD form of congenital familial lymphedema; linked most commonly to mutations in <i>FLT4</i> gene ( <i>VEGFR3</i> )
Lymphedema-distichiasis	AD; lymphedema in association with distichiasis (supplementary row of eyelashes); linked to mutations in <i>FOXC2</i> gene
Hypotrichosis-lymphedema-telangiectasia	AD; linked to mutation in <i>SOX18</i> gene
<b>SECONDARY</b>	
<b>Lymphedema Occurring after Disruption of Lymphatic Pathways by:</b>	
Disease	Filariasis
Surgery	Lymph node dissection
Radiation therapy	
Burns	
Pregnancy	
Large/circumferential wounds to the extremity	

Modified from Rockson SG. Lymphedema. Am J Med 2001;110(4):288–95, Rockson SG. Diagnosis and management of lymphatic vascular disease. J Am Coll Cardiol 2008;52:799–806, and Murdaca G, Cagnati P, Gulli R, et al. Current views on diagnostic approach and treatment of lymphedema. Am J Med 2012;125:134–40.

AD, Autosomal dominant.

(Table 12-6). Primary lymphedema is related to anatomic abnormalities in the lymphatic system, which may include hypoplasia of vessels, absence of lymphatic valves, and/or impaired contractility of the structures. Secondary lymphedema, which results in disruption or obstruction of lymphatic pathways, arises as a consequence of disease, surgery, or radiotherapy.<sup>266,267</sup> Primary lymphedema most often involves the lower extremities, whereas upper-extremity involvement is more common in secondary lymphedema.

Lymphedema presents as edema of the affected extremity. Early in the course the involved region is puffy (Fig. 12-76), whereas later in

**Figure 12-77** Lymphedema. This 10-year-old girl had long-standing, nonpitting edema of her feet bilaterally.

the course the area becomes more fibrotic and indurated. Secondary cutaneous changes may be present, including a “peau d’orange” appearance of the overlying skin, pigmentary changes, and recurrent episodes of cellulitis. When a lower extremity is involved, swelling of the dorsal aspect of the foot (Fig. 12-77) is common with a characteristic blunt, “squared off” appearance of the digits.<sup>266</sup> The staging system for lymphedema includes stages 0 or Ia (subclinical state without appreciable swelling) through III (lymphostatic elephantiasis with or without pitting and with trophic skin changes including acanthosis, deposition of fat and fibrosis, and warty overgrowths).<sup>268</sup>

Congenital lymphedema may involve a single extremity (upper or lower) or multiple limbs, and the changes are present at birth. Lymphedema praecox, which usually occurs in females around the time of puberty, presents as edema of the foot or ankle or rarely with upper extremity involvement.<sup>269</sup> Milroy disease is an inherited form of lymphedema, usually occurring with an autosomal dominant pattern of transmission, most commonly resulting from mutations in *FLT4/VEGFR3* (see Table 12-6). Limb swelling in all extremities is

possible, although bilateral lower-extremity lymphedema is most typical.<sup>270</sup>

The diagnosis of lymphedema is usually a clinical one. Useful findings include edema, fibrosis, *peau d'orange* appearance of the skin, and a positive Stemmer sign (inability of the examiner to tent the skin at the base of the digits in the involved extremity).<sup>267</sup> In cases where further diagnostic confirmation is necessary, available options include indirect radionuclide lymphoscintigraphy, lymphangiography, MRI or CT imaging, and Doppler ultrasonography. Therapy for lymphedema includes massage (manual lymphatic drainage), elevation, compression garments, physical therapy/exercise, and meticulous skin care in an effort to prevent skin breakdown and infection. Intermittent pneumatic compression may be useful. Surgical approaches are reserved for patients with severe disease who have failed conservative measures and include excision of lymphedematous tissues, use of a lymphatic collector or interposition vein segment to restore lymphatic continuity, or lymphaticovenous anastomoses. Pharmacologic therapy is of limited use but may include diuretics, benzopyrones (including rutosides and bioflavonoids), and antimicrobial agents (as needed).

### GORHAM SYNDROME

Gorham syndrome (Gorham–Stout disease, disappearing bones, vanishing bone disease, massive osteolysis) is a rare condition of unknown origin characterized by progressive bony destruction with intramedullary proliferation of thin-walled vascular structures. Many affected patients have cutaneous vascular lesions as well. Although there is no consensus on the nature of these vascular elements, several authors have proposed that they represent lymphatic vessels.

Patients with Gorham syndrome are usually children or young adults, and they show pathologic fractures and/or bone pain. Nearly any bone may be involved, but most common are the ribs, scapula, clavicle, humerus, pelvis, spine, femur, skull, and mandible.<sup>271,272</sup> It may occur in a focal fashion with spread to contiguous bony structures and occasionally with multicentric, widespread involvement. Nonskeletal manifestations include respiratory distress, pleural effusions, ascites, and chylothorax. Chylothorax is an uncommon but often fatal complication of Gorham syndrome and may be associated with malnutrition, lymphocytopenia, and infection.<sup>271</sup> The diagnosis of Gorham syndrome is confirmed by the finding of osteolytic changes on radiography without reparative bone formation and in the absence of soft-tissue mass and by histologic evaluation of biopsied material.<sup>273</sup>

The natural history of Gorham syndrome is variable, and therapy is difficult. Surgical resection, bone grafting, fractionated radiation therapy, and chemotherapy have all been used with variable results.

### MULTIFOCAL LYMPHANGIOENDOTHELIOMATOSIS WITH THROMBOCYTOPENIA

Multifocal lymphangioendotheliomatosis with thrombocytopenia (MLT; also known as *cutaneovisceral angiomyomatosis with thrombocytopenia*) is a condition characterized by multifocal, congenital, and progressive vascular papules and nodules involving the skin and GI tract in association with severe GI bleeding and thrombocytopenic coagulopathy.<sup>274</sup> Histologically these vascular lesions reveal collections of ectatic, thin-walled vessels lined by hobnailed endothelial cells and express markers such as CD31 and LYVE-1, which suggest they are consistent with lymphatic differentiation.

Clinically MLT presents with multiple vascular lesions that are red to brown to purple macules (Fig. 12-78), papules, and nodules varying in size from a few millimeters to several centimeters. They may number in the hundreds, may have a scaly surface, and may be indurated, suggesting deeper dermal or subcutaneous involvement. GI tract bleeding may be severe, and endoscopy reveals diffusely distributed mucosal vascular lesions in the stomach and the small and large intestines. Thrombocytopenia is usually present with normal to slightly elevated coagulation studies (prothrombin and partial thromboplastin times) and variable values for fibrinogen and D-dimer in patients reported to date. Other organs of potential involvement include the lungs, synovium, muscle, bone, eye, bone marrow, spleen, and brain.

Treatment for MLT is challenging, and therapies reported to date (with variable response) have included corticosteroids, interferon  $\alpha$ ,

**Figure 12-78** Multifocal lymphangioendotheliomatosis with thrombocytopenia. This neonate had multiple cutaneous vascular macules as well as multiple GI lesions with severe bleeding and thrombocytopenia. (Courtesy of Beth A. Drolet, MD.)

**Figure 12-79** Angiokeratoma. This was an isolated lesion in an otherwise-healthy 14-year-old female.

blood-product transfusions, octreotide, aminocaproic acid, thalidomide, propranolol, intravenous immunoglobulin, bevacizumab, suture ligation of GI tract lesions, and colectomy.<sup>274–277</sup>

### ANGIOKERATOMAS

Angiokeratomas are skin lesions characterized by ectasia (dilation) of the superficial vessels of the dermis and hyperkeratosis of the overlying epidermis. They present as hyperkeratotic, dark red to purple or black papules (Fig. 12-79) measuring between 1 mm and 10 mm in diameter. Several types of angiokeratoma are recognized, and although these lesions usually occur sporadically, they may occasionally be associated with potentially serious metabolic disease.

#### Solitary or Multiple Angiokeratomas

These usually occur on the lower extremities of young adults. They are blue to black in color and may sometimes be confused with malignant melanoma. These lesions may be related to preceding trauma or injury.

### Angiokeratoma Circumscriptum

This presents as a plaque composed of multiple, clustered red to purple papules. These lesions may be present at birth or develop during childhood.

### Angiokeratoma of Mibelli

This occurs on the dorsal fingers or toes or in interdigital spaces. These lesions appear during childhood or adolescence, are more common in females, and are inherited in an autosomal dominant fashion.

### Angiokeratoma of Fordyce

This is a condition that presents with numerous red to purple papules on the scrotum or vulva of adults. Scrotal lesions may be seen in association with varicocele or inguinal hernia.

Although these forms of angiokeratoma occur in the absence of associated serious abnormalities, the lesions may occasionally be seen in the setting of potentially serious metabolic disorders.

### Angiokeratoma Corporis Diffusum

Angiokeratoma corporis diffusum (ACD) is the name used to describe lesions that present as numerous dark red to black papules distributed primarily on the abdomen (Fig. 12-80), genitals, buttocks, and thighs ("bathing-trunk" distribution). The most common disorder associated with ACD is Fabry disease (FD; also known as *Anderson–Fabry disease*), a rare X-linked recessive disorder caused by deficient  $\alpha$ -galactosidase A. The genetic cause is a mutation in the *GLA* gene (encoding  $\alpha$ -galactosidase A), most often point mutations but occasionally small and large deletions or insertions.<sup>278</sup> Males with FD have an accumulation of glycosphingolipids, which results in dysfunction of the heart, kidneys, and nervous system. Acral paresthesias and acral and/or abdominal pain occur, often within the first decade of life, and may respond to treatment with carbamazepine. Other findings in FD include corneal and lenticular opacities, hypohidrosis, progressive neuropathy, progressive renal and heart failure, and cerebral artery thrombosis.<sup>279</sup> The angiokeratomas of FD may number in the thousands and tend to cluster in the iliosacral areas, on the scrotum, and around the umbilicus. The first lesions commonly appear on the scrotum and must be differentiated from angiokeratoma of Fordyce. A majority of patients have pinpoint macular purplish spots on the lips, particularly near the vermillion border of the lower lip. These lesions are smaller than those on the skin. The tongue is generally not affected, but hemoptysis and epistaxis have been reported with involvement of the buccal and nasal mucosae. In addition to the typical cutaneous lesions, fine telangiectasias have been described in the axillae and on the upper chest. Enzyme replacement therapy (ERT) with recombinant  $\alpha$ -galactosidase A (available as agalsidase  $\alpha$  and agalsidase  $\beta$ ) is available for treatment of FD, although it may not lead to complete resolution of symptoms in all patients. When started early

in life, however, ERT may halt and even reverse the progressive multi-organ deterioration seen in patients with FD and improve quality of life.<sup>280,281</sup>

There are other inherited lysosomal storage diseases that may have associated angiokeratomas of the skin. Fucosidosis is an autosomal recessive lysosomal storage disease in which deficiency of  $\alpha$ -fucosidase results in multisystem accumulation of oligosaccharides and glycosphingolipids.<sup>282</sup> This disorder is characterized by progressive neuromotor deterioration, seizures, coarse facial features, dysostosis multiplex, visceromegaly, and growth retardation. Recurrent respiratory infections may also occur. The predominant cutaneous feature of fucosidosis is ACD, which may resemble that seen in FD. In distinction to the lesions of FD, however, the angiokeratomas associated with fucosidosis tend to occur earlier in life, usually around 5 years of age and display a more generalized distribution. Other dermatologic features reported in fucosidosis include hypohidrosis or hyperhidrosis, cutaneous vascular abnormalities, and transverse nail bands.<sup>282</sup> Fucosidosis is caused by a mutation in the *FUCA1* gene.

Other metabolic disorders that may be associated with ACD include GM1 gangliosidosis, galactosialidosis,  $\beta$ -mannosidosis, sialidosis, Schindler disease type II and aspartylglycosaminuria. All of these conditions are inherited in an autosomal recessive fashion, and the diagnosis is made by urine oligosaccharide analysis or enzyme assay.

## Disorders Associated with Vascular Dilation

### LIVEDO RETICULARIS

Livedo reticularis is a mottled or reticulated, blue-red discoloration of the skin that occurs predominantly on the lower extremities (Fig. 12-81) and less commonly on the trunk or upper extremities. Ulceration may occasionally occur. Although the pathogenesis of livedo reticularis is unclear, the changes seem to be related to slow blood flow and decreased oxygen tension. Exposure to cold environments usually intensifies this vascular pattern. The distinction between livedo reticularis and cutis marmorata may be clinically difficult, although cutis marmorata tends to disappear with rewarming and may be seen as a normal finding in up to 50% of infants.

The significance of livedo reticularis lies in its possible association with a variety of systemic disorders (Box 12-5; see Chapter 22). Associated disorders may include coagulopathies, autoimmune diseases (including systemic lupus erythematosus, dermatomyositis, rheumatoid arthritis, and scleroderma), systemic vasculitides (including polyarteritis nodosa, granulomatosis with polyangiitis (formerly Wegener granulomatosis), and Churg–Strauss syndrome), arterial occlusive disease, and antiphospholipid antibody syndrome. Sneddon syndrome is characterized by the association of livedo reticularis and cerebral ischemic arterial events such as stroke or transient ischemic attack.<sup>283,284</sup> These patients may have associated antiphospholipid

**Figure 12-80** Angiokeratoma corporis diffusum in Fabry disease. This 19-year-old male had multiple lesions involving the trunk, groin, and thighs.

**Figure 12-81** Livedo reticularis.

### Box 12-5 Associations with Livedo Reticularis

- Autoimmune diseases
- Coagulation disorders
- Hematologic aberration or malignancy
- Hormone-secreting tumors
- Arterial occlusive diseases
- Sneddon syndrome (cerebral ischemic arterial disease)
- Antiphospholipid antibody syndrome
- Systemic vasculitis
- Paraproteinemia
- Drugs

antibodies. Moyamoya disease, a rare chronic cerebrovascular occlusive disease involving the circle of Willis, has also been reported in conjunction with cutaneous livedo reticularis in a child.<sup>285</sup> In rare instances, recurrent small ulcerations may develop on the lower legs and feet in adults with idiopathic livedo reticularis and has been termed *livedo vasculitis* or *livedoid vasculitis*. Mild hypertension and edema of the legs, ankles, and feet may occur in this setting. A variant of this disorder (atrophie blanche) is characterized by white atrophic areas, hyperpigmentation, and ulceration with telangiectatic vessels at their periphery. Atrophie blanche usually occurs on the ankles and dorsal feet in young to middle-aged women but may also occasionally occur in children.

Although there is no specific treatment for livedo reticularis, therapeutic options include avoidance of cold, anticoagulant therapy (especially for patients with ulceration), and treatment of the underlying associated condition.

### FLUSHING AND THE AURICULOTEMPORAL NERVE SYNDROME

Flushing, a transient diffuse erythema of the blush areas (the face, neck, and/or adjacent trunk), is caused by dilation of superficial cutaneous blood vessels mediated by neural mechanisms or the direct action of a vasodilator substance on vascular smooth muscles. Flushing can be caused by emotion; the ingestion of alcoholic or hot beverages; food additives such as sulfites, nitrites, and monosodium glutamate (MSG) in what has been termed the "Chinese restaurant syndrome"; calcium channel blockers such as nifedipine; disulfiram (Antabuse); carcinoid syndrome (a disorder caused by a neoplasm that produces large amounts of serotonin and bradykinin); and other tumors that produce catecholamines such as neuroblastoma, renal-cell carcinoma, or ganglioneuroma.

The auriculotemporal nerve (Frey) syndrome is a phenomenon characterized by unilateral (rarely bilateral) flushing, sweating, or both in the distribution of the auriculotemporal nerve. These changes usually occur in response to gustatory or olfactory stimuli. Frey syndrome is believed to be related to increased irritability of the cholinergic fibers and possibly to misdirected regeneration of fibers during the healing that comes after trauma. It may result after parotid surgery, CNS disease (cerebellopontine angle tumors), cervical sympathectomy, and radical neck dissection.<sup>286</sup> When it occurs in one of these settings, it is usually in an adult.

Frey syndrome in infants and children is less common and is most often noted after the introduction of solid food.<sup>287</sup> It may occasionally be misdiagnosed as a food allergy reaction,<sup>287,288</sup> although the unilaterality of the eruption in most cases should distinguish it from an allergic process. Table 12-7 lists some features that help to distinguish food allergy from pediatric Frey syndrome. In children, the presentation of Frey syndrome is often limited to facial flushing (without sweating), and these changes occur most often after ingestion of fruits (especially citrus fruits and apple), candy, or a favorite food. Perinatal birth trauma from forceps-assisted delivery with subsequent damage to the auriculotemporal nerve may be responsible in many pediatric cases. In those with no history of trauma to the parotid area, congenital aberration of the auriculotemporal nerve pathway between parasympathetic and sympathetic fibers is suspected. The gustatory flushing of Frey syndrome has also been observed in patients with type 1 neurofibromatosis and facial plexiform neurofibromas.<sup>289</sup> The

**Table 12-7** Useful Features for Distinguishing Food Allergy from Pediatric Frey Syndrome

	Food Allergy	Frey Syndrome
Laterality	Often bilateral	Usually unilateral (occasionally bilateral)
Distribution	Patchy and irregular; often	Segmental distribution within areas generalized innervated by auriculotemporal nerve (usually a stripe from mouth angle toward frontotemporal scalp); limited to face
Skin lesions	Urticaria	Flushing (typically without sweating in children)
Pruritus	Present	Absent
Angioedema	May be present	Absent
Other findings	May have respiratory or GI symptoms, anaphylaxis	None
Implicated foods	Commonly cow's milk, egg, soy, wheat, peanuts, tree nuts, fish, shellfish	Commonly citrus fruits, green vegetables, candy (especially sour), child's favorite foods
History	May have associated personal or family history of atopy	May have history of forceps-assisted delivery

Modified from Sethuraman G, Mancini AJ. Familial auriculotemporal nerve (Frey) syndrome. Pediatr Dermatol 2009;26(3):302–5. GI, Gastrointestinal.

clinical presentation is that of bright erythema extending in a patch from the corner of the mouth toward the preauricular cheek and as far as the frontotemporal scalp (Fig. 12-82) that occurs within a few seconds after ingestion of the responsible food. The changes resolve spontaneously over 30 to 60 minutes, and therapy is unnecessary. Spontaneous resolution may occur after a period of time and often is the case in children with Frey syndrome. In adults with severe forms of the disorder, treatments have included topical antiperspirants or anticholinergic ointments and botulinum toxin injections.

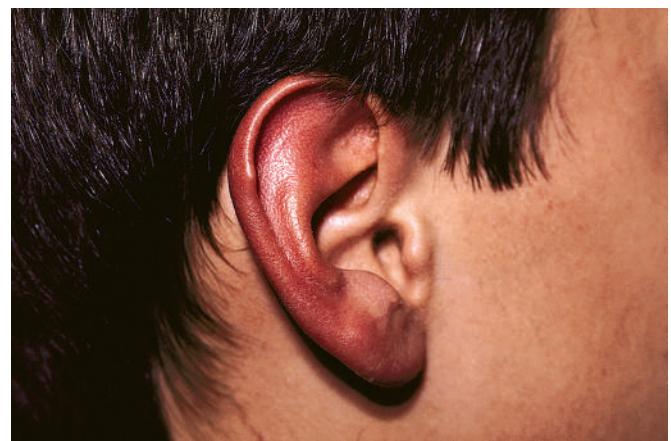

### ERYTHROMELALGIA

Erythromelalgia (also known as *erythermalgia*) is a rare condition characterized by paroxysmal intense burning pain, erythema, and warmth of the skin. It most often involves the distal limbs, especially the feet but also the hands. It may occur in primary or secondary forms and is quite uncommon in childhood. When it does occur in children, it is usually idiopathic.<sup>290,291</sup> Secondary erythromelalgia has been reported in association with various disorders including hematologic diseases (i.e., polycythemia, malignancy, spherocytosis, and thrombotic thrombocytopenic purpura), embolic disease, cardiovascular disease, connective tissue disorders (including lupus erythematosus, rheumatoid arthritis, and vasculitis), infectious diseases, neurologic disease, and musculoskeletal disease, and as a drug-induced condition.<sup>292</sup> In patients with an associated myeloproliferative disorder, the findings of erythromelalgia may precede the diagnosis by months to years.<sup>293</sup> Inherited erythromelalgia has been demonstrated to be caused by gain-of-function mutations in SCN9A, which encodes the voltage-gated sodium channel protein Na<sub>v</sub>1.7.<sup>294,295</sup> These channels are preferentially expressed in primary sensory neurons of the dorsal root and trigeminal ganglion and sympathetic ganglion neurons.<sup>296</sup>

Erythromelalgia presents with striking erythema and warmth of the affected distal extremity that is worsened by heat and relieved by cooling and elevation. The affected skin may have a purple hue. It is

**Figure 12-82** Auriculotemporal nerve (Frey) syndrome. Facial flushing extended from the mouth angle to the frontotemporal scalp in this young girl just seconds after ingestion of solid foods (in this instance, fruit snacks).

**Figure 12-83** Red ear syndrome. This young boy had recurrent episodes of painful burning and redness of the ear.

**Figure 12-84** Cutis marmorata telangiectatica congenita. The reticulate mottling was limited to the chest in this newborn male.

most often bilateral, although it may occasionally be unilateral. Occasionally proximal extension of the warmth and redness up the extremity are noted. Less often the face, ears, or nose may be affected.<sup>297</sup> When severe, erythromelalgia may have a profound effect on quality of life and sleep quality and may disrupt work and social functioning.<sup>292</sup> In a review of 32 pediatric patients with erythromelalgia, physical activity was limited in 66%, with 13% of patients becoming wheelchair-bound as a result of the condition, and school attendance was adversely affected in 34% of the patients.<sup>297</sup> Multiple therapies have been utilized for erythromelalgia with variable (and usually minimal) success. These include cooling, topical anesthetic agents (including lidocaine patches), aspirin, serotonin-reuptake inhibitors, tricyclic antidepressants, anticonvulsants, calcium channel blockers, sympathetic blocks, sympathectomies, intravenous lidocaine, mexiletine, and psychotherapy.<sup>291,292,298,299</sup>

Red ear syndrome (erythromelalgia of the ears, auricular erythromelalgia) deserves mention here. This entity presents with a painful, burning, bright red ear (Fig. 12-83) that occurs paroxysmally and is usually unilateral. Both ears may occasionally be involved. Some have termed this presentation *otomelalgia* given its similarity in presentation to erythromelalgia. Red ear syndrome may represent a migraine variant and in fact may be associated with classic symptoms of migraine headache.<sup>300</sup> Other potential associations include irritation of the third cervical root, temporomandibular joint dysfunction, or thalamic syndrome.<sup>301</sup> Patients with this presentation may respond to therapies directed at migraine headache or a tricyclic antidepressant.<sup>302</sup> Cool compresses of the ears often relieves discomfort acutely during an episode.<sup>303</sup>

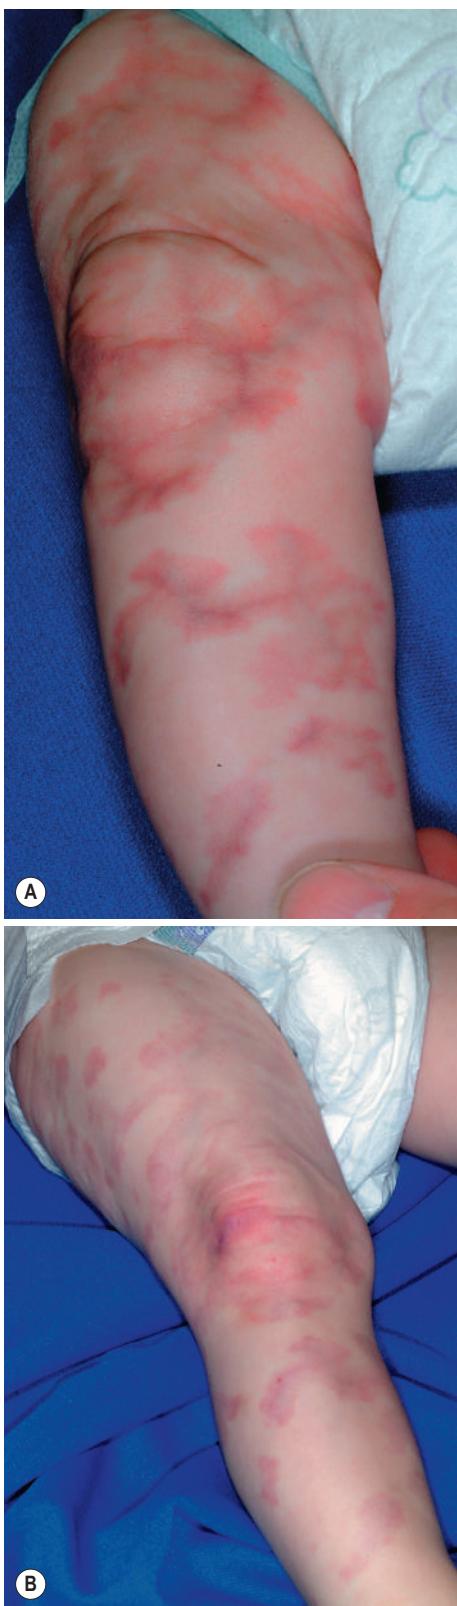

### CUTIS MARMORATA TELANGIECTATICA CONGENITA

CMTC (congenital generalized phlebectasia) is a condition characterized by either localized or generalized reticulate erythema. Although the clinical findings may resemble physiologic cutis marmorata, the changes of CMTC do not disappear with rewarming and may be associated with other abnormalities.

Patients with CMTC exhibit skin changes either at or shortly after birth. Clinical examination reveals red to violaceous, reticulate,

mottled, or mottled patches (Figs. 12-84 and 12-85). The nature of the skin changes may include prominent veins, telangiectasias, and atrophy. The changes may be limited to a localized region of the body or an extremity or may show a diffuse pattern of involvement. When localized, the distribution tends to be segmental with a sharp demarcation at the midline.<sup>304</sup> The skin changes are accentuated by a decrease in the ambient temperature. CMTC lesions may resemble livedo reticularis as well as cutis marmorata, and occasionally ulceration may be present. The color of the skin lesions may vary from light pink to dark purple.

Additional anomalies may occasionally be present in patients with CMTC. A common finding is body asymmetry, especially limb hypoplasia on the affected side.<sup>305,306</sup> Limb hyperplasia may also occasionally occur.<sup>307</sup> Other vascular anomalies may be present in patients with CMTC, most commonly PWS and less often IH.<sup>304,305,308</sup> SWS has been reported in some patients. Ophthalmologic abnormalities include glaucoma, retinal pigmentation, and retinal detachment. Neurologic abnormalities may include macrocephaly, seizures, hydrocephalus, and psychomotor retardation.<sup>221,305,306</sup> Adams–Oliver syndrome is a genetically heterogeneous disorder characterized by CMTC in association with distal transverse limb defects and aplasia cutis congenita of the scalp. Despite the potential associations, most patients with CMTC have only minor associated anomalies or disease limited to the skin. The incidence of associated findings is unclear and varies in the literature from 18% to 89%.<sup>305,307,309</sup> In the authors' experience, the majority of patients do not have associated anomalies. The syndrome previously referred to as *macrocephaly-CMTC* was subsequently renamed *M-CM syndrome* once it was recognized that the vascular

**Figure 12-85** Cutis marmorata telangiectatica congenita. **(A)** This blue-purple, reticulate mottling on the leg of this 2-month-old male does not disappear with rewarming, which distinguishes it from typical cutis marmorata. **(B)** Marked fading was noted at 2 years of age.

**Figure 12-86** Spider angioma. Note lesions on the nasal bridge and the right upper lip.

stains in this condition are actually reticulate PWSs (and not CMTC). This entity is discussed in more detail earlier in this chapter.

The pathogenesis of CMTC is unclear. Histologic examination, when skin biopsy has been performed, reveals dilated capillaries and veins in the dermis. Vascular proliferation analogous to that seen with IH has been reported.<sup>310</sup> The clinical diagnosis of CMTC is usually straightforward. The differential diagnosis may include reticulate PWS, KT syndrome, and disorders with pronounced cutis marmorata such as homocystinuria, Down syndrome, Divry–Van Bogaert syndrome, and Cornelia de Lange syndrome.<sup>304,311</sup> It is important to recognize that CMTC-like lesions may also occur in the setting of neonatal lupus erythematosus.<sup>312</sup> Diffuse genuine phlebectasia (Bockenheimer syndrome) is a rare disorder characterized by large venous ectasias usually limited to an extremity. This disorder is unlikely to be confused clinically with CMTC.

The natural history of CMTC is notable for gradual fading of the cutaneous lesions in most patients. When improvement occurs it tends to be within the first several years of life.<sup>308</sup> Treatment is unnecessary, and in fact PDL therapy seems less effective for these lesions than it is for capillary malformations (i.e., PWSs). Ophthalmologic evaluation is probably unnecessary in most patients but should be considered when there is facial involvement with the vascular process. Referral to a neurologist should be made if neurologic symptoms or features of a complex, multiorgan syndrome are present.

## TELANGIECTASES

Telangiectases are permanent dilations of capillaries, venules, or arterioles in the skin that may disappear on diascopy (gentle pressure with a microscope slide). Many processes affecting the blood vessel endothelium and its supporting structure can lead to the development of this common vascular lesion. Some of these are primary disorders of the blood vessels themselves for which the cause is unknown. Others are secondary and are related to a known disturbance, such as aging, sun exposure, radiation, or a systemic disorder in which they may serve as a useful diagnostic clue. Although telangiectases are usually a sporadic finding without associated underlying abnormalities, a benign hereditary form has also been described. Medical intervention is usually unnecessary, but PDL therapy may be considered for cosmetic purposes.

### Spider Angioma

The spider angioma (nevus araneus) is the best-known type of telangiectasia. It is characterized by a central vascular papule with symmetrically radiating thin branches ("legs") (Fig. 12-86). Spider angiomas appear most commonly on exposed areas of the face, upper trunk, arms, hands, and fingers, and occasionally on the mucous membranes of the lip and nose. They usually blanch with diascopy only to refill and reappear once the glass slide is removed. The central body is an arteriole that at times may reveal pulsations with diascopy.

**Figure 12-87** Angioma serpiginosum.

Although spider angiomas can be associated with liver disease, pregnancy, and estrogen therapy, they are commonly idiopathic and may occur in up to 15% of normal children and young adults. The etiology of spider angiomas in patients with liver disease is unclear, but they seem to be related to alcoholism and impaired liver function.<sup>313</sup>

Whereas some spider angiomas may regress spontaneously, in many individuals they tend to persist indefinitely. Treatment options, when desired, include electrocoagulation or PDL therapy.

### Angioma Serpiginosum

Angioma serpiginosum is a rare condition that manifests as multiple punctate erythematous lesions. It seems to represent a vascular malformation, although vascular proliferation has been reported. The condition is reported most often in young females.

Angioma serpiginosum presents as pinpoint red to violaceous macules that often extend in a serpiginous pattern (Fig. 12-87).<sup>314</sup> There is often some background erythema. The lesions may occasionally appear purpuric and may be confused with various purpuric dermatoses.<sup>315</sup> The disorder is usually localized, and the most common distribution is on the lower extremities, although more extensive involvement may be seen.<sup>314</sup> Angioma serpiginosum tends to be asymptomatic.

Individual puncta of angioma serpiginosum may disappear, but complete spontaneous clearing of lesions is rare. Treatment with the PDL therapy often leads to improvement or resolution.<sup>316,317</sup>

### Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT; also called *Osler–Weber–Rendu syndrome*) is an autosomal dominant vascular disorder characterized by mucocutaneous telangiectases and a bleeding diathesis, as well as vascular malformations in the lungs, liver, GI tract, and CNS. It has been estimated to affect approximately 1 in 5000 to more than 10,000 individuals.<sup>318–321</sup> Two molecular subtypes of HHT are recognized: HHT1 and HHT2. HHT1 is known to be caused by mutations in the endoglin gene, and HHT2 by mutations in the activin receptor-like kinase 1 (*ALK1/ACRV1*) gene.<sup>322,323</sup> Mutations in *SMAD4* give rise to juvenile polyposis/HHT (JPHT).<sup>319</sup> Although there is significant overlap between the clinical findings in HHT1 and HHT2, there appears to be a difference in the rates of underlying vascular anomalies.

Patients with HHT most commonly experience epistaxis and anemia, the latter usually being the result of GI blood loss. The epistaxis may begin in early childhood (an estimated 50% report having nosebleeds by 10 years of age), but the characteristic mucocutaneous telangiectases often do not appear until 5 to 30 years after the epistaxis, often during adolescence or even later.<sup>320</sup> These vascular lesions have a predisposition for certain anatomic sites, including the lips, ears, oral cavity (especially tongue and palate), palms, fingers, soles, and nasal mucous membranes. Lesions may be present under the nails. The telangiectases in HHT are often described as *punctate* or

*macular* (vs. the more classic spider variety with a central core and peripheral radiating vessels). Epistaxis occurs spontaneously on more than one occasion, and nighttime bleeds are particularly suspicious for HHT.<sup>324</sup> Other mucous membranes may also be involved, and hemorrhage may occur from any involved mucosal site. Although the distribution of lesions and associated bleeding diathesis are clinically suggestive of HHT, it may occasionally be difficult to distinguish the cutaneous lesions from those seen in benign disorders such as generalized essential telangiectasia. In addition, the classic distribution of HHT-associated telangiectases may not be observable until the third or fourth decade of life,<sup>318</sup> further compounding the challenge of rendering an early diagnosis.

AVMs may occur in patients with HHT and may be responsible for significant morbidity and even death. Pulmonary and cerebral AVMs are the most classically recognized lesions, although hepatic and spinal AVMs may also occur. Previously “silent” lesions in the lung or brain may hemorrhage, and pulmonary lesions are particularly worrisome because of the risks of hypoxemia or embolism of particulate matter through right-to-left shunts, with neurologic sequelae.<sup>325</sup> Pulmonary AVMs appear less common in HHT2 than in HHT1.<sup>318</sup> Catastrophic intracranial hemorrhage has been reported in infants and children with HHT who were not suspected of having the disease despite family histories of the syndrome.<sup>325</sup> Screening for pulmonary and cerebral AVMs, when clinically indicated, may include chest radiography, pulse oximetry, blood-oxygen determination, and high-resolution CT, MRI, and magnetic resonance angiography (MRA). Transthoracic contrast echocardiography with agitated saline contrast (echo bubble study) appears to be a sensitive test for pulmonary AVMs and is being increasingly utilized as an initial screen for HHT. Hepatic AVMs in patients with HHT do not appear to pose the same risk for catastrophic events as compared with pulmonary or cerebral lesions.<sup>318</sup> Patients may also be prone to vascular lesions in the primarily upper GI tract, which may lead to GI bleeding.

The diagnosis of HHT generally relies on history, clinical examination, and review of family history.

Deoxyribonucleic acid (DNA) diagnostic testing is technically difficult and costly, but testing is available for diagnosis of an affected individual and for prenatal diagnosis. Newborn screening by endoglin protein expression and mutation analysis of umbilical-vein endothelial cells may allow early identification of affected newborns.<sup>326</sup> Treatment of HHT is dictated by the extent of mucocutaneous and organ involvement. Therapies for epistaxis include embolization, laser ablation, and septal dermoplasty, as well as some pharmacologic alternatives such as estrogens, desmopressin (DDAVP), and antifibrinolytic agents. GI tract bleeding is treated with surgical or medical therapies, including hormones, danazol, iron replacement, and octreotide. Treatments for lung, cerebral, and hepatic AVMs depends on the extent of involvement and may include medical therapies, surgery, embolization, and transplantation.

### Unilateral Nevoid Telangiectasia

Unilateral nevoid telangiectasia is a condition characterized by multiple telangiectases in a dermatomal distribution. The condition may be congenital or acquired and may be sporadic or associated with medical conditions (such as chronic liver disease), physiologic states (i.e., puberty, pregnancy), or medications (usually estrogen hormonal therapy).<sup>327,328</sup> Although the etiology is controversial, it may be related to an increased level of estrogen receptors in involved skin.<sup>328</sup>

The condition presents with numerous skin telangiectases in a unilateral distribution, especially involving the upper body or extremities (Fig. 12-88). A dermatomal distribution may or may not be evident. Unilateral nevoid telangiectasia occurs most often in females during pregnancy or puberty. When it occurs in adult males, it is often in association with alcoholic cirrhosis. It has also been reported in association with hepatitis C virus.<sup>328</sup> Treatment is unnecessary, although PDL therapy has been demonstrated to be useful.<sup>329</sup>

### Ataxia-Telangiectasia

Ataxia-telangiectasia (A-T; or Louis–Bar syndrome) is a multisystem autosomal recessive disorder characterized by oculocutaneous telangiectases, cerebellar ataxia, a profound humoral and cellular immunodeficiency, and a predisposition toward hematologic malignancy.

**Figure 12-88** Unilateral nevoid telangiectasia. These telangiectatic macules were limited to the hand, forearm, and upper arm.

A-T is caused by a mutation in the A-T mutated (*ATM*) gene, which maps to chromosome 11q. The protein product of this gene is a nuclear protein involved in the early recognition and response to double-stranded DNA breaks.<sup>330</sup>

There is considerable phenotypic variability in patients with A-T, and patients may differ significantly in their rate of progression or appearance of features.<sup>331</sup> The initial clinical manifestation is often truncal ataxia, which may present as early as infancy.<sup>332</sup> Other neurologic features include choreoathetosis, dysarthria, myoclonic jerks, and oculomotor abnormalities. Affected patients may display drooling; peculiar eye movements; a sad, mask-like facies; and a stooped posture with drooping shoulders and the head tilted forward and to the side. Confinement to a wheelchair by the second decade is not unusual.

The mucocutaneous telangiectases are a variable feature of A-T but not uncommonly help lead to the correct clinical diagnosis. They usually appear around 3 to 5 years of age, most often on the medial and lateral bulbar conjunctivae. Skin telangiectases develop primarily on sun-exposed sites including the ears, cheeks, neck (Fig. 12-89), arms, and upper chest. Other body regions may be affected, and occasionally the cutaneous telangiectases are quite subtle. Other cutaneous findings may include subcutaneous fat loss, progeroid (premature aging) changes of skin and hair, and diffuse hair graying. Segmental, patchy hypopigmentation and hyperpigmentation have been observed,<sup>333</sup> and patients without the telangiectases have been reported.<sup>334</sup> Noninfectious cutaneous granulomas (Fig. 12-90), which present as erythematous plaques, nodules, and ulcers, are a fairly common cutaneous feature in patients with A-T.<sup>335,336</sup> They are usually located on the extremities, with the second most common site being the face. The granulomas less commonly involve the trunk.<sup>337</sup> These lesions tend to be persistent but may be improved by intralesional injections of triamcinolone or short courses of oral corticosteroids (which must be used cautiously given the underlying risk of infection). Some have suggested that these noninfectious lesions are caused by immune dysregulation and its effects on wound healing and tissue repair.<sup>337</sup>

Chronic sinopulmonary infections occur in the majority of patients with A-T. Bronchiectasis with respiratory failure may occur and is the most common cause of death. Growth failure and mental retardation may also occur. Several immunologic defects have been reported in patients with A-T, including decreased IgA, IgE, and IgG and multiple defects in cell-mediated immune responses. Decreased thymic output and skewed T- and B-cell receptor repertoires have been observed.<sup>338</sup>

Lymphoid malignancies occur with markedly increased incidence in patients with A-T. These include Hodgkin disease, non-Hodgkin lymphoma, and leukemia. There appears to be a four- to fivefold increased rate of T-cell tumors compared with B-cell tumors in patients who have A-T.<sup>339</sup> In those with Hodgkin disease there is a reduced survival compared with Hodgkin disease in the general

**Figure 12-89** Ataxia-telangiectasia, telangiectasias. (Reproduced with permission from Bolognia JL, Jorizzo JL, Rapini RR. Dermatology. Philadelphia: Mosby; 2003.)

**Figure 12-90** Ataxia-telangiectasia, granulomas. These granulomatous skin lesions are very resistant to therapy.

population.<sup>340</sup> Of the non-Hodgkin lymphomas, diffuse large B-cell lymphomas account for the majority, and T-cell acute lymphoblastic leukemia is the most common form of leukemia.<sup>339,341</sup>

The diagnosis of A-T usually rests on the clinical findings. Elevated levels of  $\alpha$ -fetoprotein and carcinoembryonic antigen support the diagnosis. Molecular diagnosis and prenatal diagnosis are possible but not readily available, and the familial mutation must be known. Treatment for A-T is largely supportive, including antimicrobial therapy for infection, early therapy for bronchiectasis, neurodevelopmental follow-up care and therapy, and aggressive surveillance for malignancy. Vigorous photoprotection is vital, because A-T patients have a lowered threshold for the development of skin malignancies, and radiation use for treatment of hematopoietic malignancy should be minimized, when feasible. Death is usually the result of chronic bronchiectasis with pulmonary insufficiency and/or pneumonia (55%) or malignancy (15%).

**Figure 12-91** Generalized essential telangiectasia. This patient had a widespread distribution of telangiectases without any bleeding diathesis.

### Generalized Essential Telangiectasia

Generalized essential telangiectasia is a disorder of multiple cutaneous telangiectases without a bleeding diathesis. The condition is notable for a widespread distribution of lesions (Fig. 12-91), progression and/or permanence of the telangiectases, accentuation by dependent positioning, and absence of other epidermal or dermal skin changes (i.e., atrophy, purpura, or dyspigmentation).<sup>342</sup> The most common site of involvement is the lower extremities, and the disorder is more common in females. Oral mucosal and conjunctival telangiectases have occasionally been reported. Although the etiology of generalized essential telangiectasia is unknown, some have suggested a possible autoimmune diathesis.<sup>343</sup> Treatment for this condition is unnecessary. In patients who desire therapy for cosmesis, pulsed-dye or Nd:YAG laser treatments appear effective.

## Pigmented Purpuric Eruptions

Pigmented purpuric eruptions (PPEs; pigmented purpura, pigmented purpuric dermatosis, progressive pigmented purpura) comprise a group of dermatoses characterized by cutaneous petechiae, purpura, and often a yellow-brown pigmentation. Histologically these disorders all reveal inflammation of the superficial dermal capillaries (capillaritis) without frank vasculitis. Table 12-8 lists the five different subtypes of PPE. The etiology of PPE is unknown, and although they occur primarily in adults, they may also occur in children. Proposed associations with PPE include capillary fragility, cell-mediated immune responses, hepatitis B and C infection, and medication reactions.<sup>344–346</sup> The vast majority of children with PPE are healthy and have no associated medical condition.

Schamberg disease is the prototype for PPE, being the most common type and the most common to present in children. Although rare, it may even occur in infants.<sup>347</sup> The primary lesion is a red-brown punctate macule, and multiple such lesions ("cayenne pepper spots") occur at the border of red-brown patches (Fig. 12-92).<sup>345,348</sup> The most common location is the lower extremities, although more widespread involvement may occur. Schamberg disease has been associated with the ingestion of several medications, including aspirin and acetaminophen. In addition there are rare reports of an association

**Table 12-8** Subtypes of Pigmented Purpuric Eruptions

Type	Comment
Schamberg disease	Red-brown patches with petechiae ("cayenne pepper spots"); mainly lower extremities
Majocchi disease	Also called <i>purpura annularis telangiectodes</i> ; punctate, perifollicular, telangiectases present; tend to become annular and hyperpigmented
Lichen aureus	Rust-yellow lichenoid papules and papules; often linear or along Blaschko lines; fairly common in children
Eczematid-like purpura of Doucas and Kapetanakis	Generalized; eczematous, with lichenification and pruritus present
Pigmented purpuric lichenoid dermatitis of Gougerot and Blum	Red-brown, lichenoid papules and plaques; very rare in children

**Figure 12-92** Pigmented purpuric eruption, Schamberg disease. Pin-point, petechial macules coalesce and are superimposed on faint, red-brown patches.

between pigmented-purpura-like eruptions and progression to cutaneous T-cell lymphoma (mycosis fungoides).<sup>349,350</sup> Although seemingly rare, these reports highlight the need to consider this diagnosis in patients (especially adults) with unusually persistent PPE.

Majocchi disease is an annular variant of PPE, presenting with punctuate, perifollicular petechiae, telangiectases, and hyperpigmented annular patches (Fig. 12-93). It occurs primarily in adolescents and younger adults and occurs on the lower extremities as well as the trunk and upper extremities.

Lichen aureus is a unique type of PPE in its presentation. Patients have lichenoid papules that coalesce to form plaques, often with a linear distribution or in some cases, distribution along the lines of Blaschko. The color of the lesions varies from pink to rust-yellow (Fig. 12-94) to purple, and again the lower extremities are the favored site of involvement.

Eczematid-like purpura of Doucas and Kapetanakis is usually a generalized form of PPE with eczematous changes and pruritus. Lichenification (skin thickening with accentuated skin markings) occurs as a result of frequent scratching. Pigmented purpuric lichenoid dermatitis of Gougerot and Blum presents with red-brown, polygonal lichenoid papules with telangiectases.

There are no satisfactory treatments for PPE. In cases where a drug reaction is possible, withdrawal of the offending agent may induce regression. Treatments utilized with variable success have included

**Figure 12-93** Pigmented purpuric eruption, Majocchi disease. Pink-tan patches with petechiae and mild central clearing were present on the lower legs of this adolescent boy.

**Figure 12-94** Pigmented purpuric eruption, lichen aureus. These golden-tan macules and patches distributed in a linear fashion revealed pinpoint petechial macules with diascopy (viewing through a glass slide while applying pressure).

topical and systemic corticosteroids, antihistamines, and psoralens and ultraviolet A (PUVA) light therapy. Therapy with ascorbic acid (vitamin C) and bioflavonoids (specifically rutoside) as well as narrowband ultraviolet B (UVB) phototherapy has also been reported as useful in open-label studies.<sup>351–354</sup> Two young adults with extensive PPE responded to pentoxifylline therapy.<sup>355</sup>

#### Box 12-6 Etiologic Associations with Purpura Fulminans

##### Severe Acute Infection

- Neisseria meningitidis*
- Staphylococcus aureus*
- Streptococcal infections (including invasive pneumococcal)
- Plasmodium falciparum*
- Others

##### Postinfectious

- Varicella
- Streptococcal infections

Diagnosis and management of neonatal purpura fulminans. *Semin Fetal Neonatal Med* 2011;16:318–22, and Thornsberry LA, LoSicco KJ, English JC. The skin and hypercoagulable states. *J Am Acad Dermatol* 2013;69:450–62. PF, Purpura fulminans.

## Purpura Fulminans

Purpura fulminans (PF) is a rare condition characterized by acute, rapidly progressive hemorrhagic necrosis of the skin and disseminated intravascular coagulation. The potential etiologic associations with PF are listed in Box 12-6. It occurs most often in association with severe bacterial (especially meningococcal and *Staphylococcus aureus* septicemia) or viral infection or as a postinfectious syndrome after infections such as varicella or scarlet fever.<sup>356,357</sup> In the latter instance, it usually occurs 10 days to 1 month after the infection. PF has also been described in association with invasive pneumococcal infection.<sup>358</sup> It may also be associated with congenital deficiencies of proteins C or S, which are vitamin K-dependent glycoproteins with antithrombotic properties. In fact, infection-associated PF may be partly the result of acquired deficiencies in these proteins.<sup>359,360</sup> Factor V Leiden, which is a mutated version of factor V, has been shown to be associated with activated protein C resistance, an increased risk of thrombotic events, and exacerbated PF in patients with meningococcal disease.<sup>356,361</sup> PF is associated with significant morbidity and is occasionally fatal, especially in the presence of concomitant meningococcal disease.

PF presents with erythematous macules that progress rapidly into purpura and ecchymoses, often with sharp irregular borders. The lesions are tender, enlarge rapidly, and coalesce with the development of central necrosis, hemorrhagic blebs (Fig. 12-95), and a raised edge with surrounding erythema. The ecchymotic lesions are most commonly distributed on the lower extremities and buttocks, with occasional involvement of the trunk and upper extremities. Deep extension with muscle necrosis and bone involvement may occur. Mucous membranes are usually spared. Chills, fever, tachycardia, anemia, and prostration are common. Visceral involvement is less common but may include CNS and retinal vessel thrombosis, hematuria, and GI hemorrhage. Adrenal gland thrombosis may result in Waterhouse–Friderichsen syndrome. Skin and muscle necrosis may be severe enough to require grafting, and digital or limb ischemia may necessitate amputation. Epiphyseal growth plate necrosis in a growing child

**Figure 12-95** Purpura fulminans. Ecchymotic patches and plaques with necrosis and a hemorrhagic bulla over the knee.

may result in limb foreshortening.<sup>362</sup> Newborn infants with protein C or S deficiency or factor V Leiden have clinical features of PF within 24 hours after birth and are at high risk for widespread thrombosis of capillaries and venules.<sup>363</sup> Children under 4 years of age and those with the factor V Leiden mutation appear to be at increased risk for severe disease and amputation.<sup>357</sup>

Laboratory evaluation in the patient with PF reveals decreased fibrinogen and thrombocytopenia. The prothrombin time and partial thromboplastin time are prolonged, and fibrin degradation products are increased. Protein C, protein S, and antithrombin III levels are decreased. Histologic evaluation of the skin lesions reveals dermal vascular thrombosis and hemorrhagic necrosis.<sup>362</sup>

The treatment for PF depends upon the underlying disorder and/or associated infection. Initial management consists of fluid resuscitation, ventilatory and inotropic support, and antibiotic administration when indicated.<sup>364</sup> Administration of proteins C and S (i.e., in the form of fresh frozen plasma or protein C concentrate) may prevent progression of lesions that are not yet necrotic.<sup>359,365</sup> Repeated infusions may be necessary because of the short half-life of protein C.<sup>359</sup> Antithrombin III concentrate has been administered to some patients. Concomitant heparin has been advocated by some (but not by others), especially when there is evidence for large vessel venous thrombosis. Long-term administration of oral anticoagulants is often necessary in patients with congenital protein C or S deficiency. Packed red blood cell transfusion, platelet transfusion, and cryoprecipitate may each need to be considered in certain patients. Surgical modalities include debridement, autologous skin grafting, tissue and muscle flaps, amputation, skin allografts, and tissue-engineered skin.<sup>366,367</sup>

## Gardner-Diamond Syndrome

Gardner-Diamond syndrome (autoerythrocyte sensitization syndrome, painful bruising syndrome, psychogenic purpura) is a rare disorder characterized by painful bruising and usually seen in patients with emotional or psychiatric disturbance. Historically the disorder was ascribed to a sensitization reaction to the patient's own erythrocytes, hence the alternative nomenclature *autoerythrocyte sensitization syndrome*.<sup>368</sup> The majority of patients with Gardner-Diamond syndrome are adolescent or adult females, with only occasional reports of involved males.

The disorder is characterized by recurrent episodes of spontaneous, painful ecchymoses that are often precipitated by emotional stress. The lesions may vary in size and may involve any part of the cutaneous surface. Most patients report a burning sensation initially. The lesions of Gardner-Diamond syndrome tend to resolve over weeks only to recur again with time. The etiology of this condition remains unclear. In the original reports, patients were noted to have a positive reaction to intradermal injection of their own erythrocytes, which resulted in an ecchymosis.<sup>369</sup> The significance of this finding has been

questioned in subsequent reports, and the immune nature of the condition remains speculative. A number of psychiatric disorders have been observed in association with the cutaneous findings, including depression, anxiety, impulse-control issues, hypochondriasis, hysterical and borderline personality disorders, and obsessive-compulsive behavior.<sup>368</sup> There is no effective treatment for Gardner-Diamond syndrome, which has a chronic unremitting course, and psychiatric evaluation is usually advisable.<sup>370</sup> Psychotropic medications, hypnotherapy, and psychotherapy have been successfully used in some patients.<sup>371</sup>

## Scurvy

Scurvy, which is caused by vitamin C deficiency, is relatively rare in developed countries, although there are several cases described in the literature in children with an inadequate dietary intake of this vitamin.<sup>372</sup> Clinicians caring for children and adolescents must therefore be aware of this disease and its clinical presentation.

Vitamin C (ascorbic acid) is a vital component of the human diet because of the inability of humans to derive it from glucose via gluconolactone oxidase.<sup>373</sup> Ascorbic acid is found primarily in fresh fruits, vegetables, and vitamin supplements. When deficiency of this vitamin occurs in a developed country, it is usually in the elderly, indigent, drug- or alcohol-abusing, or food-faddism populations or those with GI disorders or poor dentition.<sup>373,374</sup> Children at risk include those in neglectful social situations, those with neurodevelopmental disabilities or psychiatric illnesses, those with severe food allergies or GI disease, and those with unusual dietary habits or with parents who are food faddists.<sup>372-377</sup> There are several reports of scurvy in children with autism.<sup>378-381</sup> Because ascorbic acid is a cofactor in the synthesis of collagen and collagen is a vital component of the pericapillary network in the skin, capillary fragility results from deficiency of this nutrient.

Clinical manifestations of scurvy include fatigue, petechiae, ecchymoses, purpura, and perifollicular hemorrhages. The latter finding is considered pathognomonic for the condition. In addition, follicular hyperkeratosis and "corkscrew hairs" may be noted. Purpura often occurs on the lower extremities but may also involve other body regions. Gingival findings include swelling, bleeding, and loosening of teeth. Bony fractures appear to be more common in pediatric patients when compared with adults, and arthralgias, joint swelling and hemarthrosis may occur. Other findings include GI bleeding, conjunctival and intraocular hemorrhage, alopecia, and epistaxis. In some patients, musculoskeletal pain and weakness may be presenting features.<sup>373,376,377</sup> Cardiovascular manifestations of scurvy may include cardiac hypertrophy, postural hypotension, syncope, and possibly hypertension.<sup>373</sup>

Scurvy is usually diagnosed clinically, with the differential diagnosis including hematologic malignancy, vasculitis, infection, coagulopathy, child abuse, and factitial disorder.<sup>372</sup> A serum ascorbic-acid level is usually confirmatory (when <11 µmol/L), although this value may be normal if the patient has had recent intake of vitamin C. Concomitant vitamin deficiencies (especially calcium, vitamin B<sub>12</sub>, or iron) may also be present.<sup>374</sup> The clinical symptoms usually respond promptly to vitamin C replacement, with dosages for infants and children ranging from 100 to 300 mg/day.

Blisters or bullae are rounded or irregularly shaped lesions of the skin or mucous membranes that result from the accumulation of fluid between the cells of the epidermis, the epidermis and stratum corneum, or the epidermis and dermis. The term *bullae* refers to blistering lesions 0.5 to 1 cm in diameter or larger; those smaller than 0.5 cm in diameter are called *vesicles*. The classification of bullous or vesiculobullous disorders is based on clinical morphology and examination of biopsied specimens of lesional or perilesional skin by light microscopy, immunofluorescence analysis, and electron microscopy. It is well recognized that the skin of infants and children is more susceptible to blister formation than that of adults.

## Hereditary Blistering Disorders

### EPIDERMOLYSIS BULLOSA

The term *epidermolysis bullosa* (EB) refers to a group of inherited disorders characterized by bullous lesions that develop spontaneously or as a result of varying degrees of friction or trauma.<sup>1–3</sup> The various subtypes of inherited EB result from mutations in 18 different genes and have recently been reclassified. These phenotypes are divided into four major inherited forms based first on the level of skin cleavage (Fig. 13-1) (the traditional subtypes of EB: simplex, junctional, dystrophic, and Kindler syndrome, a mixed EB type). Subsequent classification is based on the clinical phenotype including distribution of lesions and presence of scarring, the relative severity of cutaneous and extracutaneous involvement, the mode of inheritance, and if available, molecular analysis. In the new classification, the only eponyms that remain are Kindler syndrome and EB simplex (EBS)-Ogna (for lack of better suggested names).

In EBS (epidermolytic EB) the blister cleavage occurs within the epidermis, and healing occurs without scarring. In junctional EB (JEB) the skin separates in the lamina lucida of the dermal–epidermal junction, and blistering leads to atrophic scarring. In dystrophic (dermolysis) EB (DEB) the blister forms in the papillary dermis below the basement membrane, and patients form scars and milia. EB with congenital absence of skin (formerly called *Bart syndrome*) can be seen at birth with any of the major forms of EB (Fig. 13-2), although it most commonly is seen with dystrophic forms of EB. Neonates most commonly show congenital localized absence of skin of the lower extremities. EB acquisita (EBA) is an acquired immune-mediated blistering disorder that can resemble DEB (see *Epidermolysis Bullosa Acquisita* section).

Skin biopsy samples for immunofluorescence mapping have traditionally been used to confirm the diagnosis of EB and to determine the subtype based on the level of cleavage from localization of known antigens in the skin and the presence of structural proteins associated with EB. Biopsies are ideally performed at the edge of a lesion freshly induced by rotating the skin with a moist Q-tip. Light microscopic evaluation of biopsy sections is generally not useful except for rare types (such as lethal acantholytic EB). Although whole exome sequencing has been shown to be more cost effective and efficient for detecting EB gene mutations than sequencing of individual genes suspected to be mutated,<sup>4</sup> at this time immunomapping studies can still be performed much more quickly, providing the family with some prognostic information.

The overall incidence of EB is 1 in every 50,000 births, although the simplex forms comprise the majority of cases. A national EB registry was established in the United States and has generated data beneficial to many families who have children with EB. The Dystrophic Epidermolysis Bullosa Research Association (DEBRA), a national

([www.debra.org](http://www.debra.org)) and international ([www.debra-international.org](http://www.debra-international.org)) group, is dedicated to research and support for patients with all forms of EB and their families.

### EPIDERMOLYSIS BULLOSA SIMPLEX

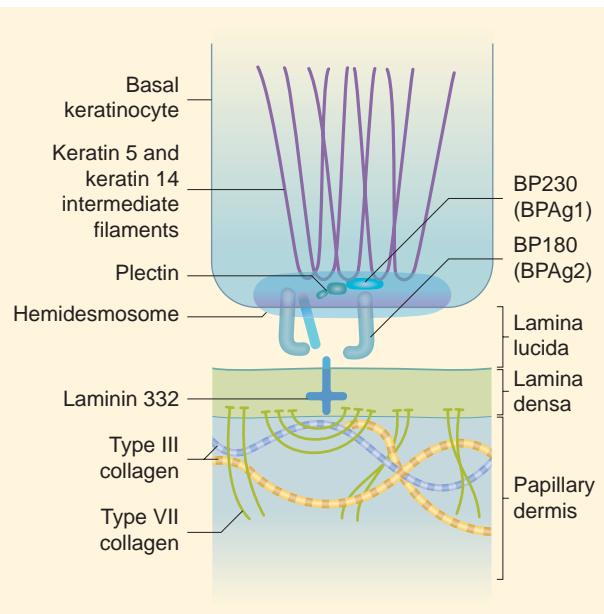

EBS is characterized by blisters that develop in areas of trauma and most commonly results from defective keratin filaments.<sup>5,6</sup> Because the blister cleavage is intraepidermal, lesions tend to heal without scarring. The most common form is basal EBS, which includes localized EBS (formerly called *Weber–Cockayne disease*), generalized intermediate EBS (formerly called *Koebner type*), and generalized severe EBS (formerly called *Dowling–Meara EBS* or *EBS herpetiformis*) (Table 13-1).<sup>3</sup> The vast majority of patients with EBS show autosomal dominant inheritance, although rare autosomal recessive forms have been described.<sup>7,8</sup> Suprabasal EBS includes a variety of autosomal recessive forms with absence of desmosomal components (for example, desmoplakin [DSP] in lethal acantholytic EB).

#### Generalized Severe Epidermolysis Bullosa Simplex

Generalized severe EBS (formerly Dowling–Meara) is the most severe form of EBS from keratin gene mutations (Table 13-2). During the newborn period, the generalized blisters tend to be large and may be difficult to distinguish from those of the severe dystrophic or junctional forms of EB despite the relatively good overall prognosis of babies with this form (Fig. 13-3).<sup>9</sup> Many young infants also show a significant inflammatory reaction in association with blistering and the formation of transient milia at sites of healed blisters, a finding usually characteristic of the dystrophic forms. The characteristic small, clustered (herpetiform) blisters may be seen in neonates, especially on the proximal extremities or trunk, but are more commonly noted during infancy and later childhood (Fig. 13-4). Blistering tends to decrease during later childhood and adulthood, and hyperkeratosis of the palms and soles may develop by 6 or 7 years of age, especially in those younger children with significant palmoplantar blistering (Fig. 13-5). During the neonatal period and early infancy, the extensive blistering may prove life-threatening. After this period, however, the blistering is rarely a threat to life. Nail involvement with sloughing is common in the generalized severe form, but the nails regrow without dystrophy. Similarly, oral and esophageal mucosal blistering may occur and cause problems with feeding and obtaining adequate nutrition, especially with the markedly increased caloric needs of more severely affected infants and younger children. Ocular mucosal blistering is less common, but natal teeth have been described.

#### Generalized Intermediate Epidermolysis Bullosa Simplex

Generalized intermediate EBS (formerly Koebner EBS) is characterized by generalized blistering of skin, most notable at sites of friction (see Table 13-2). Extensive blistering in the neonatal period and early infancy increases the risk of sepsis and may be life-threatening. In general the tendency toward blistering tends to improve with advancing age, particularly by teenage years. Hyperhidrosis is common, and mild to moderate hyperkeratosis of the soles is often present. Although erosions of the mucous membranes may be seen in the newborn as a result of vigorous sucking, mucosal involvement is generally mild and the nails are rarely affected, in contrast to the generalized severe form. Involvement of the conjunctiva and cornea has rarely been described. Migratory circinate EBS results from mutations in the tail domain of *KRT5*, and is characterized by small blisters on the hands, feet, and legs with migratory circinate erythema (Fig. 13-6) and often postinflammatory hyperpigmentation.<sup>10</sup> There is no mucosal or nail involvement.

**Figure 13-1** Schematic of the structural elements of the basal keratinocytes, basement membrane zone, and upper dermis.

**Figure 13-2** Epidermolysis bullosa (EB). Congenital localized absence of skin, also known as *Bart syndrome*, is now known to be a pattern seen in any of the three major subsets of EB. This baby with Bart syndrome has a form of junctional EB, but denudement at birth is most often seen in babies with dystrophic EB and occasionally EB simplex.

### Localized Epidermolysis Bullosa Simplex

Localized EBS (formerly Weber–Cockayne EBS) is the most common clinical variant (see Table 13-2). A relatively high threshold of frictional trauma is required to induce blister formation. Bullae are usually confined to the hands and feet (primarily the palms and soles; Fig. 13-7); they are often first seen in infants but may not appear until adolescence or early adulthood. The bullae are usually associated with trauma, occur more readily in hot weather with sweating of the feet, and do not tend to be seriously debilitating, although activities that involve trauma to the feet are often restricted. Hyperhidrosis is common, and hyperkeratosis of the palms and soles, although often present, is usually mild. Lesions heal rapidly without scarring, nail involvement rarely occurs, and the mucous membranes do not tend to be involved. In young children, blisters may develop on the knees from the frictional trauma of crawling. In adolescents and young adults, blisters often occur on the feet after long hikes or dancing or on the hands after a game of tennis or golf. EBS with mottled pigmentation is characterized by a mottled, reticulated pigmentation (Fig. 13-8), particularly of the trunk and neck, in association with mild

acral blistering (see Table 13-2). Patients often show small verrucous papules of the hands and feet and palmoplantar keratoderma.<sup>11</sup>

### Genetic Basis of Dominant Forms of Basal Epidermolysis Bullosa Simplex

Basal EBS most commonly results from mutations in the genes encoding keratin 5 and keratin 14 (the keratins expressed in basal cells). Keratins are the most abundant proteins of epidermal keratinocytes, and keratin pairs are critical for the filamentous network that provides integrity to epidermal cells. When a point mutation occurs in one of the keratin alleles, resulting in a change in one amino acid, the abnormal keratin protein is still able to form filaments, but these filaments are abnormal. The abnormal filaments do not provide adequate structural integrity to the cell, and as a result, the cell lyses. Cytolysis of epidermal basal cells is the essential histologic feature of all forms of EBS resulting from keratin gene mutations. Electron microscopic examination shows cleavage through the basal layer (above the periodic acid–Schiff-positive basement membrane of the epidermis). In the severe generalized form, clumping of tonofilaments and displacement of nuclei are seen ultrastructurally. The risk of cell lysis and the trauma required to elicit the blistering depend on the site of the mutation and how critical that gene region is for resultant keratin function. The sites of mutations in the most severe generalized form are most critical for keratin function (end-terminal rod domains), whereas the sites mutated in the localized type are least critical. The mutations that lead to EBS with mottled pigmentation tend to be at the head region

**Table 13-2** Characteristics of Major Forms of Epidermolysis Bullosa Simplex, Basal

Type	Clinical Manifestations
EBS, localized (formerly Weber–Cockayne)	Easy blistering on palms and soles May be focal keratoderma of palms and soles in adults ≈25% show oral mucosal erosions Rarely show reticulated pigmentation, especially on arms and trunk and punctate keratoderma (EBS with mottled pigmentation)
EBS, generalized, intermediate (formerly Koebner)	Generalized blistering Variable mucosal involvement Focal keratoderma of palms and soles Nail involvement in 20% Improves with advancing age
EBS, generalized, severe (formerly Dowling–Meara)	Most severe in neonate, infant; improves beyond childhood Large, generalized blisters; later, smaller (herpetiform) blisters Mucosal blistering, including esophageal Nails thickened, shed but regrow May have natal teeth
EBS with mottled pigmentation	Reticulated hyperpigmentation, especially on arms and trunk Punctate keratoses and keratoderma

EBS, Epidermolysis bullosa simplex.

**Figure 13-3** Generalized severe epidermolysis bullosa (EB) simplex. During the infantile periods the blistering is often severe and generalized, making distinction clinically from other forms of EB difficult. Note the thickening and sloughing of nails.

**Figure 13-4** Generalized severe epidermolysis bullosa (EB) simplex. With advancing age the blisters often become smaller and more clustered (herpetiform) in this form of EB. Blisters may be hemorrhagic and quite inflamed.

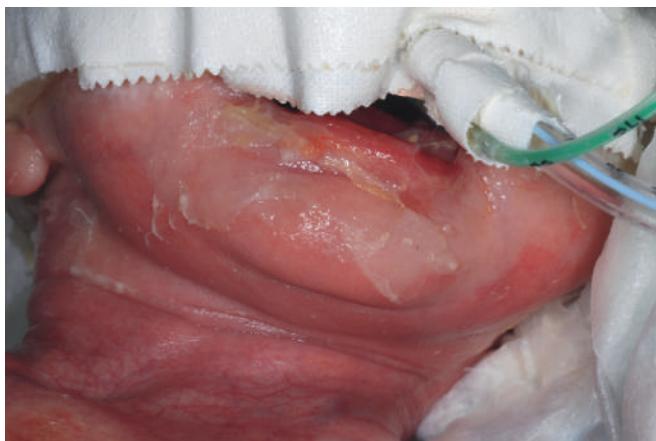

**Figure 13-5** Generalized severe epidermolysis bullosa simplex. Blistering on the palms and soles may be severe, but palms and soles show thickening with advancing age that is likely protective.

**Figure 13-6** Generalized intermediate epidermolysis bullosa simplex, migratory circinate form. This boy had a mutation near the tail of KRT5.

**Figure 13-7** Localized epidermolysis bullosa simplex. Note the superficial blistering with both intact bullae and denuded skin. This form tends to be limited to the palms and soles.

**Figure 13-9** Suprabasal acantholytic epidermolysis bullosa simplex. Note the sheet-like peeling of skin on the chin. This baby, who died as a neonate, had total body denudement, extensive mucosal sloughing, and complete alopecia from a mutation in *DSP*.

**Figure 13-8** Epidermolysis bullosa simplex with mottled pigmentation. The reticulated pigmentation may be bothersome to affected individuals, but the mild blistering, as seen proximal to the knee, is not.

of *KRT5* or *KRT14* (most often a mutation that changes the twenty-fifth amino acid of keratin 5),<sup>12,13</sup> suggesting that this site on the keratin protein is vital for the transfer of pigment from melanocytes to keratinocytes. The migratory circinate form has been linked to mutations in the tail region of *KRT5*.

#### Recessive Forms of Basal Epidermolysis Bullosa Simplex

Basal EBS less commonly is autosomal recessive, including with biallelic mutations in *KRT5* or *KRT14* (which can phenotypically show localized or generalized blistering). Three clinically distinct forms of EBS result from mutations in the gene-encoding plectin (*PLEC1*): EBS-Ogna, EBS with muscular dystrophy, and EBS with pyloric atresia.<sup>14,15</sup> EBS-Ogna, the only disorder with abnormal plectin that is autosomal dominant, mainly shows acral blistering, although more generalized blistering has been described; affected individuals characteristically bruise easily and may show onychogryphosis. EBS with muscular dystrophy presents in the neonatal or infantile period with generalized blisters, but the onset of muscular dystrophy varies from infancy to adulthood. Patients may show ptosis, granulation tissue with stenosis of the respiratory tract, and focal keratoderma. EBS with pyloric atresia presents with the same widespread congenital absence of skin (especially on the extremities), generalized blistering and pyloric atresia as in JEB with pyloric atresia. Malformed pinnae and nasal alae, joint contractures, and cryptorchidism are other shared features.

Plectin interacts with  $\alpha 6\beta 4$  integrin, providing a rationale for similar clinical manifestations. The mutations of EBS with muscular dystrophy cluster in exon 31, which is spliced out in one of the two isoforms of plectin, explaining the much milder phenotype of EBS with muscular dystrophy.<sup>16</sup> Two mild recessive forms have also been more recently described. EBS with autosomal recessive BP230 deficiency (EBS-AR BP230) results from mutations in encoding dystonin-e (DST-e), the epidermal isoform of bullous pemphigoid (BP) antigen (BPAG1e or BP230).<sup>17,18</sup> Affected individuals experience localized lifelong blistering and erosions beginning in infancy, but lesions are primarily localized to the ankles and feet. EBS with autosomal recessive exophilin 5 deficiency (EBS-AR exophilin 5) results from mutations in *EXPH5*, encoding exophilin-5 (or *SLAC2-B*), which is a protein involved in vesicle transport.<sup>19</sup> Small, localized erosions and bleeding primarily affect site of trauma, primarily the lower back, knees, and ankles. Ultrastructural studies of biopsies provide the clue to diagnosis, showing keratin filament clumping and acantholysis (as can be seen in EBS) but also typical perinuclear cytoplasmic vesicles.

#### Suprabasal Epidermolysis Bullosa Simplex

To date, biallelic mutations in four genes (*DSP*, *PKP1*, *JUP*, and *TGM5*) can lead to autosomal recessive suprabasal forms of EBS. The lethal acantholytic form of EB (LAEB) presents at birth with generalized denudement and absence of hair and nails.<sup>20,21</sup> Frank blisters are not seen, but the skin peels in sheets (Fig. 13-9). Mucosal sloughing is severe, and affected neonates may be born with teeth. All babies to date have died in the neonatal period. Cardiomyopathy is usually associated. Mutations have been described in the C-terminal domain of *DSP*. Less deleterious mutations in *DSP* also cause skin fragility and woolly hair syndrome (see Chapter 7), characterized by superficial erosions and crusting with woolly hair, palmoplantar keratoderma, and cardiomyopathy. Acantholytic EBS from mutations in *JUP*, encoding plakoglobin, manifests at birth as generalized erythroderma with superficial peeling and erosions. Patients have alopecia, dystrophic nails, and recurrent infections and generally die in the neonatal period, but there are no cardiac issues.<sup>22</sup> As with other mutations in desmosomal components, a milder form allows survival but the development of generalized erosions, sparse woolly hair, and focal keratoderma. Plakophilin deficiency (skin fragility and ectodermal dysplasia syndrome) results from mutations in *PKP1*, the gene encoding plakophilin-1.<sup>23-26</sup> Affected patients show generalized erythroderma at birth with blistering. The soles are often most disabling, with palmoplantar keratoderma and painful fissures. Superficial erosions and crusting are prominent in the perioral area, and tongue fissures have been described. The hair tends to be short, sparse and woolly, and the nails are thickened and dystrophic. Affected individuals show variable hypohidrosis, blepharitis, and growth retardation.<sup>24</sup> Plakophilin-1 is a

LOC, laryngooxychocutaneous syndrome.

structural component of the desmosomes that allows cell–cell adhesion; biopsies of affected skin show acanthosis, acantholysis, widening of the space between keratinocytes, and few poorly formed desmosomes.<sup>27</sup> Acral peeling skin syndrome, which results from mutations in *TGM5*, the gene encoding transglutaminase 5, involves subcorneal cleavage and can be confused with localized EB on the hands and feet.<sup>28</sup> Of note, peeling skin syndrome in an acral or generalized distribution can also result from mutations in other genes (see Chapter 5). EBS superficialis involves cleavage of the upper epidermis and stratum corneum in which superficial erosions occur and one can easily induce sheet-like peeling of skin. The mode of transmission and genetic basis remain unclear, but it is classified with the suprabasal forms of EBS.<sup>29</sup>

### JUNCTIONAL EPIDERMOLYSIS BULLOSA

Junctional EB (JEB) is a group of mechanobullous disorders in which the cleavage plane occurs in the lamina lucida at the junction of the epidermis and dermis (Table 13-3).<sup>30,31</sup> Encompassing a spectrum from severe life-threatening disease to relatively mild involvement, various subtypes of this disorder have been described, each transmitted in an autosomal recessive manner (Table 13-4). Autosomal dominant disorders (mutation on one allele) with only dental manifestations from a missense mutation in *LAMB3*,<sup>32</sup> dental issues and blistering from a missense mutation in *COL17A1*,<sup>33</sup> or the corneal erosions from a missense mutation in *COL17A1* (termed *epithelial recurrent erosion dystrophy* [ERED])<sup>34</sup> have been described.

Early diagnosis of the subtype of JEB is critical and is based on immunomapping (including detection of level of cleavage and lamina lucida proteins) and if available, genotyping. Immunomapping studies of sections from skin adjacent to a freshly induced blister show cleavage at the lamina lucida level. Electron microscopic evaluations reveal markedly reduced or absent hemidesmosomes, anchoring structures that span the lamina lucida of the basement membrane of skin and mucosae.

**Table 13-4** Characteristics of Major Forms of Junctional Epidermolysis Bullosa

Type	Clinical Manifestations
JEB, generalized severe (formerly Herlitz)	50% of patients die by 2 years old Blisters heal with atrophic scarring but no milia Periungual and fingerpad blistering, erythema Blistering of oral and esophageal mucosae Laryngeal and airway involvement with early hoarseness Later, perioral granulation tissue with sparing of lips Anonychia Dental enamel hypoplasia, excessive caries Growth retardation Anemia
JEB, generalized, intermediate (formerly non-Herlitz)	Less severe, but similar manifestations to Herlitz type, including dental, nail and laryngeal involvement Granulation tissue is rare Perinasal cicatrization Less mucosal involvement Alopecia Anemia but not as severe as JEB, generalized severe
JEB, localized	Localized blisters without residual scarring or granulation tissue Minimal mucosal involvement Dental and nail abnormalities as in JEB, generalized severe
JEB, generalized with pyloric atresia	Usually lethal in neonatal period Generalized blistering, leading to atrophic scarring May be born with large areas of cutis aplasia No granulation tissue Nail dystrophy or anonychia Pyloric atresia, genitourinary malformations Rudimentary ears Dental enamel hypoplasia (survivors) Variable anemia, growth retardation, mucosal blistering

JEB, Junctional epidermolysis bullosa.

In the severe generalized form of JEB (formerly called JEB-Herlitz), blistering begins at birth and death occurs in 45% by 1 year of age and 54% by 2 years of age.<sup>35</sup> Survival into adulthood is common for most other forms of JEB but has been occasionally described for individuals with the severe generalized type of JEB.

Severe generalized JEB is characterized by the generalized distribution of blisters and large erosions mainly on the buttocks, perioral area, trunk, and scalp. Blistering is almost always present at birth (see Fig. 13-2). Blistering of the fingertips with sloughing of the nails (Fig. 13-10) and perioral involvement (Fig. 13-11) with sparing of the lips are important if not diagnostic features of the junctional forms of EB. Granulation tissue, especially of the perioral region, is characteristic of this severe form (and laryngooxychocutaneous [LOC] syndrome), and is usually present by a few years of age. Sites of healing tend to be atrophic but show far fewer milia than the dystrophic forms. The mucous membranes are affected, especially the oral mucosae. Hoarseness and laryngeal involvement are common, and airway involvement may lead to death. The genitourinary and gastrointestinal tracts are often affected as well. The teeth are dysplastic, and a cobblestone appearance to the dental enamel is characteristic. Severe growth retardation and recalcitrant anemia are common. Mutations in this severe generalized form always affect a gene encoding one of the three chains of laminin 332 (*LAMA3*, *LAMB3*, and *LAMC2* encoding  $\alpha 3$ ,  $\beta 3$ , and  $\gamma 2$  chains, respectively).

**Figure 13-10** Generalized severe junctional epidermolysis bullosa (JEB). Blistering of the fingertips with periungual erythema and sloughing of the nails is characteristic of JEB.

**Figure 13-12** Junctional epidermolysis bullosa, pyloric atresia type. The rudimentary ears and extensive denudement of the extremities is typical of this type of epidermolysis bullosa. This baby had a mutation in the gene encoding integrin  $\beta 4$ .

**Figure 13-11** Generalized severe junctional epidermolysis bullosa. Perioral blistering with formation of granulation tissue is characteristic. Note that the lips are relatively spared, but the teeth show enamel dysplasia.

Generalized intermediate or localized JEB, may also result from less deleterious mutations in one of the laminin 332 genes. Mutations in the  $\alpha 3$  chain of laminin 332 can lead to the localized form, LOC syndrome (Shabbir syndrome).<sup>36,37</sup> LOC syndrome occurs most often in the Punjab region of India and Pakistan. It features excessive granulation tissue of the larynx (leading to hoarseness and potentially airway obstruction), conjunctival granulation tissue (leading to symblepharon, corneal scarring, and potentially blindness), and erosive blisters most commonly on the face and neck. Death is common because of respiratory-tract involvement. JEB inversa presents with blisters predominantly in intertriginous areas (axillary areas and groin). Mucosal blistering tends to be variable in extent but less than in the generalized forms. A rare form, JEB with respiratory and renal involvement, shows limited skin blistering on the legs and buttocks but congenital nephrotic syndrome and severe neonatal respiratory distress with interstitial pneumopathy. The disorder results from biallelic mutations in the gene encoding integrin  $\alpha 3$ , and affected infants die within the first months of life.

Generalized intermediate JEB (previously called *non-Herlitz* JEB or *generalized atrophic benign EB* [GABEB]) most commonly affects the gene encoding BP180 (collagen XVII; COL17A1) but occasionally reflects at least one missense mutation in a gene encoding laminin 332. In general, the features tend to be less severe than in the severe generalized form, but granulation tissue is rarely seen and EB nevi are

common. EB nevi are dark, irregular hyperpigmented patches that may be worrisome dermoscopically<sup>38</sup> but show benign nevi or increased basal pigment deposition histologically<sup>39,40</sup> and clear spontaneously during the subsequent months to years. Diffuse alopecia (scarring or nonscarring) is a key feature of this form, and narrowing of the nares is often seen. Squamous cell carcinoma (SCC) occasionally occurs in affected areas later in life; the occurrence of these features that are not typically seen in the severe generalized form may reflect the greater lifespan in this form.

JEB with pyloric atresia results from mutations in either  $\alpha 6$  integrin (*ITGA6*) or its hemidesmosome partner,  $\beta 4$  integrin (*ITGB4*).<sup>16</sup> Blistering is generalized at birth, often with large areas of cutis aplasia. Other features in addition to pyloric atresia are rudimentary and malformed ears (Fig. 13-12) and genitourinary tract malformations, attesting to the important role of  $\alpha 6\beta 4$  integrin in the development of the ears, pylorus, and genitourinary tract. Less commonly, EB with pyloric atresia results from plectin abnormalities. A late-onset form of JEB has been described with onset in young adulthood or later; nails are dystrophic or absent and dental enamel is hypoplastic, but blistering is milder than in other junctional forms. Patients may have hyperhidrosis and absent dermatoglyphics.

### Dystrophic Epidermolysis Bullosa

The scarring (dystrophic) types of EB are predominantly divided into dominant dystrophic epidermolysis bullosa (DDEB) and recessive dystrophic epidermolysis bullosa (RDEB) forms with varying degrees of severity (Tables 13-5 and 13-6). The recessive forms have been further subdivided into the severe generalized and generalized other forms. In general, the dominant forms are considerably less severe; affected individuals are generally healthy, are of normal stature, and show limited blistering of the skin. The severe generalized form of RDEB, conversely, is severe and incapacitating. Functional deformities of the hands and feet result from extensive scarring, growth and development are retarded, and profound anemia and hypoalbuminemia are standard. All forms of DEB affect anchoring fibrils, critical elements for epidermal–dermal cohesion, and result from mutations in type VII collagen.<sup>41–43</sup>

### Dominant Dystrophic Epidermolysis Bullosa

Generalized dominant dystrophic epidermolysis bullosa (DDEB) usually presents at birth or shortly thereafter, although mild cases may not show blistering or nail changes until adulthood. The blisters and resultant scars and milia formation primarily involve the extensor areas of the extremities and the dorsum of the hands (see Fig. 13-15). Nail thickening, dystrophy, or complete nail destruction are seen in 80% of cases (Fig. 13-13).<sup>44</sup> Although mucous membrane lesions appear in 20% of cases, they tend to be mild and not problematic. The teeth and hair are generally not affected, and physical development is normal. Some forms of DDEB are localized, including localized to the

**Table 13-5** Classification and Cause of Major Forms of Dystrophic Epidermolysis Bullosa

Type	Inheritance	Gene Defect
Dominant		
DDEB, generalized	AD	<i>COL7A1/collagen VII</i>
DDEB, rare types: acral, pretibial, pruriginosa, nails only, bullous dermolysis of newborn	AD	<i>COL7A1/collagen VII</i>
RDEB, generalized severe	AR	<i>COL7A1/collagen VII</i>
RDEB, generalized intermediate	AR	<i>COL7A1/collagen VII</i>
RDEB, inversa	AR	<i>COL7A1/collagen VII</i>
RDEB, rare types: localized, pretibial, pruriginosa, centripetalis, bullous dermolysis of the newborn	AR	<i>COL7A1/collagen VII</i>

AD, Autosomal dominant; AR, autosomal recessive; DDEB, dominant dystrophic epidermolysis bullosa; RDEB, recessive dystrophic epidermolysis bullosa.

**Table 13-6** Characteristics of Major Forms of Dystrophic Epidermolysis Bullosa

Type	Clinical Manifestations
Dominant dystrophic	Onset at birth to early infancy Blistering predominates on dorsum of hands, elbows, knees, and lower legs Milia associated with scarring Some patients develop scar-like lesions, especially on the trunk 80% have nail dystrophy
Recessive dystrophic, severe generalized	Present at birth Widespread blistering, scarring, milia Deformities: pseudosyndactyly, joint contractures Severe involvement of mucous membranes, nails; alopecia Growth retardation, poor nutrition Anemia Mottled, carious teeth Osteoporosis, delayed puberty, cardiomyopathy, glomerulonephritis, renal amyloidosis, IgA nephropathy Predisposition to squamous cell carcinoma in heavily scarred areas
Recessive dystrophic, generalized intermediate	Generalized blisters from birth with milia, scarring Less anemia, growth retardation, mucosal but more esophageal issues with advancing age

IgA, immunoglobulin A.

nails (DDEB, localized, nails only) or acral areas and/or hands and feet. The pretibial form of DDEB shows lichenoid or atrophic papules and plaques on the pretibial areas but also hand, foot, and nail involvement. DEB pruriginosa (DEB-Pr) is a poorly understood form of DEB (usually dominant) with the onset of severe associated pruritus and prurigo-like, scarred vesicles and papules primarily of the pretibial areas that is often delayed until adolescence or adulthood.<sup>45-48</sup> Bullous dermolysis of the newborn (DEB-BDN; formerly called *transient BDN*) shows skin blistering, often extensive, at birth or in early infancy (Fig. 13-14). However, blistering dramatically improves during the first months to 2 years of life, and beyond mild residual atrophy, scarring,

**Figure 13-13** Dominant dystrophic epidermolysis bullosa (DDEB). Nail dystrophy, especially of the toenails, is commonly seen in individuals with DDEB.

**Figure 13-14** Transient bullous dermatolysis of the newborn. After extensive blistering of the lower extremity at birth, no further blisters developed. Immunomapping showed the split to be in the upper dermis, and staining for type VII collagen was reduced.

and nail dystrophy and an increased risk of dental caries, ongoing blistering is not a problem. The disorder results from mild mutations in *COL7A1* and can be inherited in a dominant or recessive manner.

### Severe Generalized Recessive Dystrophic Epidermolysis Bullosa

Children with severe generalized RDEB (formerly called the *Happleau-Siemens type*) have a severe life-altering bullous disease characterized by widespread dystrophic scarring and deformity and by severe involvement of mucous membranes. RDEB may manifest as a less severe form (generalized intermediate RDEB) with less severe blistering of the skin and mucosae that may be mistaken for DDEB (Fig. 13-15); individuals with this form often begin to have problems with esophageal function in adolescence. Two other forms of RDEB have more localized cutaneous involvement. Blistering in RDEB inversa tends to involve the intertriginous axial, lumbosacral, and acral sites in addition to extensive mucosal involvement, including esophageal strictures and external auditory canal stenosis. RDEB centripetalis is a rare RDEB form that starts with limited involvement (hands, feet, nail dystrophy) but progresses with an advancing border to involve most of the extremities by mid-adulthood; face, truncal, and mucosal involvement never occur.<sup>49</sup>

Although any area of the skin may be involved in infants with generalized severe RDEB, the most commonly affected areas are the hands, feet, buttocks, scapulae, face, occiput, elbows, and knees. In older children the hands, feet, knees, elbows, and posterior neck and/

**Figure 13-15** Generalized intermediate recessive dystrophic epidermolysis bullosa. This boy and his brother had mild involvement of the hands, feet, and legs with nail dystrophy. The sites and appearance of lesions resembled dominant dystrophic epidermolysis bullosa, but the involvement in his brother and subsequent genotyping showed the biallelic mutation in *COL7A1*.

**Figure 13-16** Recessive dystrophic epidermolysis bullosa (RDEB). This young girl demonstrates the “shawl sign” of RDEB. Despite haircuts, dressings, and vigorous protection, this area has continued to be blistering and open for the past 5 years.

or upper mid-back (Fig. 13-16) are most commonly involved. Bullae may be hemorrhagic, and large areas, especially on the lower extremities, may be completely devoid of skin. When a blister ruptures or its roof peels off, a raw painful surface is evident. The Nikolsky sign (production or enlargement of a blister by slight pressure or the production of a moist abrasion by slight pressure on the skin) is often positive. Fluid contained in bullae, although at first sterile, may become secondarily infected, which can lead to sepsis; *Staphylococcus aureus* and *Pseudomonas aeruginosa* are the most common organisms.

Bullae are often followed by atrophic scars and varying degrees of hyperpigmentation or hypopigmentation. Milia overlying the scars are characteristic. EB nevi are common (see above). The hands and lower aspects of the legs are particularly susceptible to severe blistering and scarring. The fingers and toes may become fused, with resultant pseudosyndactyly in which the digits become bound together by a glove-like epidermal sac, with resulting claw-like clubbing or mitten-like deformities (Fig. 13-17). The fingers and toes become immobile (usually during the first years of life), and the wrists, elbows, knees, and ankles may become fixed in a flexed position from contractures, leading to immobility and often confinement to a wheelchair.

Oral mucosal involvement occurs soon after birth (Fig. 13-18), leading to dysphagia and limiting the ability to suck well. Erosions of the esophagus may at times result in segmental stenosis (most

**Figure 13-17** Recessive dystrophic epidermolysis bullosa. Pseudosyndactyly or mitten deformity of the foot in this young boy with extensive atrophic scarring.

**Figure 13-18** Recessive dystrophic epidermolysis bullosa. Oral mucosal blistering in a neonate.

often in the upper third) with consequent difficulty in swallowing. Gastroesophageal reflux disease often occurs, especially presenting as effortless vomiting. Constipation is common and may be related to anal fissuring, inadequate dietary fiber, and administration of iron. Affected children are reluctant to eat and often fail to thrive, given their increased nutritional needs owing to loss of protein and other nutrients through wounds. As the child grows older there is a tendency for the disease to become less severe, but the affected individual soon learns to avoid hot drinks, rough foods, and large particles that might produce blistering of the mouth, pharynx, or esophagus. Typically, patients show microstomia owing to intraoral scarring and a frenulum that is bound down. The eyes may develop blisters with associated ocular inflammation and later corneal scarring, potentially leading to visual impairment.<sup>50</sup> Hoarseness, aphonia, and even laryngeal stenosis may result from laryngeal blistering and scarring. Bone mineralization is low in patients with EB, particularly those with RDEB, probably owing to a combination of insufficient nutrition, reduced physical activity, and chronic inflammation.<sup>1,51</sup>

The teeth in RDEB are particularly susceptible to early and commonly severe caries. The progressive intraoral scarring leads to microstomia and decreased salivation.<sup>1,52</sup> Even routine dental care may cause the eruption of bullae and erosions on the lips, gingivae, and oral mucosa. The nails may show severe dystrophy or complete absence of nails. Scalp and body hair may be sparse, and there may be patches of cicatricial alopecia.<sup>53</sup>

In patients with the severe generalized form of RDEB, death may occur during infancy or childhood as a result of septicemia,

pneumonia, or renal failure. Patients with RDEB (and rarely DDEB) have an increased risk of glomerulonephritis, renal amyloidosis, and immunoglobulin (Ig) A nephropathy.<sup>1,54–56</sup> The tremendous loss of fluid, blood, and protein through the skin coupled with malnutrition can lead to hypoalbuminemia and anemia. Dilated cardiomyopathy is an uncommon complication (4.5% by 20 years of age)<sup>57</sup> but may be fatal, especially in the presence of concurrent chronic renal failure. The cause of the cardiomyopathy may be multifactorial, including from transfusion-associated iron overload, viral myocarditis, and deficiency of selenium and carnitine. Other complications of RDEB include erosions and scarring of the anal area (often resulting in severe discomfort, chronic constipation, or soiling), urethral stenosis, urinary retention, hypertrophy of the bladder, and occasionally hydronephrosis.<sup>2,54</sup>

Patients with RDEB (and to a lesser extent JEB but not DDEB) show a progressively increasing risk of developing cutaneous SCCs (7.5%, 68%, 80%, and 90% by 20, 35, 45, and 55 years of age, respectively)<sup>58</sup> in heavily ulcerated and scarred areas of skin.<sup>59</sup> These lesions are predominantly over joints and on the distal extremities and present as nodular lesions or nonhealing ulcers.<sup>60,61</sup> Suspicious masses should be biopsied to distinguish SCCs from benign lesions such as verruciform xanthoma.<sup>62,63</sup> *MMP13* expression is strongly positive in SCC but is negative in benign hyperkeratotic lesions.<sup>64</sup> Cutaneous carcinomas tend to be locally aggressive, often requiring amputation, and tend to metastasize, leading to death.

Death during childhood is most common with JEB (median age 4 to 6 months).<sup>35</sup> Sepsis, failure to thrive, and respiratory failure are the major causes of death during childhood. Children with RDEB generally survive the neonatal and infantile periods but succumb to infection later during childhood or to aggressive cutaneous carcinomas during adulthood.

### KINDLER SYNDROME

Kindler syndrome is characterized by generalized progressive poikiloderma, congenital acral skin blistering, diffuse cutaneous atrophy (Fig. 13-19), skin fragility, webbing of the fingers and toes with digital tapering, nail dystrophy, oral mucosal lesions, and photosensitivity, sometimes within minutes after exposure.<sup>65,66</sup> Other features are hyperkeratosis of the palms and soles; leukokeratosis; ectropion; red friable hyperplastic gums; constipation and sometimes severe colitis; esophageal, laryngeal, anal, vaginal and urethral meatal stenosis; and phimosis.<sup>67</sup> Although the photosensitivity and the blister formation seem to decrease with age, the atrophic scarring and poikiloderma increase. The incidence of SCC of the acral skin or mouth is increased after the age of 30 years. Because the blistering arises at multiple levels within and/or beneath the basement membrane zone, Kindler syndrome has been classified as mixed EB. Treatment of this disorder requires the avoidance of trauma and the proper use of emollients, appropriate sun protection, and the judicious use of antibiotics to

prevent secondary infection. Regular dental care and surveillance for early malignancies are important, as are iron replacement if the patient is anemic and management of the stenoses and colitis. The gene mutated in Kindler syndrome is *FERMT1* (formerly called *KIND-1*), which encodes fermitin family homolog 1 (FFH1) protein or kindlin-1, a focal adhesion protein that regulates keratinocyte cell adhesion, motility, and stem cell homeostasis.<sup>68–71</sup>

### Treatment of Epidermolysis Bullosa

As in any inherited disorder, it is the responsibility of the physician to inform parents of the risks of transmitting genetic abnormalities.<sup>72</sup> When the condition is determined by a dominant gene (as in DDEB)<sup>73,74</sup> and a parent is affected, the risk of the disorder in siblings is 50%. In a family in which a child manifests abnormalities because of a recessive gene (as in RDEB), parents risk a 25% possibility with each pregnancy of the disorder occurring in future offspring. Appropriate genetic counseling, however, depends on accurate diagnosis. Since the clinical course of many forms of EB is variable, especially during the neonatal and infantile periods, it is recommended that patients be carefully evaluated as early as possible with immunofluorescent mapping, monoclonal antibody studies, and deoxyribonucleic acid (DNA) analysis if appropriate in an effort to establish the correct diagnosis. Prenatal diagnosis of all forms of EB is now available using molecular techniques, but is easiest if the gene defect is known in that family.<sup>75</sup> The current availability of whole exome sequencing has allowed concurrent investigation of several types of EB for a fraction of the price of sequencing any one individual gene.<sup>4</sup> Preimplantation diagnosis has been performed and is an option that utilizes *in vitro* fertilization to ensure a normal fetus without the risk of abortion.<sup>76,77</sup>

The psychosocial effects of EB, especially the more severe forms, on the affected individual and family are among the most dramatic of any skin disease.<sup>72</sup> Affected children are concerned about having itchy skin, being in pain, having difficulty with participation, failing to understand others, and feeling different.<sup>78</sup> Parents of affected children worry about the child being different, the child suffering pain, feeling uncertain about the future, restrictions on employment and leisure, problems with organizing care, being constantly on duty, family problems, the ignorance and lack of skills of alternative care providers, and resistance by the child to care.<sup>79</sup> These problems should be discussed and psychological support for patients and their families offered as part of optimal care.

The treatment of EB is largely palliative, with protection from friction or overheating, avoidance of abrasion and constriction, control of secondary infection, nutritional supplementation, and pain control.<sup>80,81</sup> Because blisters result from mechanical injury, measures should be taken to relieve pressure and prevent unnecessary trauma. Clothing should be soft and worn inside out. Labels that may rub the skin should be removed. Velcro closures are less traumatizing than other traditional closures. Mittens can be worn to minimize self-induced trauma. Shoes should be soft and fit well; leather shoes with leather linings, ideally with external seams (e.g., moccasins), are usually recommended.<sup>72</sup> During the summer, canvas shoes and jelly sandals are the best choices. Shoes should be large enough to accommodate dressings and minimize friction. Insoles can be made from cooling gel, sheepskin, or protective dressings. Affected babies can be lifted and moved on a soft pad, and the bathtub can be lined with a thick towel. A cool environment and lubrication of the skin to decrease surface friction are helpful in the reduction of blister formation. When blisters occur, extension may be prevented by aseptic aspiration of blister fluid. The roofs of blisters should be left intact whenever possible to protect the underlying skin.

Keeping palms and soles with EBS cool and dry helps to minimize blistering, especially during hot weather. Hyperhidrosis is often a concomitant feature, and measures to minimize the increased blistering associated with hyperhidrosis can be helpful. These include applying 20% aluminum chloride hexahydrate at night and gently drying the area with a cool hair dryer, wearing socks that absorb moisture,<sup>72</sup> and sprinkling of affected areas with absorbent powder such as Zeasorb. For extreme cases and in older patients with the localized form of EBS, injections of botulinum toxin A have been advocated.<sup>82</sup> Silver-impregnated socks can decrease infections and increase foot comfort.

**Figure 13-19** Kindler syndrome. This boy shows poikiloderma, cutaneous atrophy, webbing of the fingers, and nail dystrophy.

**Figure 13-20** Recessive dystrophic epidermolysis bullosa (RDEB). Non-adherent dressings should be placed between the fingers and toes of children with RDEB to reduce the risk of pseudosyndactyly. Note the scarred skin and anonychia.

A water mattress and a soft fleece covering will help to limit friction and trauma. Daily baths and topical application of protective petrolatum to eroded areas or, especially if slightly crusted, antibiotic ointments (usually bacitracin, mupirocin, or gentamicin) are helpful. Protective dressings that do not adhere to wounds should be applied to eroded areas to promote healing but prevent further denudation when dressings are changed (e.g., petrolatum-impregnated gauze, Telfa, Mepilex, Mepilex Transfer, Mepitel, Restore).<sup>83</sup> In children with RDEB, dressings should be carefully placed between the digits, although the ameliorative effect of this practice to decrease the risk of pseudosyndactyly (Fig. 13-20) has not been tested. Sterile precautions must be taken when changing dressings to reduce the risk of bacterial infection. Tape and any significant pressure to skin must be avoided. Dressings can be held in place by rolled gauze (such as Kerlix) or loose self-adherent wraps) with tape only applied to the dressing itself or by stockinette (such as Surgifix or Spandage). Dressings with silver have helped patients with recurrent infections, but application of silver sulfadiazine has been associated with argyria.<sup>84,85</sup> Families need to weigh the antiinfective benefits with the risk of potentially high blood levels of silver.<sup>86</sup> Bacteriostatic dressings with methylene blue and crystal-violet dyes (such as Hydrofera blue) and medical-grade honey<sup>87</sup> are also available. Crusted or purulent areas should be cultured and treated based on the sensitivity of organisms. Topical application of mupirocin and/or gentamicin ointments may be useful for limited areas of crusting (see mention of *readthrough* with gentamicin ointment below). More extensive involvement requires administration of systemic antibiotics. Excessive usage of systemic antibiotics, however, should be avoided because of the high risk of development of resistance. Gentamicin soaks (480 mg/L saline), acetic-acid soaks (diluted white vinegar), and addition of small amounts of bleach to the bathwater (e.g.,  $\frac{1}{4}$  to  $\frac{1}{2}$  cup per tub) have been used to decrease the overgrowth of *Pseudomonas* and staphylococcal organisms. The risk of sepsis with cutaneous infection is high in neonates and infants, and patients should be monitored carefully. Topical and systemic steroids are generally not useful for patients with EB and should be avoided in view of their promotion of infection and other side effects. However, limited application of potent topical steroid, or oral thalidomide has been helpful for the granulation tissue of laminin 332 defects.<sup>88</sup>

Pain control is an important component of EB care, especially in affected infants. The changing of dressings at blistered sites is excruciatingly painful for patients yet must be performed from a few times weekly to up to twice daily, depending on the extent of drainage and the presence of infection. In one study, saltwater baths led to a significant reduction in pain and pain medication use in 91% and 66%, respectively, of 16 children with primarily RDEB.<sup>89</sup> Methadone and liquid cough suppressants with dextromethorphan have been used to relieve discomfort in infants. For older children, acetaminophen with

codeine, oral midazolam, or morphine has been used before dressing changes and baths to improve tolerance. Amitriptyline and cognitive behavioral techniques have also been suggested to relieve the chronic pain and discomfort.<sup>90</sup>

Overall 85% of patients with EB complain of pruritus, which can be more problematic on a five-point Likert scale than pain.<sup>91</sup> The itch is less problematic with EBS than with the more severe JEB and DEB types and can interfere with sleep. Exacerbants are healing wounds, a hot environment, infection, high humidity, and stress. Antihistamines and topical creams and ointments are of limited value,<sup>80,92</sup> but short-term courses of mid-potency topical steroids and as second-line agents, low-dose gabapentin or pregabalin can be considered.<sup>80</sup>

Nutritional supplementation is critical for patients with the more severe forms of EB to prevent failure to thrive, which has been linked to mortality in 20.5% of patients with generalized severe JEB by 2 years of age. The loss of protein, iron, and blood through the open areas of skin leads to hypoalbuminemia and deficiency of iron and trace minerals. Furthermore, the chronic disruption of the epithelial lining of the small intestine leads to gross malabsorption of nutrients, and the pain with ingestion of food decreases intake. Consultation with a nutritionist is important to maximize caloric and protein intake and provide specific nutrients and vitamins such as iron, zinc and vitamin D<sub>3</sub>. Oral iron may be poorly tolerated by the gastrointestinal tract, and constipation is a potential issue; intravenous administration of iron or blood transfusions may be needed to maintain a hemoglobin (Hgb) level of at least 8 g/dL in severely affected children. Soft nipples such as the Haberman feeder should be used, with the opening enlarged to minimize the need for sucking. The lips should be protected with petrolatum before initiating feeding. In general, nasogastric-tube feeding should be avoided, or if necessary, a tube suitable for long-term feeding should be used. Placement of a button gastrostomy tube should be considered in infants who start to drop off of their growth curve, as a means of supplemental feeding to increase caloric intake and as an alternative route to oral feeding; early gastrostomy placement should be considered for severe generalized forms of JEB and RDEB. Regular dental intervention is essential to decrease caries; teeth can be cleaned with soft, moist gauze and rinses of chlorhexidine<sup>93</sup>; some advocate use of MI Paste for the teeth. Endosseous implants have been placed successfully in patients with EB.<sup>94</sup>

Dysphagia is the major symptom of esophageal involvement in RDEB.<sup>95,96</sup> It may result from a reversible inflammatory reaction or from a permanent stricture. Barium studies demonstrate esophageal lesions; endoscopy, however, is not recommended. Softening of the diet for several weeks may result in modest to marked improvement of symptoms. If conservative management fails to result in proper nourishment, esophageal dilation, ideally through fluoroscopic guidance, should be performed and may be repeated if stenosis recurs. Esophageal perforation is the most serious complication of dilation. Surgery is an alternative, through colonic interposition and resection of localized strictures with end-to-end anastomosis, but the procedures carry a high risk. Gastroesophageal reflux may be exacerbated by esophageal dilation but responds to medical management with thickening of the milk, histamine 2 receptor (H2)-blockers, proton pump inhibitors, or promotility agents. Constipation is usually managed by maintaining adequate fluid intake and dietary fiber and by administering laxatives such as polyethylene glycol 3350 (MiraLax). Restoration of function in severe fusion and flexion deformities of the hands and feet can often be helped by physiotherapy and appropriate plastic surgery, especially to separate the thumb and straighten digits.<sup>97</sup> However, partial recurrence is the norm, especially on the nondominant hand. Healing in these “degloving” procedures may be facilitated by application of biologic dressings with the tissue-engineered skin substitutes and autologous epidermal grafts to the wounds (Fig. 13-21).<sup>98-100</sup> Anesthesia management for procedures is complicated, but may include mask anesthesia, endotracheal tube, intravenous sedation, and local anesthetic blocks.<sup>101,102</sup>

With repeated blistering, ulceration, and scar formation, SCCs may sometimes develop on the involved skin or mucous membrane, particularly in RDEB and to a lesser extent generalized JEB. Wounds that fail to heal or appear atypical, especially in affected adults, deserve biopsy to consider the possibility of SCC. SCCs rarely appear on the

**Figure 13-21** Biologic dressings for epidermolysis bullosa. Biologic dressings can be used selectively to promote healing of denuded areas.

tongue or esophagus. The accumulative risk in RDEB is 13% by 20 years of age, 57% by 35 years, and 87% by 45 years of age.<sup>2</sup> Melanoma may arise in children with RDEB, and the risk of developing basal cell carcinomas seems to be increased in adults with generalized severe EBS. Early intervention using full-thickness excision with wide margins is key.<sup>103,104</sup> Mohs surgery offers no long-term benefit in decreasing local recurrence, metastases or death. Amputation is required in 42% of patients with RDEB and SCC, with approximately equal outcomes on the hands and legs. Surgical debulking and radiation therapy are palliative to reduce pain or bleeding. Recently, cetuximab (epidermal growth factor receptor [EGFR] antagonist) has controlled SCC metastasis in a patient.<sup>80,105,106</sup>

During the past few years, considerable research has shown the value of protein and gene replacement for the recessive forms of EB in animal models.<sup>107</sup> Intradermal injection of allogeneic fibroblasts temporarily stimulates increased expression of type VII collagen from the patient (not donor) fibroblasts, especially in patients who have RDEB with less severe disease.<sup>108–110</sup> Recombinant type VII collagen, whether intralesional, intravenous, or topical, has been shown to home to the dermal–epidermal junction of wounded skin in mouse models and decrease blistering.<sup>111–114</sup> Intradermally injected recombinant type VII collagen is currently approved for early human trials; studies with intravenous and topical administration are planned. One potential concern is that overexpression of type VII collagen in RDEB SCC cell keratinocytes increased cell invasion,<sup>115</sup> raising the caution that giving high concentrations of type VII collagen may increase cancer-associated risks. In patients with null mutations, it is possible that topical gentamicin may lead to “readthrough,” essentially skipping the stop codon and allowing full-length gene expression, as has been demonstrated *in vitro*.<sup>116</sup>

Stem cell transplantation, more recently with the use of mesenchymal stem cells and reduced-intensity conditioning regimens, has led to the transfer of cells producing collagen VII to the basement membrane and clinical improvement in patients with RDEB<sup>117</sup> and severe generalized JEB. Two commercially available drugs, AMD3100 and tacrolimus, have recently been shown in combination to mobilize stem cells to skin wounds, leading to the possibility of mobilizing more stem cells toward EB wounds after transplantation with this combination.<sup>118,119</sup> Transplantation of viral vector gene-corrected cultured epidermal stem cells from a patient with non-Herlitz JEB led to persistent, normal-appearing skin (now almost 7 years later).<sup>120,121</sup> In an effort to avoid the risk of insertional mutagenesis with viral vectors, transcription activator-like effector nuclease (TALEN) technology has been used *in vitro* to target specific mutations in *COL7A1* for nuclelease-induced double-stranded DNA break and homologous recombination with the normal gene sequence.<sup>122</sup> More recently, cells from a patient with RDEB were made into induced pluripotent stem cells (iPSCs), corrected by adenovirus-associated genome editing, and after removal of any cells with mutations predisposing to cancer, allowed to differentiate into keratinocytes.<sup>123</sup>

Individuals with EB may have “revertant mosaicism,” in which a second gene change in a localized area leads to functional and clinical normalization (Fig. 13-22)<sup>124,125</sup> or nonrevertant mosaicism, in which

**Figure 13-22** Recessive dystrophic epidermolysis bullosa with revertant mosaicism. Note that the right side of the back shows no blistering, in contrast to the extensively blistered and scarred left side of the back. This clear area of revertant mosaicism only became visible for assessment after years of blistering and residual inflammation and scarring.

a gene change in some but not all somatic cells either leads to a mosaic dominant disorder (one allele affected) or converts a carrier state into a recessive disorder (both alleles affected) at the involved sites, as has recently been described for RDEB.<sup>126</sup> Detection of normal-appearing skin sites, which are most common in generalized intermediate JEB because of mutations in *COL17A1*, allows an unlimited source of cultured keratinocytes, fibroblasts, or even iPSCs for stem cell transplantation or for grafting.<sup>125,127</sup>

## Immune-Mediated Blistering Disorders

The chronic nonhereditary bullous diseases of childhood are a group of largely autoimmune disorders with autoantibodies directed against structural components of the skin. Diagnosis is based on clinical characteristics and histologic and immunofluorescent features of skin biopsy specimens.<sup>128</sup> Treatment of autoimmune blistering disorders (which tend to be quite rare overall in children) usually requires systemic immunosuppressive agents. In general, pemphigus, mucous membrane pemphigoid, and EBA are more challenging to manage.

### PEMPHIGUS

*Pemphigus* is a term applied to a group of severe, chronic, sometimes fatal blistering disorders characterized by flaccid bullae that develop on normal-appearing skin and mucous membranes. Pemphigus can be classified into pemphigus vulgaris, pemphigus foliaceus, IgA pemphigus, drug-induced pemphigus, and paraneoplastic pemphigus. The blister formation in pemphigus results from acantholysis, which is loss of cohesion between epidermal cells owing to intercellular edema and the disappearance of intercellular bridges in the lower epidermis. The structural components against which autoantibodies are generated in pemphigus are all components of desmosomes.

#### Pemphigus Vulgaris

Pemphigus vulgaris is a potentially life-threatening chronic vesiculobullous disease characterized by flaccid bullae and persistent erosions with a predilection for middle-aged individuals. An extremely uncommon disorder of childhood, the prognosis is better in children than in adults.<sup>129</sup> The cutaneous lesions of pemphigus vulgaris favor the seborrheic areas (the face, scalp, neck, sternum, axillae, groin, and periumbilical regions) and pressure areas of the feet and back (Fig. 13-23). The oral mucosae are affected in 95% of patients and are the initial site in the majority of patients, often months before the appearance of skin lesions. Intact blisters are rarely seen on the oral mucosa, because they rupture soon after formation, leaving raw denuded painful erosions that heal slowly. Other mucosal surfaces, the

**Figure 13-23** Pemphigus vulgaris. The cutaneous bullae and erosions are uncommon in children. The most common manifestation of pemphigus vulgaris is oral mucosal blistering. (Courtesy of Moise Levy, MD.)

anogenital areas, conjunctivae,<sup>130</sup> vermillion borders of the lips, pharynx, and larynx may be similarly involved. Pemphigus in children can involve the esophagus and ileum, leading to protein-losing enteropathy.<sup>131</sup> Because a majority of patients with proven pemphigus vulgaris have painful oral erosions for weeks to months before they develop the characteristic bullous eruption (and the disease may be limited to mucosae), children with severe recurrent mucocutaneous lesions or chronic erosive mucous membrane disease should be examined carefully.<sup>132</sup> Mucosal biopsy should be performed if skin lesions are not present.

The primary cutaneous lesions of pemphigus vulgaris appear as vesicles or bullae that arise on erythematous plaques or normal-appearing skin. The initial lesions may remain localized to one area of the skin or mucous membrane for weeks or months before other areas of the skin are involved. With the onset of new lesions, the patient may experience some pruritus, burning, or local discomfort. Blisters generally measure 1 cm or less at onset but may increase by peripheral extension to several centimeters in diameter. Lateral pressure applied to the normal-appearing skin at the periphery of a lesion results in lesional extension and shearing of skin (the Nikolsky sign). This phenomenon, a manifestation of defective epidermal cohesion, is not pathognomonic of pemphigus, since the Nikolsky sign may also be seen in patients with superficial forms of EB, BP, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Vertical pressure may also produce peripheral extension of lesions. The blisters rupture easily, and the resultant erosions are painful, bleed easily, and heal slowly. Scaling and crusting are common, and patients commonly are misdiagnosed as having impetigo or infected seborrheic dermatitis.

A variant of pemphigus vulgaris, pemphigus vegetans, is differentiated by the hypertrophic granulomatous tissue (vegetations) after healing and the tendency for predilection for the face, flexural, and intertriginous areas. Patients commonly show small pustules at the periphery of ruptured bullae.<sup>133</sup>

Routine histologic evaluation, as well as direct immunofluorescent (DIF) and indirect immunofluorescent (IIF) assays and enzyme-linked immunosorbent assay (ELISA) provide complementary studies to diagnose and monitor the course of pemphigus vulgaris. The earliest histologic change is intercellular edema with loss of cohesion between epidermal cells, resulting in the formation of clefts and bullae in a suprabasal location. The basal cells, although separated from one another, remain attached to the dermis with a resultant "row of tombstones" appearance. A rapid Tzanck smear will show acantholytic cells.<sup>134</sup> DIF tests on biopsied samples show IgG and complement bound to intercellular areas of the epidermis. IIF studies of the serum of patients with pemphigus vulgaris show IgG antibodies binding to the intercellular spaces. The targeted structural antigen in patients with only mucosal pemphigus is desmoglein 3, a desmosomal component expressed in the mucosa and lower region of the epidermis, and the presence of antibody can be tested by ELISA. Desmoglein 1 can

**Figure 13-24** Pemphigus foliaceus. Children with pemphigus foliaceus are often thought to have impetigo and treated unsuccessfully with courses of antibiotics as a result; the target of this immunobullous disorder, desmoglein 1, is the same target as the exfoliatin produced by *S. aureus* infection.

compensate for desmoglein 3, and antibodies against both desmogleins must be present for both mucosal and skin blistering to occur in pemphigus. Increases in antidesmoglein antibody titers may precede clinical flares and decreases in titer correlate with clinical responses. ELISA assays with anti-desmoglein 1 and to a lesser extent, anti-desmoglein 3 antibodies have correlated with disease activity better than indirect immunofluorescence assays in some studies.<sup>135-138</sup>

A transient form of pemphigus vulgaris, neonatal pemphigus vulgaris, may be seen in neonates of pregnant women with circulating anti-desmoglein 3 antibodies, even without active mucocutaneous disease. Blistering subsides in affected neonates within a few weeks, concomitant with the catabolism of maternal antibodies.<sup>139-142</sup>

### Pemphigus Foliaceus

Pemphigus foliaceus (superficial pemphigus) is a more superficial form of pemphigus.<sup>143</sup> The disease most commonly affects middle-aged persons and although rare in children, is more common than pemphigus vulgaris in prepubertal children. The disorder in children is more benign than that in adults, and the course is milder than that of pemphigus vulgaris.

Bullae, when seen, are usually small and flaccid. They rupture easily, and because of their superficial location leave shallow erosions. Slowly spreading crusted plaques thought to be impetigo but resistant to oral antibiotics are the most common presenting manifestation (Fig. 13-24). Patients often show an arcuate configuration to lesions. Common areas of erosive involvement include the scalp,<sup>144</sup> face, upper chest, abdomen, and back. Bullae are more likely to be intact if located on the lower extremities. Patients generally are not severely ill but may rarely complain of pruritus, pain, and burning. At times, however, the clinical picture may progress to resemble that of a severe generalized exfoliative dermatitis. Oral lesions are rarely seen in pemphigus foliaceus and when present, usually consist of small, superficial, often inconspicuous erosions.

Histologic findings in pemphigus foliaceus are similar to those of pemphigus vulgaris and demonstrate epidermal bullae and intercellular acantholysis of the epidermis. The acantholysis seen in pemphigus foliaceus, however, is more superficial and occurs in the upper epidermis, usually in the granular layer or just beneath it, with resultant formation of clefts in a superficial, often subcorneal, location. DIF shows an intracellular deposition of IgG and C<sub>3</sub> that is indistinguishable from that of pemphigus vulgaris. The targeted antigen is desmoglein 1, a desmosomal component localized to the suprabasal keratinocytes, which is also the target of bacterial exfoliative toxins in patients with bullous impetigo and staphylococcal scalded skin syndrome (see Chapter 14).<sup>145</sup> Although desmoglein 1 is also found in the mucosa, desmoglein 3 at this location provides stabilization, and patients with pemphigus foliaceus, as a result, do not tend to have oral

mucosal lesions.<sup>146</sup> Neonatal pemphigus has not been observed in infants born to mothers with active fogo selvagem (IgM and IgG4 do not cross the placenta<sup>147</sup>) but has been described in babies of mothers with sporadic pemphigus foliaceus and high titers of anti-desmoglein 1 antibodies.<sup>148–150</sup>

Pemphigus erythematosus (Senear–Usher syndrome) is a variant of pemphigus foliaceus in which lesions often localize to the butterfly area of the face, the scalp, upper chest, and back. Patients may show detectable antinuclear antibodies.<sup>151,152</sup> Fogo selvagem (endemic pemphigus; Brazilian pemphigus) is a variant of pemphigus foliaceus found in tropical regions but is clinically and immunologically indistinguishable from sporadic pemphigus foliaceus.<sup>153</sup> Certain human leukocyte antigen (HLA) alleles and exposure to certain blood-sucking insects are risk factors. Patients with fogo selvagem show pathogenic anti-desmoglein 1, IgG4, and IgM autoantibodies,<sup>154,155</sup> which may develop as a result of antigenic mimicry initiated by an environmental stimulus in predisposed persons.<sup>156</sup> Endemic in Brazil and to a lesser extent in other South American countries, 15% of patients are children. The striking distribution of lesions on sun-exposed skin, its burned appearance, and the painful burning sensation in lesions (more so than in sporadic pemphigus foliaceus) are responsible for the name *fogo selvagem* (Portuguese, meaning *wildfire*). In chronic cases hyperpigmentation, hyperkeratosis, and loss of hair over the scalp and body are prominent features of this disorder.

### Drug-Induced Pemphigus

Drug-induced pemphigus is particularly rare in children. The most commonly implicated agents are penicillamine and captopril (both thiol drugs), but other drugs have also been implicated (Box 13-1). Sulfhydryl groups are thought to interact with the sulfhydryl groups in desmogleins 1 and 3, thus modifying the antigenicity of the desmoglein. In contrast to other types of drug reactions, drug-induced pemphigus often requires several months of exposure to the medication before onset. Initially a nonspecific morbilliform, annular, or urticarial eruption may be seen, eventually evolving after a variable latency period into the blistering process. The disorder typically resembles pemphigus foliaceus more often than pemphigus vulgaris. Oral lesions are rare.

### Immunoglobulin A Pemphigus

Immunoglobulin A (IgA) pemphigus, characterized by the intercellular deposition of IgA rather than IgG autoantibodies, has been divided into the subcorneal pustular dermatosis form and intraepidermal neutrophilic IgA dermatosis based on the subcorneal or intraepidermal localization of the blister histologically. Both conditions clinically show vesicles, small bullae, and pustules overlying well-circumscribed erythema. IgA pemphigus resembling pemphigus vegetans has also been described.<sup>157</sup> The youngest reported patient was 1 month of age.<sup>158</sup> The autoantigen for the subcorneal pustular dermatosis form has been shown to be the desmosomal protein desmocollin 1.<sup>159</sup> Although circulating antibodies against either desmoglein 1 and desmoglein 3 have been identified in patients with intraepidermal neutrophilic IgA dermatosis, other patients have shown no identifiable autoantigen.<sup>160–162</sup>

The pustular form may be the same disorder as subcorneal pustular dermatosis (Sneddon–Wilkinson disease), a condition that rarely occurs in children, although it has been described in individuals as young as 7 weeks of age.<sup>163</sup> The disease generally begins with small pustules or vesicles on an erythematous base. Occasionally only vesicles may be present, but these soon change into sterile pustules. The

pustules tend to appear in crops and spread to large parts of the body, forming large circinate or gyrate patterns that coalesce to form serpiginous patterns, especially on the abdomen, axillae, and groin. Individual lesions tend to last for periods of 5 days with new lesions appearing as others disappear. As the pustules resolve they are replaced by a superficial leafy scale or crust. After the eruption resolves, a faint blotchy brown hyperpigmentation without atrophy or scarring remains. The condition is benign and is characterized by remissions and exacerbations that may last for 5 to 8 years. Histopathologic examination of an intact lesion of subcorneal pustular dermatosis reveals a subcorneal blister filled almost entirely with neutrophilic polymorphonuclear leukocytes, but immunofluorescence analysis shows no immunodeposits.

### Paraneoplastic Pemphigus

Paraneoplastic pemphigus, a rare autoimmune disorder associated with malignancy, has been described occasionally in children.<sup>164,165</sup> The majority of pediatric patients have underlying Castleman disease, a lymphoproliferative disorder characterized by massive growth of lymphoid tissue usually located in the retroperitoneum or mediastinum.<sup>166,167</sup> Sarcoma, T-cell lymphoblastic lymphoma, and myofibroblastic tumor may also underlie paraneoplastic pemphigus; occasionally no underlying tumor is detected.

All patients tend to show intractable stomatitis, particularly involving the labial mucosa and resembling the labial manifestations of Stevens–Johnson syndrome. Two-thirds of patients show conjunctival involvement sometimes leading to symblepharon and visual impairment. Skin changes can be bullous and/or may resemble lichen planus or erythema multiforme. The trunk and extremities are most commonly involved. Palmoplantar involvement and paronychial inflammation, which may result in nail shedding, are commonly seen. Mucosae of the tracheobronchial system are also involved, and respiratory involvement with the development of bronchiolitis obliterans may be fatal.<sup>168</sup>

Biopsies show intraepithelial acantholysis, keratinocyte dyskeratosis, and basal cell vacuolar changes, combining the histologic features of pemphigus and Stevens–Johnson syndrome. Direct immunofluorescence is often negative, but immunoblots show several circulating autoantibodies directed against a variety of epidermal proteins, particularly of the desmogleins and plakin family (BP antigen 1, DSP, envoplakin, and periplakin).

Paraneoplastic pemphigus must be distinguished from Stevens–Johnson syndrome, toxic epidermal necrolysis, pemphigus vulgaris, bullous and cicatricial forms of pemphigoid, lichen planus pemphigoides, and mucosal infections from herpes or candida. Once the diagnosis is suspected in a child or adolescent, evaluation for malignancy should be initiated. Complete physical examination, particularly of the liver, spleen, and lymph nodes; complete blood count; serum protein electrophoresis; and computerized tomographic scans of the chest, abdomen, and pelvis should be performed to seek evidence of malignancy.

### Treatment of Pemphigus

A support group for patients with pemphigus can be accessed at [www.pemphigus.org](http://www.pemphigus.org). The treatment of choice for pemphigus vulgaris has been systemic corticosteroid therapy given either as high doses orally (1 to 2 mg/kg per day) or as intravenous pulses.<sup>169</sup> In one study, intervention led to complete recovery in only 18% of children, although partial improvement with minor relapses in 79%.<sup>170</sup> The majority of children with pemphigus developed serious side effects from their immunosuppression, including cushingoid features in 65% and growth retardation in 50%, stressing the need for steroid-sparing agents.<sup>171–173</sup> Rituximab (monoclonal anti-CD20 antibody) has now been used as an alternative off-label agent for children as young as 18 months of age<sup>174</sup> with dramatic clinical results and long-term remission.<sup>175,176</sup> In one study with 10 children, complete remission was achieved with single-agent rituximab by a mean of 21 weeks; relapses occurred in about half of the children, but a repeat cycle led to good response when used.<sup>175</sup> Infusion reactions are the most common side effect. Other steroid-sparing agents for pemphigus vulgaris are dapsone,<sup>177</sup> mycophenolate mofetil (600 to 1200 mg/m<sup>2</sup> per day),<sup>178,179</sup> cyclosporine (5 mg/kg per day), methotrexate,<sup>180</sup> azathioprine (2 to

4 mg/kg per day),<sup>181</sup> or high-dose intravenous immunoglobulin,<sup>182,183</sup> and can be added to allow the corticosteroid to be tapered, although each of these agents has significant potential side effects.

Pemphigus foliaceus is a milder disorder. Suprapotent topical corticosteroids may be effective in some patients, but often treatment with dapsone with or without systemic corticosteroids (initially 1 mg/kg per day) may be required for clearance. In all forms of pemphigus, therapy should be tapered gradually as tolerated when improvement is noted, which may require several months in severe cases.<sup>184</sup> Although patients with Brazilian pemphigus (*fogo selvagem*) may respond to antimalarial therapy (quinine or quinacrine), systemic corticosteroids continue to be the treatment of choice. Once the disease has cleared, pemphigus foliaceus has a lesser tendency to recur than pemphigus vulgaris.

Drug-induced pemphigus usually clears with treatment of the pemphigus and withdrawal of the offending medication. IgA pemphigus in children usually responds to treatment with dapsone or sulfapyridine within 24 to 48 hours but tends to be more difficult to control with steroids and other systemic anti-inflammatory agents. Oral retinoids have been used in patients with IgA pemphigus who do not respond to systemic administration of corticosteroids and dapsone.<sup>185</sup>

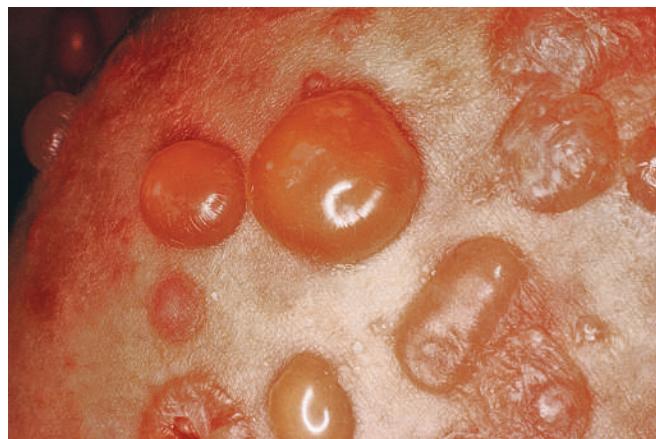

Patients with paraneoplastic pemphigus often have their conditions clear or improve significantly with surgical removal of the Castleman disease, but not until 6 to 18 months after tumor removal. The prognosis is much worse with malignant neoplasms. The majority of patients succumb within months of the diagnosis, usually to respiratory failure or secondary infection. Aggressive treatment of the malignancy coupled with immunosuppressive therapy such as the combination of systemic corticosteroids and cyclosporine should be initiated but may not affect the prognosis. Plasmapheresis has been used in conjunction with corticosteroids and tumor resection.<sup>186</sup>

## BULLOUS PEMPHIGOID

BP is a blistering disorder characterized by large, tense, subepidermal bullae that appear on normal-appearing or erythematous skin.<sup>187</sup> Although usually seen in elderly persons, BP may also occur occasionally in infants<sup>188</sup> and children,<sup>189–192</sup> the youngest reported being a 1-month-old infant.<sup>191,193</sup> Several infantile cases have been described after vaccination<sup>194–198</sup> or primary varicella infection.<sup>199</sup> Childhood BP has been described as a manifestation of chronic renal allograft rejection.<sup>200</sup>

The disorder often starts as mild to moderate pruritus with urticarial or erythematous plaques that evolve over weeks to months into large, tense, sometimes hemorrhagic bullae. Lesions may appear on normal skin or on an erythematous base. The blisters commonly occur at the periphery of annular or polycyclic erythematous plaques. Bullae typically measure 0.25 to 2 cm in diameter. The lower abdomen, anogenital region (including the vulva), and flexural areas of the arms and legs are most often involved, although bullae not uncommonly occur on the face in children. The Nikolsky sign is characteristically absent, and blisters do not extend or increase in size as they do in patients with pemphigus vulgaris. Blistering of the palms and soles is seen in virtually all affected infants,<sup>193</sup> whereas penile involvement is more common in older children.<sup>188,191,201,202</sup> The bullae tend to be more tense and inflamed than those of pemphigus vulgaris (Fig. 13-25), and the course of BP is more indolent than that of pemphigus vulgaris. Blisters resolve without scarring. Oral lesions are seen in approximately 25% of patients, especially in older children.

Variants include cicatricial pemphigoid, which affects mucosal surfaces, and a localized form (chronic pemphigoid of Brunsting-Perry) that is generally limited to the head and neck. The predominant localization of blisters in cicatricial pemphigoid is mucosal<sup>203</sup> (Fig. 13-26), with only 25% of patients showing skin involvement, particularly on the face, neck, and upper chest. Recurrent bullae are seen in the oral mucosa, conjunctivae, and other mucous membranes such as those of the nasopharynx, esophagus, larynx, genitalia,<sup>204</sup> and anus.<sup>205</sup> Oral involvement often takes the form of a desquamative gingivitis,<sup>206</sup> and ocular involvement may not occur until many years after the onset of the condition. Eye involvement often presents as dryness of the eyes with a feeling of chronic, intractable conjunctival irritation. Conjunctival involvement can lead to entropion, trichiasis (ingrowing

**Figure 13-25** Bullous pemphigoid. Large, tense bullae are seen on the lower region of the abdomen in this 13-year-old boy.

**Figure 13-26** Cicatricial pemphigoid. This 3-year-old boy showed blistering of the oral and ocular mucosae. Early diagnosis is critical to prevent the scarring and permanent blindness. The minority of patients with this condition show cutaneous involvement.

eyelashes), symblepharon, dryness of the cornea, corneal ulceration, and in 25% of patients, blindness. Esophageal lesions may result in stricture formation. Laryngeal lesions, when present, can be life-threatening. Adhesions of the genitourinary region may lead to phimosis in boys and narrowing of the vaginal opening in affected girls. Lichen planus pemphigoides is an overlap disease in which the lichen planus develops first<sup>207</sup>; most cases respond to dapsone (see Chapter 4).

Biopsy specimens of cutaneous lesions show subepidermal blister formation generally without papillary microabscesses (an important diagnostic feature of dermatitis herpetiformis [DH]). Eosinophils are often seen in sections, and peripheral eosinophilia is common. DIF reveals deposition of C<sub>3</sub> and IgG at the lamina lucida of the basement membrane zone. Although indirect testing of serum for circulating IgG anti-basement membrane zone antibodies (IIF) is positive in 72% of children, antibody titers do not correlate with clinical disease activity. These circulating immune deposits bind to the roof of salt-split skin, in which the cleavage runs through the lamina lucida of basement membrane. Antibodies are most commonly directed against the NC16A domain of BP180 antigen (collagen XVII) but may be directed against BP230.<sup>201</sup> ELISA assays have been shown to be more sensitive and just as specific as IIF.<sup>208</sup>

Potent topical corticosteroids may be effective for localized areas of involvement and in patients who are mildly affected.<sup>209</sup> In general, systemic corticosteroids are the mainstay of treatment (1 to 2 mg/kg per day). Sulfapyridine (60 to 150 mg/kg per day), dapsone (1 to 2 mg/kg per day), azathioprine, mycophenolate mofetil,<sup>210</sup>

**Figure 13-27** Pemphigoid gestationis. Cutaneous involvement of the newborn has been noted in about 10% of infants born to mothers with this disorder. In the neonate the condition subsides within several weeks as maternal antibodies wane. (Courtesy of Moise Levy, MD.)

intravenous immunoglobulin,<sup>194</sup> and rituximab<sup>174</sup> have been used as steroid-sparing agents and in steroid-resistant cases.<sup>211</sup> Erythromycin (50 mg/kg per day) with or without nicotinamide (25 to 40 mg/kg per day) has been beneficial in some children, presumably owing to its anti-inflammatory effects. Omalizumab, which targets IgE, has been effective as a steroid-sparing agent.<sup>212,213</sup> Rarely plasma exchange and extracorporeal photochemotherapy have been used for childhood BP.<sup>214</sup> The disorder remits in most children within a year and has an excellent prognosis.

### Pemphigoid Gestationis

Pemphigoid gestationis (formerly called *herpes gestationis*) usually presents during the second or third trimester of pregnancy or in the immediate postpartum period.<sup>215</sup> It occurs in 1:50,000 pregnancies. Maternal skin lesions often start at the umbilical area and spread to the abdomen and thighs. Before the development of bullae, initial lesions may be pruritic, eczematous, or erythema multiforme-like erythematous papules and plaques. The disorder can start for the first time with any pregnancy but then tends to recur in subsequent pregnancies. Although the eruption tends to clear in the majority of patients within a few days of delivery, it can persist for many months after delivery. Mild recurrences occasionally have been noted to appear at the time of menstruation, in women who take oral contraceptives, and in women with choriocarcinomas and hydatidiform moles. Cutaneous involvement of the newborn has been noted in about 10% of infants born to mothers with this disorder (Fig. 13-27); on the basis of immunofluorescent findings, a high percentage of newborns have been noted to have subclinical forms of pemphigoid gestationis as well.

The immunopathologic hallmark of pemphigoid gestationis is deposition of C<sub>3</sub>, with or without IgG, distributed in a linear band along the basement membrane. The targeted antigens in skin are BP180 and less commonly, BP230.<sup>216</sup>

The course of pemphigoid gestationis is characterized by alternating exacerbations and remissions. Systemic corticosteroids are the most reliable mode of therapy, and with certain precautions are generally considered safe for both mother and fetus, especially after the first trimester of pregnancy. Alternate-day dosage, if possible, is preferable to daily treatment. To avoid fetal adrenal suppression, dosages should be reduced to a minimum during the final weeks of pregnancy. The cutaneous lesions in infants with this disorder generally remit within several weeks and do not require therapy. Although there may be an increased risk of prematurity or intrauterine growth restriction, pemphigoid gestationis does not result in an increased mortality risk for the mother or the fetus.

### DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis (DH; Duhring disease) is characterized by an intensely pruritic papulovesicular and sometimes bullous eruption that responds dramatically to orally administered doses of sulfones or

sulfapyridine.<sup>217</sup> Although the disorder may affect infants and children, DH generally occurs during the second to fifth decades of life. It is most common in individuals of Northern European descent and is rare in African-Americans. DH is considered the cutaneous form of celiac disease and affects about 5% to 17% of patients with celiac disease.<sup>218,219</sup>

Diagnosis of this disorder cannot be based solely on the morphologic aspects and distribution of lesions but on the constellation of clinical appearance, histopathologic characteristics, immunofluorescent findings, serologic testing, and response to therapy. The major environmental trigger is ingested gluten and particularly its gliadin component. IgA antibodies develop against gliadin but also two structurally homologous autoantigens, tissue transglutaminase (tTG; widely distributed; most important for celiac disease) and epidermal transglutaminase (eTG or transglutaminase 3; epidermis-specific and most important for DH).<sup>220-223</sup> Virtually all patients with DH have intestinal sensitivity to gluten, but the minority show gastrointestinal symptoms. Of children with DH, 16% have chronic diarrhea, 10% have iron-deficiency anemia, and growth retardation is rare.<sup>224,225</sup>

DH tends to affect the extensor surfaces: the elbows, knees, sacrum, buttocks, and shoulders, and occasionally the face, eyelids, facial hairline, posterior nuchal area, and scalp. Lesions are usually grouped and symmetrical in distribution with centrifugal extension and vesicles predominantly at the periphery. In association with the onset of intense pruritus or burning, erythematous and at times, urticarial lesions may develop. Characteristic of this disorder are minute, clear, relatively tense vesicles that measure from 0.3 to 4 mm in diameter. These vesicles rupture easily, either spontaneously or when scratched. Not uncommonly, the grouped ("herpetiform") vesicles and papules are seen amid excoriated papules and postinflammatory hypopigmentation and hyperpigmentation. The palms, flexor fingers, and soles may show hemorrhagic, purpuric, or petechial lesions with active DH,<sup>226-228</sup> found in 64% in one pediatric study.<sup>229</sup> Palmoplantar hyperkeratosis, chronic urticaria, and prurigo have been described in atypical cases. The general course of this disorder is chronic (often lasting 5 to 10 years or more) with frequent exacerbations and remissions.

Childhood DH can be confused with arthropod bites, dermatitis, urticaria, scabies, and pityriasis lichenoides et varioliformis acuta. Serum IgA anti-transglutaminase 3 levels have been proposed as a screening test for DH, although confirmation of the diagnosis requires lesional biopsy for routine histologic evaluation and most importantly, perilesional biopsy (within 1 cm away) for immunofluorescent analysis. Subepidermal microabscesses with accumulations of neutrophils and eosinophils are found at the tips of the dermal papillae by routine histology. IgA is seen at the tips of the dermal papillae in a granular pattern by immunofluorescent microscopy of perilesional skin.<sup>230</sup> Patients should be eating a gluten-containing diet for biopsy or any serologic testing, or false-negative results may occur. If the DIF testing on biopsy sections is negative but the clinical presentation is typical, then serologic testing showing antibodies against tTG and endomysial antibodies (or, even better, the more sensitive anti-eTG or deamidated anti-gliadin if available) can allow a provisional diagnosis and lead to a trial of medical and dietary intervention.

Sulfones (dapsone) and sulfapyridine are effective in relieving the symptoms and suppressing the eruption of DH in children as well as adults. Dramatic relief from the use of these agents, often as early as 24 to 48 hours after initiation, is often helpful in making the diagnosis. The recommended initial dosage for dapsone is 0.5 mg/kg per day. If no response is seen in a week, the dosage can be increased by 0.5 mg/kg per day to a maximum of 2 mg/kg per day, assuming blood counts are normal before each dosage increase. Once existing lesions have been suppressed, the dosage may be tapered to a minimal level (usually 12.5 to 50 mg/day). Baseline blood counts and glucose-6-phosphate dehydrogenase (G6PD) levels are important before initiating therapy. Blood counts should be repeated at least monthly for the first 6 months. Side effects are uncommon but can include hemolytic anemia (especially seen in patients with G6PD deficiency, a contraindication to use), agranulocytosis, methemoglobinemia (manifested most commonly by headache and fatigue but sometimes by bluish discoloration of the face, mucous membranes, and nails), nausea, vomiting, headache, giddiness, tachycardia, psychoses, anemia, leukopenia, fever, exfoliative dermatitis, liver necrosis, lymphadenitis, and

**Figure 13-28** Chronic bullous disease of childhood. Clear or hemorrhagic bullae are commonly found on the legs, as well as the face, lower part of the trunk, and genitalia.

peripheral neuropathy. If at all possible, a gluten-free diet should be instituted. By gluten-free diet alone, children experience remission in approximately 11 months, and clearance of IgA deposits can take years. Reintroduction of gluten leads to rapid clinical deterioration. Adherence for at least 5 years to a gluten-free diet is also thought to lower the increased risk of developing lymphoma (most commonly involving the gastrointestinal system and non-Hodgkin lymphoma). Adherence is particularly difficult, however, in affected adolescents. Support and information about DH and gluten-free diets can be found online (<http://celiac.org/celiac-disease/dermatitis-herpetiformis/>; [www.gluten.net](http://www.gluten.net); [www.dermatitisherpetiformis.org.uk](http://www.dermatitisherpetiformis.org.uk)).

#### LINEAR IMMUNOGLOBULIN A BULLOUS DERMATOSIS

Linear immunoglobulin A (IgA) bullous dermatosis of childhood (chronic bullous disease of childhood) is a subepidermal blistering disease that may be indistinguishable both clinically and histologically from BP.<sup>231-233</sup> Its onset is usually in the first decade of life, particularly during preschool years. Spontaneous remission usually occurs after several months to 3 years and almost always before the onset of puberty. IgA nephropathy is a rare complication.<sup>234</sup> It can follow an infection or represent a manifestation of drug hypersensitivity, especially to antibiotics such as vancomycin, amoxicillin-clavulanate, and trimethoprim-sulfamethoxazole, generally 1 to 13 days after the first dose.<sup>235-237</sup>

The eruption is characterized by large, tense, clear or hemorrhagic bullae measuring 1 to 2 cm in diameter on a normal or erythematous base. The eruption is widespread, and areas of predilection include the face, scalp, lower part of the trunk (including the genitalia and pubis), buttocks, inner thighs, legs, and dorsal aspect of the feet (Fig. 13-28). The bullae may form characteristic annular or rosette-like lesions composed of sausage-shaped blisters resembling a cluster of jewels surrounding a central crust, the string-of-pearls sign (Fig. 13-29). Mucous membrane lesions occasionally occur. Pruritus is a variable feature and may be mild to moderate, intense and distressing, or completely absent.

Histologically, chronic bullous disease of childhood is characterized by subepidermal bullae with edema of adjacent dermal papillae and a dermal infiltrate of polymorphonuclear leukocytes, eosinophils, and mononuclear cells. The immunofluorescent findings of linear IgA deposits in the lamina lucida zone of the dermal–epidermal junction obtained from perilesional skin confirm the diagnosis; occasionally children show both IgA and IgG antibodies.<sup>238,239</sup> Circulating IgA basement membrane-zone antibody is found in up to 80% of patients and usually binds the epidermal side of salt-split skin. Antibodies are most commonly directed against a 120 kDa fragment of BP180 (also called linear IgA disease antigen-1 [LAD-1]) and less commonly, a 97 kDa fragment that is generated from the 120 kDa fragment.<sup>240</sup>

**Figure 13-29** Chronic bullous disease of childhood. The bullae may form characteristic annular or rosette-like lesions resembling a cluster of jewels surrounding a central crust, the string-of-pearls sign.

**Figure 13-30** Epidermolysis bullosa acquisita (EBA). This disorder may resemble dystrophic epidermolysis bullosa (DEB). Note the scarring, milia, and nail dystrophy. The immunodeposits in patients with EBA are directed against collagen VII, the same protein missing or dysfunctional in patients with DEB.

Some children with clinically typical chronic bullous disease of childhood show “mixed immunobullous disease of childhood,” in which both IgG and IgA autoantibodies are detected.

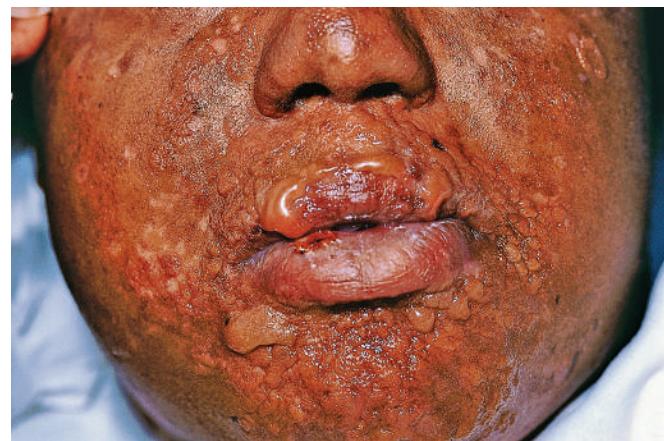

Response to therapy is generally favorable.<sup>241</sup> Dapsone, as in DH, is the drug of choice, although patients have responded to administration of erythromycin, dicloxacillin, or sulfonamides.<sup>242-245</sup> Responses to antibiotics, however, are often transient, and their use has been advocated initially while awaiting results of diagnostic tests or in patients unable to take dapsone and sulfapyridine.<sup>246</sup> If response to dapsone or antibiotics is inadequate, sulfapyridine, systemic corticosteroids, and mycophenolate mofetil are alternative therapies.

#### EPIDERMOLYSIS BULLOSA ACQUISITA

Epidermolysis bullosa acquisita (EBA; acquired EB) is a subepidermal blistering disorder that usually takes on one of two forms: a generalized inflammatory eruption clinically indistinguishable from BP and a noninflammatory acral blistering disorder that results in scarring and milia formation (Fig. 13-30) reminiscent of DDEB. Approximately 40 cases in children have been described.<sup>247</sup> A neonate with EBA from transplacental transfer of antibody has been described (Fig. 13-31).<sup>248</sup> Blisters may be hemorrhagic or serous and tend to be localized to sites

**Figure 13-31** Epidermolysis bullosa acquisita (EBA). This baby developed EBA by transplacental passage of maternal antibodies against type VII collagen. Tense blisters resulted in neonatal denudement and subsequent milia formation, as in dystrophic epidermolysis bullosa.

**Figure 13-32** Bullous systemic lupus erythematosus. Pruritic vesicles and tense bullae develop and may leave intense postinflammatory hypopigmentation or hyperpigmentation. This adolescent responded to the combination of prednisone, azathioprine, and dapsone.

of trauma or pressure, especially on the extensor areas of the extremities. Oropharyngeal mucous membrane erosions are commonly seen; the conjunctival, esophageal, and anogenital mucous membranes are less commonly involved, although blindness may result. The nails may be dystrophic, and scarring alopecia may be seen.

The condition results from the deposition of IgG and less commonly IgA,<sup>249,250</sup> autoantibodies directed against type VII collagen (see Fig. 13-1). Type VII collagen is a structural component of anchoring fibrils that is missing or abnormal in children with RDEB or DDEB, respectively. Immunofluorescence examination shows the linear deposition of IgG and sometimes C<sub>3</sub> at the lower lamina densa or sublamina densa zones of the basement membrane. IIF shows IgG binding to the dermal side of salt-split skin (e.g., beneath the lamina lucida). Immunoblotting analysis shows binding to a 290 kDa protein that corresponds to type VII collagen and recognition primarily of the NC1 noncollagenous domain of type VII collagen; however, children may show antibodies directed against additional domains, particularly children with EBA younger than 10 years of age with the inflammatory phenotype.<sup>251</sup>

EBA has a chronic course with flares but seems to have a better prognosis in children than in adults. Dapsone and corticosteroids are first-line therapy and often lead to remission within about 2 years; mycophenolate mofetil may be steroid-sparing. Rituximab is now also used for treatment-resistant EBA.<sup>252,253</sup> Childhood IgA-mediated EBA has responded to mycophenolate mofetil.<sup>250</sup> Colchicine, infliximab, photophoresis,<sup>254</sup> rituximab,<sup>255</sup> and intravenous immunoglobulin have been helpful for some patients.<sup>256</sup> The recent demonstration that T cells are critical in initiation of EBA suggests that T cell-directed immunomodulatory strategies may be effective in the future.<sup>257</sup>

## BULLOUS SYSTEMIC LUPUS ERYTHEMATOSUS

Similar to patients with EBA, patients with systemic lupus erythematosus (SLE) who manifest immune-mediated bullae show antibodies directed against type VII collagen.<sup>258–261</sup> However, the clinical manifestations more closely resemble those of BP or DH. African-American adolescents and young women are most often affected, with a mean age of onset of 22 years.<sup>262</sup> Occasionally bullous SLE is the presenting sign of lupus,<sup>263–265</sup> but more typically it develops in a patient with known SLE (see Chapter 22). Typical lesions are pruritic vesicles and tense bullae with occasional erythematous macules and papules

(Fig. 13-32).<sup>266</sup> Lesions tend to leave postinflammatory hypopigmentation or hyperpigmentation. Sun-exposed areas are most commonly involved, but flexor and extensor skin surfaces, as well as oral mucosae, may be affected. Bullous SLE in a linear pattern following Blaschko lines has been described in a child.<sup>267</sup>

Immunofluorescence examination shows deposition of IgG and sometimes IgM, IgA, or C<sub>3</sub> at the basement membrane and upper dermis. Granular, linear, and mixed patterns have all been described. Prognosis is usually favorable and is largely determined by the course of the associated SLE. Most patients generally respond quickly to dapsone therapy (in contrast to EBA), but rituximab has also been used in refractory cases.<sup>268</sup> Administration of systemic corticosteroids with or without additional immunosuppressive agents (e.g., methotrexate, mycophenolate mofetil, azathioprine, cyclophosphamide, or cyclosporine) has led to variable response.

The normal skin of healthy infants and children is resistant to invasion by most bacteria, because the cutaneous surface provides a dry mechanical barrier from which contaminating organisms are constantly removed by desquamation. Under normal conditions the skin is sterile at delivery and for a short period thereafter. During the process of vaginal birth it acquires organisms from the birth canal, which gradually increase in number during the first 10 days of life. If the newborn is delivered by cesarean section, however, the cutaneous surface remains sterile until after delivery but soon becomes exposed to bacteria from human contactants and fomites.

Almost any organism may live on the cutaneous surface under appropriate conditions. A complete list of transient organisms accordingly would include virtually all microorganisms found in the human environment. The number of species composing the resident flora, however, is relatively small and consists predominantly of Gram-positive organisms and a few Gram-negative species, including *Propionibacterium acnes* (normally found in high concentrations about the pilosebaceous follicles of the face and less commonly the axillae and forearms), aerobic diphtheroids (*Corynebacterium minutissimum* and *Corynebacterium tenuis*), *Staphylococcus epidermidis* micrococci, and anaerobic Gram-positive cocci. Others include Gram-negative bacilli (*Escherichia coli*, *Proteus*, *Enterobacter*, and *Pseudomonas*, among others) found uncommonly on normal skin except in the moist intertriginous areas of the groin, axillae, and toe webs and *Staphylococcus aureus*, a common pathogen that appears to usually be seeded from the carrier state in the anterior nares.

Because the cutaneous surface is continuously exposed to microorganisms, it is most helpful to distinguish among transient, resident, and pathogenic flora. The transient flora consists of multiple organisms that are deposited on the skin from the environment, presumably do not proliferate, and are removed easily by washing or scrubbing of the affected area. The resident flora consists of a smaller number of organisms that are found more or less regularly in appreciable numbers on the skin of normal individuals, multiply on the skin, form stable communities on the cutaneous surface, and are not easily dislodged. Pathogenic bacteria, not ordinarily a regular part of this flora, persist on the skin if there is continuous replacement from some internal or external source or if the integrity of the skin is disrupted by injury or disease. It should be noted that the mere presence of potentially pathogenic bacteria in a cutaneous lesion does not necessarily prove the demonstrable organism to be a cause of bacterial infection.

Children have a more varied cutaneous flora than adults and often harbor soil bacteria on their skin. Prepubertal children lack sebum and accordingly have fewer diphtheroid organisms than adults. It is estimated that 10% to 30% of individuals are nasal carriers of *S. aureus* and that 70% to 90% are transient carriers.<sup>1,2</sup> Such coagulase-positive staphylococci are not considered part of the normal cutaneous flora of glabrous skin in adults but are common transients acquired from carrier sites such as the anterior nares and perineum. In a recent 1-year study of 333 healthy preschool children ages 3 to 6 years, 34% of nasal swab samples yielded *S. aureus* from 185 (55%) carriers, and based on consecutive genotype analysis, 15% of the children were classified as persistent carriers (the remaining were considered to be intermittent carriers).<sup>3</sup>

The introduction of a vast array of antibiotics and chemotherapeutic agents has affected striking changes in the management of bacterial infections. With increased use of these agents the focus of attention has shifted to identifying the specific bacterial cause and its antimicrobial sensitivity pattern when feasible, permitting the appropriate choice of antibacterial agent(s). In purulent skin infections it is

relatively easy to obtain adequate specimens for examination and culture. With dry or crusted lesions, the yield will be greatest if the crust is gently lifted off and cultures are obtained from the moist underlying surface. In nonpurulent infections like erysipelas or cellulitis, past recommendations were for aspiration of the most active zone (not the surrounding area of erythema) with a 25-gauge needle attached to a syringe containing sterile saline without added preservatives. This procedure, unfortunately, has a very high false-negative rate, and often the clinician in this setting is forced to rely on clinical features or other diagnostic findings.

## Bacterial Infections

### IMPETIGO

Impetigo is a common, contagious superficial skin infection caused by streptococci, staphylococci, or both. Although seen in all age groups, the disease is most common in infants and children. Lesions may involve any body surface but occur most often on the exposed parts of the body, especially the face, hands, neck, and extremities.

There are two classic forms of impetigo: bullous and nonbullous (or crusted). Nonbullous impetigo accounts for more than 70% of cases.<sup>4</sup> It begins with a 1- to 2-mm erythematous papule or pustule that soon develops into thin-roofed vesicle or bulla surrounded by a narrow rim of erythema. The vesicle ruptures easily with release of a thin, cloudy, yellow fluid that subsequently dries, forming a honey-colored crust, the hallmark of nonbullous impetigo (Fig. 14-1). The infection is easily spread by autoinoculation (Fig. 14-2) through fingers, towels, or clothing, with resultant satellite lesions in either adjacent areas or other parts of the body. Individual lesions may extend peripherally with central clearing, resulting in annular or gyrate morphologies. Nonbullous impetigo historically was caused primarily by group A β-hemolytic streptococci (GABHS) but now appears to be most commonly caused by *S. aureus*.<sup>4,5</sup> Anaerobic organisms may also be recovered from lesions of nonbullous impetigo.<sup>5</sup>

Bullous impetigo, which is nearly always caused by *S. aureus*, presents as flaccid, thin-walled bullae or more commonly, tender, shallow erosions surrounded by a remnant of the blister roof (Figs. 14-3 and 14-4). Common locations include the diaper region (Fig. 14-5), face, and extremities. Lesions of bullous impetigo can be thought of as a localized form of staphylococcal scalded skin syndrome (SSSS) (see *Staphylococcal Scalded Skin Syndrome* section), the characteristic lesions being the result of the same exfoliative toxin as implicated in that condition. Neonatal pustulosis (see Chapter 2), another condition favoring the diaper region and other fold areas in infants, is usually caused by *S. aureus* and presents with small pustules on an erythematous base that rupture easily upon swabbing.

Fever and regional lymphadenopathy may occur later in the course of impetigo but appear to be more common with the nonbullous type caused by GABHS. Potential complications of both bullous and nonbullous impetigo include sepsis, osteomyelitis, septic arthritis, lymphadenitis, and pneumonia.<sup>4</sup> Cutaneous streptococcal disease may be associated with guttate psoriasis, scarlet fever, and poststreptococcal glomerulonephritis when a nephritogenic strain of GABHS is implicated.

An important reservoir for staphylococci is the upper respiratory tract of asymptomatic persons. Asymptomatic nasal carriage occurs in 20% to 40% of normal adults and up to 80% of patients with atopic dermatitis. The perineum is another common site of carriage, albeit not as common as the nares. These carriers spread the agent to the skin of infants and young children, probably with their hands. The

**Figure 14-1** Nonbullous (crusted) impetigo. Erythematous papules with honey yellow-colored crusting.

**Figure 14-2** Nonbullous (crusted) impetigo. These multiple lesions have spread as a result of autoinoculation.

**Figure 14-3** Bullous impetigo. Multiple tender, erythematous patches with a peripheral collarette, representing remnants of the blister roof.

reservoir for streptococci involved in skin infections appears to be skin lesions of other individuals, not the respiratory tract of affected or asymptomatic persons. Factors such as trauma and insect bites probably contribute to the pathogenesis of this infection.

Treatment for impetigo depends on the clinical presentation. Untreated, the disorder may last for 2 to 3 weeks with continuous spread and development of new lesions. In severe cases there may be

**Figure 14-4** Bullous impetigo. Thin-walled vesicles and shallow erosions with peripheral collarettes and mild crusting on the buttock and posterior thigh.

**Figure 14-5** Bullous impetigo. Inguinal and suprapubic involvement in an infant female. Lesions of bullous impetigo have a preference for this location in diapered infants.

large, crusted vegetations with deep extension and ulceration. Gentle cleansing, removal of crusts, and drainage of blisters and pustules may help prevent local spread of disease. If crusts are firmly adherent, warm soaks or compresses are useful.

Topical antibiotics may be useful in the treatment of mild, localized disease caused by *S. aureus*. With streptococcal or more severe staphylococcal infections, however, systemic antibiotics produce a swifter response and fewer failures. Bacitracin, polymyxin, gentamicin, and erythromycin are all effective topical agents and are relatively nonallergenic. Bacitracin, however, is a potential contact allergen, and this should be remembered in patients treated with this agent who develop worsening erythema and evidence of contact dermatitis.<sup>6,7</sup> In addition, treatment failures are common when bacitracin is used for impetigo.<sup>8</sup> Neomycin is another effective topical agent, although reports of contact allergy have traditionally appeared to be more common with this agent than with other topical antimicrobials (see Chapter 3). Mupirocin exerts a high level of bactericidal activity against a broad spectrum of Gram-positive organisms including *S. aureus* and GABHS and has little or no potential for irritation, side effects, or cross-reaction with other antibiotics. It is effective against methicillin-resistant *S. aureus* (MRSA), although some resistance to mupirocin has emerged

in recent years, especially after prolonged use.<sup>9–12</sup> Some studies have demonstrated equal or greater effectiveness of topical mupirocin over oral erythromycin in the treatment of impetigo in children.<sup>13,14</sup> Mupirocin is typically applied three times daily for 7 to 10 days.<sup>15</sup> Nasal carriage of *S. aureus* may be reduced with the use of intranasal mupirocin, which should be considered in known carriers with recurrent impetigo or in the setting of epidemic outbreaks. Retapamulin, a newer pleuromutilin-class topical antibiotic for the treatment of skin and skin-structure infections, has been demonstrated effective against both *S. aureus* and GABHS and is another treatment option for localized impetigo.<sup>16,17</sup> Retapamulin is also active against MRSA and many anaerobes, including *Propionibacterium* species, *Bacteroides* species, and *Clostridium* species.<sup>15</sup> The benefits of retapamulin include its lower propensity toward the development of resistance and twice daily dosing.<sup>18</sup>

Oral therapy for impetigo should be with an agent that covers both *S. aureus* and GABHS, because distinguishing between these etiologies clinically is often not possible. In areas with a low prevalence of erythromycin-resistant *S. aureus*, erythromycin ethylsuccinate or erythromycin estolate are reasonable options. If known erythromycin resistance is present in the community, alternative oral agents with a good track record include a penicillinase-resistant penicillin (i.e., cloxacillin or dicloxacillin), amoxicillin plus clavulanic acid, a first- (i.e., cephalexin) or second- (i.e., cefprozil) generation cephalosporin, clindamycin, or in some cases, other macrolide antibiotics (i.e., clarithromycin or azithromycin). Oral therapy is used by most clinicians when the involvement is more widespread and/or severe.

In severe or recalcitrant cases, skin swab for bacterial culture and sensitivity testing should be performed. The evolving epidemiology of community-associated MRSA (CA-MRSA) (see below) infection must be considered in this setting, as highlighted by multiple observations of the increasing prevalence of this pathogen. These patients often lack traditional risk factors for MRSA, and the isolates may be more susceptible to clindamycin and trimethoprim-sulfamethoxazole.<sup>19,20</sup>

A review of the National Ambulatory Medical Care Survey data on office visits for impetigo from 1997 to 2007 revealed that a majority of the 4 million patients were treated by nondermatologists (pediatricians, internists, emergency room and family physicians), and systemic antibiotics were the most commonly prescribed therapy, followed by topical antibiotics.<sup>21</sup> A recent Cochrane review found that topical mupirocin and topical fusidic acid (not available in the United States) were equally or more effective than oral treatment in the studies that met their inclusion criteria.<sup>22</sup> This highlights a potential opportunity for physician education, because increased utilization of topical therapy for patients with more limited impetigo could decrease the morbidity associated with oral antibiotic treatment, in line with the principles of antibiotic stewardship.

Lesions of impetigo caused by GABHS are shallow and usually heal well, and rheumatic fever does not occur after streptococcal skin infection. In contrast, acute glomerulonephritis and scarlet fever can occur after cutaneous streptococcal infection. As in the case of nephritis after streptococcal pharyngitis, only certain serologic types, different from those producing nephritis as a sequel of streptococcal pharyngitis, appear to result in this complication of cutaneous infection.<sup>16</sup> This complication is uncommon except for certain epidemics resulting from nephritogenic strains of streptococci. Although systemic antibiotics help eliminate cutaneous streptococci, they do not appear to prevent glomerulonephritis caused by streptococcal impetigo. In general, however, with the changing bacteriology and the fact that staphylococci are a more common cause of both types of impetigo, concerns about postimpetigo glomerulonephritis have been greatly reduced.

## METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS INFECTIONS

The epidemiology of *S. aureus* skin and soft-tissue infections has changed over the last decade, with an increasing prevalence of CA-MRSA infections observed in both the United States and elsewhere. Since the initial descriptions of children lacking predisposing risk factors with CA-MRSA infection in the late 1990s, marked increases in *S. aureus* isolates with this characteristic were observed,

both in endemic and epidemic forms. By the mid-first decade of the twenty-first century, up to 50% of community-associated *S. aureus* infections in many US centers were being identified as MRSA.<sup>23</sup> Increases in the number of children hospitalized with MRSA infections have also been observed, but fortunately the mortality rate for these children remains low.<sup>24</sup>

MRSA originated after the introduction of a mobile genetic element, staphylococcal chromosomal cassette (SCC) carrying the *mecA* gene, into strains of methicillin-sensitive *S. aureus* (MSSA). This gene encodes an altered penicillin-binding protein.<sup>25</sup> In distinction to hospital-associated MRSA, CA-MRSA is generally classified as such when there is no history of prior MRSA infection or colonization, when the positive culture was obtained in the outpatient setting or isolated within 48 hours of hospitalization, and when the patient lacks an exposure history (i.e., to a healthcare facility, chronic care facility, or indwelling catheter).<sup>23,25</sup> Molecular characteristics of the isolate are also useful in distinguishing the strains. Many CA-MRSA strains produce Panton–Valentine leukocidin (PVL), a toxin that kills neutrophils, although this toxin is also produced by some of the other more-sensitive strains of *S. aureus*.<sup>26,27</sup> The exact role of PVL in CA-MRSA infections remains controversial, although it appears to be increasingly associated with follicular infections (see Furunculosis section).

CA-MRSA infections seem to disproportionately affect children, young adults, and individuals from ethnic minority and low socioeconomic groups.<sup>28</sup> Spread is facilitated by crowding, skin-to-skin contact, skin compromise, and shared personal hygiene items. Cutaneous CA-MRSA infections are common in athletes, most notably collegiate football players.<sup>29,30</sup> The potential clinical manifestations associated with CA-MRSA infection are listed in Box 14-1. The constellation of disorders caused by infection with CA-MRSA have been grouped under the designation of *skin and soft-tissue infections* (SSTIs). Empiric outpatient therapy decisions for CA-MRSA infections should incorporate the type and site of infection, prevalence of the organism in the community, and local antibiotic susceptibility patterns.<sup>28</sup> Abscesses (including furuncles and carbuncles), which are collections of pus within the dermis and deeper skin layers, are a common manifestation of CA-MRSA infection (Figs. 14-6 and 14-7) and are most commonly located on the buttocks.<sup>31</sup> Incision and drainage of abscesses is often useful and sometimes sufficient as monotherapy for purulent uncomplicated infections. However, better studies are required to determine

### Box 14-1 Clinical Associations with Community-Associated MRSA Infection

**Figure 14-7** Community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA). This 6-year-old female with a history of atopic dermatitis had an acute onset of a painful, fluctuant nodule over the thumb. Culture of the drainage revealed MRSA, and the infection cleared with an appropriate systemic antibiotic.

the role of antibiotics in treating abscesses that have been adequately drained.<sup>32</sup>

The most commonly utilized oral antibiotics in the United States are: trimethoprim-sulfamethoxazole, clindamycin, doxycycline, linezolid, rifampin, and the fluoroquinolones. Fusidic acid is also utilized in the United Kingdom, Australia, and other countries.<sup>33</sup> Inducible clindamycin resistance has increased in recent years and should be considered when testing reveals clindamycin susceptibility and erythromycin resistance. In these instances, a "D test" should be performed and used to guide the choice of therapy. Management of colonization has been attempted with intranasal mupirocin and skin disinfection (i.e., with chlorhexidine washes), with variable success.<sup>34</sup> Recently it was shown that persistent colonization with MRSA in outpatients is associated with increased household colonization pressure (colonization of household contacts).<sup>35</sup> In addition, MRSA colonization and infection has been increasingly observed in companion animals, especially cats and dogs, and may serve as reservoirs for human infection.<sup>36–38</sup>

## ECTHYMA

Ecthyma is a deep or ulcerative type of pyoderma commonly seen on the lower extremities and buttocks of children, and caused most often by GABHS. It may occur as small punched-out ulcers or a deep spreading ulcerative process. The disorder begins in the same manner as

**Figure 14-8** Ecthyma. Well-demarcated, punched-out ulcers on the thigh of this 10-year-old male.

**Figure 14-9** Ecthyma gangrenosum. These hemorrhagic, necrotic skin lesions were accompanied by *Pseudomonas aeruginosa* bacteraemia in this immunosuppressed child being treated with chemotherapy.

impetigo, often occurring after infected insect bites or minor trauma, but penetrates through the epidermis to produce a shallow ulcer. The initial lesion is a vesiculopustule with an erythematous base and firmly adherent crust. Removal of the crust reveals a lesion deeper than that seen in impetigo with an underlying saucer-shaped ulcer and raised margin (Fig. 14-8). The lesions are painful and heal slowly over a few weeks, often with scar formation. When multiple, lesions of ecthyma may be confused with child abuse related to cigarette burns. *S. aureus* (including MRSA) may occasionally be cultured from the lesions, and epidemic outbreaks have been reported, occasionally in association with poststreptococcal glomerulonephritis or other systemic sequelae.<sup>39,40</sup> Treatment consists of warm compresses and the appropriate systemic antibiotic.

Ecthyma gangrenosum is a cutaneous finding that may be seen in patients with *Pseudomonas aeruginosa* bacteraemia. Most of the affected individuals have an underlying immunodeficiency (either congenital or acquired) or a history of cancer chemotherapy. There are reports of ecthyma gangrenosum in apparently healthy, immunocompetent children (often with diaper-area involvement), but the diagnosis should prompt a thorough investigation for occult immunodeficiency.<sup>41,42</sup> Neutropenia may be a risk factor for ecthyma gangrenosum. The characteristic lesions are hemorrhagic papules with a pink or violaceous rim (Fig. 14-9) that progress to bullae, ulcers, and necrotic plaques. Eschar formation eventually occurs (Fig. 14-10), and old lesions heal with scarring. The diagnosis can be confirmed by Gram stain and bacterial culture of lesions or blood cultures, which are positive for *P. aeruginosa*. Treatment with appropriate

**Figure 14-10** Ecthyma gangrenosum. This child with congenital immunodeficiency developed thick eschars, which required a diverting colostomy and eventual skin grafting.

**Figure 14-12** Bacterial folliculitis. Erythematous follicular papules and papulopustules on the buttocks of a young boy. This is the most common location for bacterial folliculitis in children.

**Figure 14-11** Bacterial folliculitis. Erythematous, follicular papulopustules.

antipseudomonal therapy (i.e., aminoglycoside and an antipseudomonal penicillin) should be instituted early.

## FOLLICULITIS

The term *folliculitis* refers to an infection of hair follicles. The clinical appearance varies according to the location and depth of follicular involvement. Deeper follicular infections (furuncles and carbuncles) are discussed later. Superficial folliculitis (Bockhart impetigo), an infection of the follicular ostium, begins with superficial small, yellow-white pustules, often with a narrow red areola (Fig. 14-11) and a hair shaft protruding from the center of the lesion. It occurs most commonly in children and usually is seen on the buttocks (Fig. 14-12) and extremities, especially the thighs. Most lesions are painless, occur in crops, and heal over 7 to 10 days with postinflammatory hyperpigmentation. *S. aureus* is by far the most common pathogen; other possible etiologies include streptococci, Gram-negative organisms, and even dermatophytes. In immunocompromised children, commensal organisms may cause folliculitis, including *Pityrosporum* and *Demodex* (see Chapter 18). Superficial folliculitis is not always infectious in origin. "Sterile folliculitis" may be seen after skin contact with oil or other occlusive products and results in follicular plugging and inflammation. A classic example of sterile folliculitis is the scalp pustulosis occasionally associated with application of hair oils.

Superficial folliculitis usually responds to gentle cleansing with antibacterial soaps and the application of topical antibiotics such as clindamycin, erythromycin, or mupirocin. More extensive or resistant

**Figure 14-13** Folliculitis barbae. Follicular papules, pustules, and crusting with autoinoculation and caused by shaving.

cases should be treated with a systemic antibiotic (a penicillinase-resistant penicillin or cephalosporin, depending on local resistance patterns). In such instances, bacterial culture should be obtained before the initiation of systemic therapy. Sodium hypochlorite (bleach) baths or washes on a twice to three-times weekly basis may be useful for individuals or families with recurrent folliculitis or furunculosis (see below). The recommended concentration for bleach baths is  $\frac{1}{2}$  cup of bleach (around 5% to 6% sodium hypochlorite) dissolved in a full bathtub (around 40 gallons) of water, or approximately 1 mL/L (final concentration approximately 0.005%).

### Folliculitis Barbae

*Folliculitis barbae* (*sycosis barbae*) is a term used to describe a deep-seated folliculitis of the beard area involving the entire depth of the follicle and perifollicular region (Fig. 14-13). A pruritic papule is usually the initial lesion, with the process spreading from one follicle to another by trauma from scratching and/or shaving. The disorder is

**Figure 14-14** Pseudomonal (hot-tub) folliculitis. Erythematous, follicular papules and papulopustules of the thighs, correlating with areas covered by the swim garment.

characterized by follicular papules and pustules and with progression, erythema, crusting, and boggy infiltration of the skin. Although occasionally other bacteria may be isolated, the etiology is usually *S. aureus*. The use of an electric rather than traditional razor or complete avoidance of shaving can sometimes be helpful in prevention and treatment of this condition. Warm compresses and topical antibiotics are often sufficient to control minor forms of sycosis barbae. If the condition is severe or recurrent, several weeks of systemic antibiotics may be necessary.

#### Pseudofolliculitis Barbae

Pseudofolliculitis barbae (PFB) (see Chapter 7) is a common, noninfectious inflammatory disorder of the pilosebaceous follicles of the beard that may be confused with sycosis barbae. PFB (commonly referred to as *razor bumps*) is caused by shaved hairs that curve inward with resultant penetration of the skin followed by an inflammatory foreign body reaction. This form of folliculitis is seen particularly in African-Americans and individuals with curly hair. Mild cases may be managed by careful shaving and occasionally by changing from a traditional to an electric razor. Discontinuation of shaving is quite effective but not always acceptable to the patient. Close shaving, which promotes oblique penetration of hairs into the skin, should be avoided whenever possible. Other treatment options include chemical depilatory creams, topical retinoids or glycolic acid, topical steroids, benzoyl peroxide, and topical antibiotics. Epilation laser therapy (see Chapter 7) has also been demonstrated to be effective for the condition.<sup>43,44</sup>

#### Pseudomonal Folliculitis (Hot-Tub Folliculitis)

Pseudomonal folliculitis is a form of folliculitis caused by *P. aeruginosa* that occurs after exposure to poorly chlorinated hot tubs, whirlpools, or swimming pools. It has also been reported in association with a contaminated water slide,<sup>45</sup> a contaminated loofah sponge,<sup>46</sup> swimming in a children's pool filled with well water,<sup>47</sup> and after shower/bath exposure.<sup>48,49</sup> It is characterized by erythematous, follicular pustules and vesiculopustules that occur most often on the trunk, buttocks, and legs (Fig. 14-14), especially in sites occluded by swimming garments. Lesions usually develop within 1 to 2 days after exposure. Mild constitutional symptoms may be present, including fever, malaise, headache, and arthralgias. More serious associations, including urinary tract infection and pneumonia, have also been reported.<sup>50,51</sup> Lesions of hot-tub folliculitis generally subside spontaneously over 7 to 10 days. Antipseudomonal antibiotic therapy (i.e., with ciprofloxacin) may be necessary in severe cases. Preventive measures include maintenance of appropriate chlorination, frequent water changes, and thorough scrubbing of whirlpool baths and hot tubs with each water change. Importantly, 21% of 108 water and swab samples of hot tubs and indoor swimming pools were positive for *P. aeruginosa* in one study, and 96% of these isolates were multidrug resistant.<sup>52</sup> The Centers for Disease Control and Prevention recommend maintaining

**Figure 14-15** *Pseudomonas* hot foot syndrome. Tender papules and papulopustules on the plantar foot. Culture of a swab from one of the pustules grew out *P. aeruginosa*. (Courtesy of John J. Van Aalst, MD.)

the concentration of free chlorine in swimming pools to between 1 and 3 ppm and the pH at 7.2 to 7.8.<sup>53</sup>

*Hot hand-foot syndrome* (also known as *Pseudomonas* hot foot syndrome) presents with painful, erythematous palmoplantar nodules (Fig. 14-15) after exposure to water containing a high concentration of *P. aeruginosa* and may be seen in conjunction with hot-tub folliculitis.<sup>54</sup> When pustules are present, the organism can be easily cultured from skin swab material. An epidemic occurred in children exposed to the same community wading pool with a floor that was coated with abrasive grit and which, along with the inlets and a drain, yielded *P. aeruginosa* on culture.<sup>55</sup> This disorder may be related to (or the same condition as) idiopathic palmoplantar hidradenitis of childhood (see Chapter 20). Similar palmoplantar inflammatory lesions have been reported in otherwise healthy children infected with *Mycobacterium abscessus*, also in association with exposure to public swimming pools (see Nontuberculous ["Atypical"] Mycobacterial Infection section).

#### Eosinophilic Pustular Folliculitis/Eosinophilic Folliculitis of Infancy

Eosinophilic pustular folliculitis (EPF; Ofuji disease) is a dermatosis of unknown cause characterized by erythematous patches with follicular papules and pustules, often in an annular or serpiginous arrangement, with occasional peripheral eosinophilia and leukocytosis. It was classically reported in Japanese individuals, although it may be seen in people of diverse ethnic backgrounds, and men appear to be affected more than women.<sup>56</sup> Although this disorder is not bacterial in origin, it is included here because it is in the differential diagnosis of folliculitis. EPF may involve any surface area, including the face, trunk, and extremities. A form of EPF is recognized as an extremely pruritic dermatosis in adult patients with human immunodeficiency virus (HIV) infection, usually presenting late in the course of infection.<sup>57</sup>

A distinct form of EPF occurs in otherwise healthy infants and toddlers and has been called *eosinophilic folliculitis of infancy*. It presents with recurrent crops of itchy follicular pustules of the scalp (most commonly; Fig. 14-16), trunk, and extremities with eventual spontaneous involution (see Chapter 2). The outbreaks occur in a cyclical fashion and may last from 3 months to 5 years, occasionally longer. Peripheral eosinophilia may be present.<sup>58</sup> Whereas adults tend to have annular, serpiginous, or polycyclic lesions, the prominent scalp involvement and failure to form annular rings appear to distinguish the infantile form. Occasionally, eosinophilic folliculitis of infancy may be a presenting feature of the hyperimmunoglobulin-E (hyper-IgE) syndrome (see Chapter 3).<sup>59</sup>

Treatment options for EPF include topical corticosteroids, oral erythromycin, dapsone, indomethacin, colchicine, topical tacrolimus,

**Figure 14-16** Eosinophilic folliculitis of infancy. This 8-week-old female had recurrent, pruritic, follicular papules and papulopustules on the scalp in conjunction with a peripheral eosinophilia. She was ultimately diagnosed with hyper-IgE syndrome.

**Figure 14-17** Furuncle. This tender, fluctuant papulonodule was located on the thigh in the same patient with folliculitis shown in Figure 14-12.

antihistamines, and ultraviolet B (UVB) phototherapy, which have each been used with variable success. The majority of patients respond to treatment with the former two agents; in one study of 51 patients treated with low- to medium-potency topical steroids, 46 (90%) responded well.<sup>60</sup> The other treatments have been demonstrated successful but carry a greater risk of adverse effects.

## FURUNCLES AND CARBUNCLES

Furuncles (or “boils”) are painful, deep infections of the hair follicle in which purulent material extends into the dermis and subcutaneous tissues, forming perifollicular abscesses (see above). These lesions have a tendency toward central necrosis and suppuration. They are caused by *S. aureus* and are seen most often in older children and adults. They usually develop from a preceding folliculitis with deeper extension into the dermis and subcutaneous tissue. Chronic carriers of *S. aureus* are particularly predisposed,<sup>61</sup> and familial spread of PVL-producing MSSA isolates has been observed and may be associated with greater numbers and more intensely erythematous lesions.<sup>62</sup> Furuncles caused by CA-MRSA infection are increasing in incidence in the United States and are strongly related to production of the PVL virulence factor.<sup>63</sup> Furuncles are most common in areas of skin that are hairy and subject to friction and maceration, particularly the back, axillae, thighs, buttocks, and perineum. They present as tender red nodules (Fig. 14-17) that gradually become fluctuant and if untreated,

**Figure 14-18** Carbuncle. Large, tender, erythematous nodule on the lateral trunk of this 14-year-old obese male. Note the adjacent, smaller furuncle.

### Box 14-2 Predisposing Factors for Furuncles and Carbuncles

- Diabetes mellitus
- Obesity
- Alcoholism
- Scabies
- Hematologic disorders
- Immunodeficiencies, including hyper-IgE syndrome
- Malnutrition
- Chemotherapy
- Corticosteroid therapy
- Local skin trauma (abrasions, cuts, excoriations)
- Debilitated state

may have a purulent blood-tinged discharge. There is a high rate of contagion in patients with furunculosis.

Carbuncles are larger, deep-seated staphylococcal abscesses composed of aggregates of interconnected furuncles that drain at multiple points on the cutaneous surface (Fig. 14-18). They are usually seen in males on the posterior neck, back, thighs, and buttocks and extend into the deeper dermis and subcutaneous tissues, reaching a larger size than furuncles (up to 10 cm in diameter). They undergo necrosis and suppuration more slowly than furuncles and may present with severe pain and constitutional symptoms. Several factors predispose to the development of furuncles and carbuncles (Box 14-2).

The treatment of furuncles and carbuncles depends on the extent and location of lesions. The mainstay of therapy is systemic anti-staphylococcal antibiotics with incision and drainage of fluctuant lesions. Cultures with sensitivity testing should be considered, especially in geographic areas with an increasing prevalence of staphylococcal resistance. Lesions caused by MRSA may respond (as discussed) to incision and drainage alone. Topical antibiotics (as discussed for impetigo and folliculitis) are not sufficient for the treatment of furuncles and carbuncles, given the depth of the process. The triple regimen of chlorhexidine skin disinfection (21 days), mupirocin applied to the nares (5 days), and oral clindamycin (21 days) was found to be very effective with a prolonged remission in nearly 90% of patients in an open-label study that included patients with both MSSA and MRSA furunculosis.<sup>64</sup> Many practitioners recommend sodium hypochlorite baths or washes for patients with recurrent disease (see *Folliculitis* section). Lastly, attention to predisposing factors with appropriate treatment or modification (as feasible) is indicated.

## CELLULITIS

Cellulitis is an acute infection of the skin, particularly the subcutaneous tissues, characterized by erythema, swelling, and tenderness. The

**Figure 14-19** Cellulitis. Erythematous patches and plaques with edema involving the arm of this 18-month-old male. Note the multifocal nature and partial clearing as a result of parenteral antibiotic therapy.

borders of cellulitis are not elevated or sharply defined, which helps to contrast it from the more superficial form called *erysipelas* (see *Erysipelas* section).

Cellulitis usually occurs after some form of skin trauma including puncture wounds, lacerations, dermatitis, burns, varicella, or dermatophyte infections. It presents with markedly red, tender, warm swelling of the skin with an infiltrated appearance (Fig. 14-19), and the most common location is the lower extremities. Constitutional symptoms including malaise and fever are often present. The most common causes of cellulitis are *S. aureus* and GABHS, although occasionally other bacterial agents may be implicated. MRSA appears to be a rare cause of nonsuppurative cellulitis when extrapolated from staphylococcal patient-colonization data, although colonization may not be a primary risk factor in the pathogenesis of this infection.<sup>65</sup> In young children, particularly those under 2 years of age, *Haemophilus influenzae* type b (Hib) was traditionally implicated in a facial cellulitis termed *buccal cellulitis*, although this form is now less common since licensure of the conjugated Hib vaccine.<sup>66</sup> Buccal cellulitis characteristically reveals a dusky red to blue discoloration of the involved skin. Children with *H. influenzae* cellulitis may be quite toxic, with accompanying upper respiratory tract symptoms and bacteremia or septicemia. *Streptococcus pneumoniae* is another potential etiology of facial cellulitis in children, occurring especially in those under 36 months of age who are at risk for pneumococcal bacteremia. Because 96% of the serotypes (in one large series of *S. pneumoniae* facial cellulitis) are included in the heptavalent-conjugated pneumococcal vaccine now licensed in the United States, this cause of cellulitis will likely become significantly less relevant in years to come.<sup>67</sup> Lastly, in children younger than 3 months of age, cellulitis is most commonly caused by group B streptococci (GBS) and is more likely to be associated with invasive disease, including bacteremia and meningitis.<sup>68</sup> These children require blood, urine and cerebrospinal fluid (CSF) sampling and cultures as part of their initial evaluation.

Periorbital cellulitis is a unique form of cellulitis that deserves special mention here, given the potential confusion with orbital cellulitis and the associated complications. Periorbital (preseptal) cellulitis is a form of the disease that presents with erythema and swelling of the periorbital tissues. It may appear after skin trauma, in which case it is usually caused by *S. aureus* or GABHS infection or may result from cutaneous spread of pathogens from the paranasal sinuses or bloodstream, where it may result from Hib or *S. pneumoniae* infection. If the infection traverses the orbital septum (a continuation of the periosteum of the bony orbit to the margins of the upper and lower eyelids), it may result in orbital cellulitis, a more serious condition that may be complicated by abscess formation or cavernous sinus thrombosis.<sup>69</sup> Patients with orbital cellulitis may experience proptosis, ophthalmoplegia, and decreased visual acuity in addition to the cutaneous findings. Computed tomography (CT) and ophthalmologic examina-

tions are indicated if orbital cellulitis is suspected. The microbiology of periorbital and orbital cellulitis has also changed with the advent of Hib immunization, and Hib is now a very uncommon cause of these disorders, being supplanted by streptococcal species (including *S. pneumoniae* and GABHS) and *S. aureus*.<sup>70-72</sup>

Treatment of cellulitis depends on the clinical presentation and knowledge (and identification, when possible) of the affecting organisms. The diagnosis of cellulitis is generally a clinical one, although fine-needle aspiration with Gram stain and bacterial culture may be helpful when unusual organisms are suspected (i.e., the immunocompromised host).<sup>61</sup> Antibiotic therapy that covers for GABHS and *S. aureus* will be appropriate in most cases of routine, nonfacial cellulitis. In geographic areas with high rates of CA-MRSA, antibiotic selection should include coverage against this organism. There is no consensus on the choice between oral and intravenous antibiotics, although blood cultures, intravenous antibiotics, and hospitalization have traditionally been recommended for children at high risk for cellulitis. In recent years, short-course intravenous antibiotic therapy has been increasingly used in emergency department (ED) settings but may be associated with a higher failure rate and longer ED stay.<sup>73</sup>

In children with facial or periorbital cellulitis, the possibility of *S. pneumoniae* and Hib infection should be considered in conjunction with the patient's age and immunization status, and antibiotics should be chosen accordingly. Imaging (most often contrast-enhanced CT or diffusion-weighted magnetic resonance imaging [MRI]) is recommended in these patients to define the extent of involvement and help guide appropriate therapy.<sup>74</sup> In infants younger than 3 months of age with cellulitis, GBS should be presumed as a potential etiologic agent, and in these infants, as well as the patient with periorbital or orbital cellulitis who is young, toxic, or shows signs of meningeal irritation, laboratory evaluation for sepsis and meningitis should be performed. Hospitalization with parenteral antibiotic therapy (and ophthalmologic consultation in those with orbital cellulitis) is indicated in these latter settings.

## ERYSIPelas

Erysipelas is a superficial cellulitis of the skin with marked lymphatic involvement, resulting in most cases from GABHS. The organism usually gains access by direct inoculation through a break in the skin, but occasionally hematogenous infection may occur. The initial lesion begins as a small area of erythema that gradually enlarges to reveal a characteristic warm, painful, shiny, bright red infiltrated plaque with a distinct and well-margined border. The face, scalp, and hands are the most common sites of involvement, although erysipelas may involve any skin surface. Penicillin, or a macrolide antibiotic in patients with penicillin allergy, is the drug of choice for therapy. In occasional patients, *S. aureus* may be a copathogen, in which case antimicrobial therapy directed against this organism is necessary.

## PERIANAL STREPTOCOCCAL DERMATITIS

Perianal streptococcal dermatitis (PSD, also known as *perianal dermatitis*, *perianal cellulitis*, *perianal streptococcal cellulitis*, and *streptococcal perianal disease*) is a well-defined entity that may be often overlooked. It presents as sharply circumscribed perianal erythema with occasional fissures, purulent discharge, and/or functional disturbances.<sup>75</sup> GABHS is the etiology in most cases of PSD, although *S. aureus* and coliform bacteria have also been recovered.<sup>76,77</sup> An epidemic outbreak in a daycare center has been reported.<sup>78</sup> In a recent series of 26 patients with perianal dermatitis, *S. aureus* was the most common isolate and clinically was notable for concurrent papules and pustules of the buttocks and extension of the erythema to the adjacent buttock skin.<sup>79</sup>

The skin findings in PSD are variable, from a dry pink appearance to bright red erythema (Fig. 14-20) with a wet surface and occasionally the presence of a white pseudomembrane.<sup>80</sup> The surface is often tender to touch, and associated symptoms include rectal itching or discomfort, painful defecation, blood-streaked stools, and constipation. In males, balanoposthitis or in females, vulvovaginitis may be present.<sup>81</sup> Fever is notoriously rare in patients with PSD. Streptococcal

**A****B**

**Figure 14-20** Perianal streptococcal dermatitis. Bright red erythema with a moist, tender surface (**A**) and pink maceration with mild exudate or pseudomembrane (**B**). Both patients were tender to palpation and had painful defecation.

pharyngitis may concomitantly be present in patients with PSD, but the exact associations between pharyngitis, PSD, and streptococcal colonization is unclear.<sup>80</sup> There is some suggestion that specific GABHS isolates may have a tropism for perineal tissues, but the mechanism of infection is not yet clear.<sup>81</sup> Guttae psoriasis (see Chapter 4), which is classically associated with streptococcal pharyngitis, may also be associated with PSD, and in any patient with new-onset guttate psoriasis, a thorough anogenital examination should be performed.

The differential diagnosis of PSD is broad and includes psoriasis, candidiasis, seborrheic dermatitis, cutaneous Crohn disease, pinworm infestation, and sexual abuse. The diagnosis can be confirmed by bacterial culture of a perianal swab, but when performing cultures to confirm the diagnosis of PSD, it is important to notify the laboratory of the microbe (GABHS) in question, because several labs utilize media selective for enteric pathogens with rectal swabs. Treatment with oral penicillin V, amoxicillin, a first-generation cephalosporin, or a macrolide or azalide (i.e., erythromycin, clarithromycin, or azithromycin) for patients allergic to penicillin is usually effective, with or without concomitant topical mupirocin. Some have suggested, however, that the risk of clinical recurrence is greater in patients treated initially with penicillin or amoxicillin.<sup>82</sup> Oral cefuroxime was demonstrated more effective than penicillin in one study and is another reasonable option.<sup>83</sup> If staphylococcal infection seems more probable clinically or is isolated in culture, the antibiotic regimen should be adjusted accordingly.

**Figure 14-21** Blistering dactylitis. Edema and a tense bulla on the thumb of this 7-year-old girl. Culture of the blister fluid yielded *Staphylococcus aureus* rather than the more commonly seen group A  $\beta$ -hemolytic streptococci.

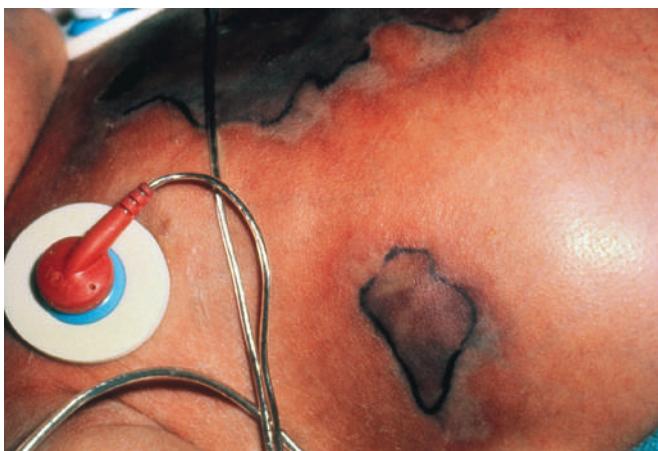

### BLISTERING DACTYLITIS

Blistering dactylitis (also known as *blistering distal dactylitis*) is a unique bullous manifestation of GABHS infection or only occasionally, other bacteria including *S. aureus* and GBS.<sup>84–86</sup> It is rarely reported in association with MRSA infection.<sup>87</sup> In its classic form, blistering dactylitis presents as a painful, tense, superficial blister on an erythematous base (Fig. 14-21) most often located over the volar fat pad of the distal phalanx of a finger or several fingers. It is most common in children between the ages of 2 and 16 years, although it is also reported in adults, most notably immunocompromised ones. The blisters may occasionally extend to involve the dorsal surfaces of the fingers. Systemic manifestations including fever are rare. The differential diagnosis of blistering dactylitis includes bullous impetigo, herpetic whitlow, traumatic blistering, burns, and epidermolysis bullosa. Coexistent whitlow and blistering dactylitis have been reported.<sup>88</sup> The diagnosis is confirmed by Gram stain and culture of blister fluid. If herpes infection is suspected, Tzanck smear, direct fluorescent antibody testing, or viral culture should be performed. Streptococcal blistering dactylitis is successfully treated with penicillin or erythromycin, but given recognition of the increasing role that staphylococci may play in the etiology, empiric antimicrobial therapy to cover for both organisms is recommended.

### NECROTIZING FASCIITIS

Necrotizing fasciitis is a rapidly progressive, potentially fatal, necrotizing infection of the skin and subcutaneous tissues commonly associated with severe systemic toxicity. Over the years it has been known by several different names, including *hospital gangrene*, *acute infective gangrene*, *streptococcal gangrene*, *gangrenous erysipelas*, *synergistic necrotizing cellulitis*, and *Meleney ulcer*. A popular term in the lay media is *flesh-eating bacteria disease*. Although usually caused by GABHS, necrotizing fasciitis may be polymicrobial in nature and has been reported in association with other streptococci, *P. aeruginosa*, *S. aureus*, *Klebsiella* species, *E. coli*, *Enterobacter cloacae*, *Serratia* species, *Proteus* species, *Enterococcus*, a variety of anaerobic agents including *Clostridium* species and *Bacteroides* species, and even *Vibrio* species.<sup>89–93</sup> CA-MRSA has been described as a potential monomicrobial cause of necrotizing fasciitis.<sup>94</sup> The disorder is most common in individuals with decreased local resistance (skin trauma, surgery, varicella), malnutrition, or chronic disease. Necrotizing fasciitis is rare in children. In neonates, it has been observed in association with omphalitis, balanitis, mammatitis, fetal scalp monitoring, and postoperative complications, with omphalitis being the most common.<sup>95,96</sup>

Necrotizing fasciitis most commonly presents on an extremity and is characterized by pain, edema, and erythema with exquisite

**Figure 14-22** Necrotizing fasciitis. Erythema and necrosis of the abdominal wall are seen in this severely ill toddler.

tenderness to palpation. These changes quickly progress through several sequential stages including ecchymosis, bullae, necrosis (Fig. 14-22), gangrene, and with deep and extensive infection, overlying skin anesthesia.<sup>90</sup> The inflammation extends deeply along fascial planes, highlighting the importance of rapid diagnosis and surgical exploration. Laboratory findings include leukocytosis, elevated serum creatine kinase level, hyponatremia, coagulopathy, and bacteremia. Fever, shock, and altered mental status typically develop within 48 hours. The most serious complication of necrotizing fasciitis is streptococcal toxic shock syndrome (TSS) (see below), which is characterized by hypotension, renal impairment, coagulopathy, liver abnormalities, respiratory distress, and a diffuse erythematous cutaneous eruption. Clinical clues that suggest necrotizing fasciitis over cellulitis include intense pain (often out of proportion to the clinical examination), rapid progression, bullae, necrosis, and lack of a rapid response to antibiotic therapy. Imaging studies may be useful in confirming the diagnosis, especially if soft-tissue gas is present, although this is not a consistent finding. MRI may be useful in distinguishing necrotizing fasciitis from uncomplicated infective fasciitis.<sup>97</sup> Confirmation of infection can be accomplished with Gram stain and culture of blister fluid, lesion discharge or tissue, blood culture, and polymerase chain reaction (PCR) analysis for pyrogenic exotoxin B on tissue biopsy specimens.<sup>91</sup>

Prompt thorough surgical debridement of necrotic tissue is of prime importance in the management of patients with this disorder, because without exploration and debridement, the mortality rate approaches 100%.<sup>98</sup> Additionally, greater delays in time to initial surgical debridement are associated with increased mortality in children, as in adults with similar infections.<sup>99</sup> Antimicrobial therapy should be initiated immediately, and the chosen agents should have activity against Gram-positive, Gram-negative, *Clostridium*, and anaerobic organisms.<sup>90,93</sup> Clindamycin in particular seems to be quite effective as part of the antimicrobial regimen, given its ability to suppress both toxin and M protein synthesis.<sup>92</sup> Antimicrobial therapy should be adjusted based on the results of Gram stain and bacterial cultures of the surgical specimen. In addition to these specific therapies, fluid resuscitation and blood pressure/blood product support are often indicated. The roles of hyperbaric oxygen therapy and intravenous immunoglobulin (IVIG) remain controversial, the latter being used primarily in the setting of GABHS infection with TSS.

## NOMA

Noma (cancrum oris, necrotizing ulcerative stomatitis) is a rare, progressive destructive infection usually involving the soft and hard tissues of the oral and paraoral structures. Most reported cases of noma are in children who are severely malnourished or chronically debilitated, and the disease tends to be most common in sub-Saharan Africa, South America, and Asia. The peak ages of incidence are

between 1 and 4 years.<sup>100</sup> The triad of malnutrition, poor oral hygiene, and periodontal disease contributes to the increased incidence in these locations.<sup>101</sup> It is usually caused by anaerobic organisms, including *Fusobacterium* species, *Prevotella intermedia*, *Actinomyces* species, *Pestotreptococcus micros*, and *Borrelia* species and is characterized by a gangrenous, ulcerative infection of the gingivae, buccal mucosa, and eventually the cheeks and jaw.

The initial stage of noma is characterized by a painful, small purple-red lesion that becomes indurated and progresses to edema, necrosis, and ulceration. With expansion, underlying bone involvement occurs with resultant loss of dentition. Bony sequestrations of the mandible or maxilla may occur. Patients may also have fever, tachycardia, tachypnea, and anorexia, and their medical history may reveal recurrent fevers, diarrhea, and history of parasitic and/or viral infections.<sup>102</sup> Treatment of noma includes antibiotics, wound care, and debridement with eventual surgical reconstruction. Without treatment, the mortality rate is 70% to 90%, and survivors suffer the long-term sequelae of orofacial mutilation and functional impairment.<sup>103</sup> Rehydration, attention to electrolyte balance, and nutritional rehabilitation to correct protein and micronutrient deficiencies are other important aspects of therapy.<sup>102</sup>

Noma neonatorum is a gangrenous process of the nose, eyelids, oral cavity, and anogenital region in low-birthweight infants and usually caused by *P. aeruginosa*. Most patients also have *Pseudomonas* sepsis, and the mortality rate without antimicrobial therapy is extremely high. Noma neonatorum, which is also more common in developing countries, was so named because of the clinical and histologic similarity to noma. However, there is significant overlap with the clinical presentation of ecthyma gangrenosum. Although some of the reported infants had immunodeficiency, it was either absent or not tested for in the majority of published cases. Noma neonatorum may represent a neonatal form of ecthyma gangrenosum.<sup>104</sup>

## MENINGOCOCCEMIA

Meningococcal infection, caused by the Gram-negative diplococcus *Neisseria meningitidis*, is a major world health problem in children under 5 years of age and is the leading cause of bacterial meningitis in children. Three serogroups of *N. meningitidis*, A, B, and C, account for more than 90% of cases of meningococcal disease, and along with groups Y and W-135 are implicated most commonly worldwide as causes of invasive disease.<sup>105,106</sup> Person-to-person spread of *N. meningitidis* usually occurs through inhalation of droplets of infected nasopharyngeal secretions by direct or indirect oral contact.<sup>107</sup> Meningococcal disease typically presents between 1 and 14 days after nasopharyngeal acquisition of *N. meningitidis*.<sup>108</sup>

Acute meningococcemia may present in a variety of ways, from transient fever to fulminant disease. After an upper respiratory prodrome, patients develop high fever and severe headache. If meningitis develops, stiff neck, nausea, vomiting, and coma may be present. Up to two-thirds of patients develop a skin eruption, most classically a petechial rash of the skin and mucous membranes. Other cutaneous morphologies include macular, morbilliform, and urticarial eruptions, as well as a gray-colored acrocyanosis. The petechiae are usually small, stellate, and gray-purple with a raised border and slightly depressed, vesicular, or pustular center.<sup>109</sup> The trunk and lower extremities (especially ankles and wrists) are common sites of predilection, whereas the palms, soles, and head tend to be spared. Mucosal surfaces including the palpebral and bulbar conjunctivae may be involved.<sup>105</sup> More extensive hemorrhagic lesions are seen in fulminant meningococcal infections, and a progressive increase on all areas of the body may be followed by coalescence of lesions to form large purpuric patches with sharply marginated borders (Fig. 14-23). These may progress to bullae, necrosis with sloughing, and eventual eschar formation. Autoamputation related to digital ischemic necrosis is a potential complication. Consumptive coagulopathy may be present and when occurring in the setting of progressive cutaneous hemorrhage and necrosis, is termed *purpura fulminans*.<sup>110</sup> This finding is felt to portend a poor prognosis for the patient with meningococcemia. Three important clinical features that are suggestive of early acute meningococcal disease are leg pain, cold hands and feet, and abnormal skin color.<sup>111</sup>

**Figure 14-23** Meningococcemia. Erythematous macules and papules with petechiae, purpura, and early skin necrosis.

Chronic meningococcemia is a rare form of meningococcal infection that is unusual in children. It is characterized by intermittent episodes of skin lesions in conjunction with fever, joint pain, myalgia, and episcleritis. The cutaneous lesions seen in the majority of patients appear in crops coincident with or after the fever. Individual lesions are usually macular and occasionally purpuric or pustular. Because of potential confusion with other infectious or collagen vascular illnesses, a high index of suspicion is necessary.<sup>112</sup> Patients with complement deficiencies, especially of the terminal complement system (C5-9), have an increased risk of both acute and chronic meningococcal infections.<sup>113</sup>

The differential diagnosis of meningococcemia includes gonococcemia, Henoch–Schönlein purpura, rickettsial diseases, enteroviral infections, erythema multiforme, atypical measles, hypersensitivity vasculitis, and other bacterial septicemias or meningitides. The diagnosis is confirmed by culture of the blood and CSF. Isolation of meningococci from the nasopharynx is presumptive but not diagnostic, because asymptomatic carriage is not uncommon.<sup>105</sup> Petechial lesions can be smeared and examined for the presence of Gram-negative diplococci and may be cultured for organisms. Serologic assays that can detect *N. meningitidis* capsular polysaccharide antigen in CSF, urine, serum, and other bodily fluids are also available. A serogroup-specific PCR test to detect *N. meningitidis* is used routinely in the United Kingdom and may be useful in patients who receive antimicrobial therapy before cultures have been obtained.<sup>106</sup> The diagnosis of chronic meningococcemia is best confirmed by blood culture taken during a febrile episode, although several cultures may be necessary.<sup>114</sup>

Meningococcal disease is treated with penicillin G, but at the time of presentation the initial choice of antimicrobials should be based on the clinical differential diagnosis and local antibiotic susceptibility patterns. Antibiotics with more expanded coverage such as cefotaxime or ceftriaxone are often used initially in patients with sepsis or meningitis until the diagnosis is confirmed.<sup>105</sup> In patients with a history of anaphylaxis to penicillin, chloramphenicol is recommended.<sup>106</sup> Supportive therapy with fluid, pressor, and blood product support as indicated is vital. Chemoprophylaxis of close contacts of patients with invasive meningococcal disease is recommended within 24 hours of diagnosis of the index case. Selective immunization is recommended for children 2 years of age and older in high-risk groups (asplenia, terminal complement deficiencies, or travel to endemic or epidemic areas). Routine immunization with the licensed quadrivalent vaccine is recommended for adolescents at the 11- to 12-year visit and at high school entry or 15 years of age (whichever comes first), as well as students entering college who plan to live in dormitories and military recruits. However, routine childhood immunization is not recommended because of the low incidence of disease, the poor response in young children, the short-lived immunity, and the potential impaired response to subsequent vaccine doses in some serogroups.<sup>106,115</sup>

**Figure 14-24** Gonococcemia. Hemorrhagic, erythematous papules and nodules involve the distal digits in this 17-year-old female with disseminated gonococcal infection and underlying systemic lupus erythematosus.

## GONOCOCCEMIA

Gonococcemia is associated with cutaneous lesions similar to those of meningococcemia and presents with fever, chills, arthralgia, and myalgia in patients with gonococcal septicemia. Symptoms of sexually transmitted gonococcal infection may or may not be present, including vaginitis, pelvic inflammatory disease, urethritis, proctitis, or pharyngitis. Hematogenous spread of *Neisseria gonorrhoeae* occurs in up to 3% of untreated persons with mucosal gonorrhea.<sup>116</sup> Skin lesions develop within 3 to 21 days of contact, are located primarily over joints of the distal extremities, and usually appear as petechiae, small erythematous or hemorrhagic papules, or vesiculopustules (Fig. 14-24). They usually heal spontaneously in 4 to 6 days.

The causative agent, *N. gonorrhoeae*, is a Gram-negative diplococcus and may be demonstrated by smear, culture, or immunofluorescence studies of skin lesions or by culture of the blood, anogenital tract, pharynx, or joint fluid on Thayer–Martin medium (chocolate agar with the addition of antibiotics to inhibit normal flora and nonpathogenic neisserial organisms). Nucleic acid amplification studies (i.e., PCR) are also available and have a high sensitivity and specificity when performed on urethral or cervicovaginal swabs.<sup>116</sup>

The treatment of choice for gonococcemia is parenteral ceftriaxone or cefotaxime. Alternatives for individuals with β-lactam allergy include ciprofloxacin, ofloxacin, or spectinomycin. If concomitant infection with *Chlamydia trachomatis* is suspected, initial therapy should also include erythromycin, doxycycline, or azithromycin.

## STAPHYLOCOCCAL SCALDED SKIN SYNDROME

SSSS is a term used to describe a blistering skin disease caused by the epidermolytic (or exfoliative) toxin (ET)-producing *S. aureus*. It was previously known as *Ritter disease* or *pemphigus neonatorum* and tends to occur most often in neonates and young children. Its severity may range from mild, localized blistering to widespread exfoliation. Mild cases are probably more common yet less often reported.<sup>117</sup>

The pathogenesis of SSSS relates to the production of ETs, of which there are two serotypes affecting humans, ETA and ETB. These toxins have high sequence homology and are both capable of cleaving the epidermis at the superficial level of the stratum granulosum. The pathogenic mechanisms of ETA and ETB have been clearly elucidated, and they have been shown to target desmoglein 1, a cell–cell adhesion molecule found in desmosomes of the superficial epidermis.<sup>118–120</sup> Desmoglein 1 is the same molecule targeted in the autoimmune blistering disease, pemphigus foliaceus (PF) (see Chapter 13).<sup>118</sup> Once it was determined that antibodies against desmoglein 1 cause PF, astute researchers hypothesized and eventually proved that the target of the staphylococcal exfoliative toxin was also desmoglein 1.<sup>121</sup> There are two main theories for the observation that SSSS preferentially affects

**Figure 14-25** Staphylococcal scalded skin syndrome. Periorbital and perioral erythema and erythema of the neck folds and upper trunk in this 4-year-old boy with early infection.

neonates and children: lack of protection from antitoxin antibodies and decreased renal excretion of the toxin.<sup>122</sup> In adults, SSSS is quite rare and usually occurs in the setting of immunosuppression, malignancy, heart disease, or diabetes.<sup>123</sup>

Outbreaks of SSSS have been reported in neonatal intensive care units and well-baby nurseries. In these settings, asymptomatic or clinically infected healthcare workers often act as carriers of the epidemic strain of *S. aureus*, and given the potential severity of infection in the premature infant, prompt recognition with institution of strict infection-control strategies is vital to prevent further nosocomial spread.<sup>124,125</sup> In a series of 39 neonates with SSSS, pneumonia was the most common complication, followed by myocarditis.<sup>126</sup>

SSSS generally begins with localized infection of the conjunctivae, nares, perioral region, perineum, or umbilicus. Separation of perioral crusts often leaves behind radial fissures around the mouth, resulting in the characteristic facial appearance of SSSS (Figs. 14-25 and 14-26). Other infections that may serve as the initial nidus for SSSS include pneumonia, septic arthritis, endocarditis, or pyomyositis. Fever, malaise, lethargy, irritability, and poor feeding subsequently develop, and the generalized eruption begins. The rash is characterized by erythema that progresses to large, superficial fragile blisters that rupture easily, leaving behind denuded, desquamating, erythematous, and tender skin (see Fig. 14-26; Fig. 14-27). The eruption is most marked in flexural creases but may involve the entire surface area of skin. The Nikolsky sign (progression of the blister cleavage plane induced by gentle pressure on the edge of the bulla) is positive. With extensive denudation of skin, patients may have decreased thermoregulatory ability, extensive fluid losses, and electrolyte imbalance and are at serious risk for secondary infection and sepsis. With appropriate management the skin heals without scarring, given the superficial cleavage plane of the blisters.

SSSS is usually diagnosed based on the clinical presentation. The main differential diagnosis is toxic epidermal necrolysis (TEN), a severe exfoliative condition that is usually drug-induced and has a high mortality rate. The most helpful distinguishing feature of TEN is mucosal involvement, including of the mouth, conjunctivae, trachea, and genital mucosa, which is lacking in SSSS.<sup>122</sup> Other less common differential diagnoses include scalding burns, epidermolysis bullosa, graft-versus-host disease, nutritional deficiency dermatosis, and bullous ichthyosis (in the neonate). The diagnosis of SSSS is confirmed by isolation of *S. aureus*. It must be remembered that the majority of blisters in SSSS are sterile, because they are caused by the hematogenous dissemination of the bacterial toxin and not the bacteria itself. The organism is most easily recovered from pyogenic (not exfoliative) foci on the skin, conjunctivae, nares, or nasopharynx. When the diagnosis remains in question, differentiation from TEN can be made by microscopic examination of a skin snip of the blister roof or a skin

**Figure 14-26** Staphylococcal scalded skin syndrome. Facial and neck-fold erythema with desquamation, crusting, and perioral radial fissures (A) and a distant ruptured bulla on the toe (B) of an infant girl with the disorder.

**Figure 14-27** Staphylococcal scalded skin syndrome. Diffuse peeling and erythema in a 4-week-old African-American infant girl who also had *Staphylococcus aureus* isolated from her blood.

biopsy. In SSSS, cleavage occurs in the superficial epidermis at the level of the granular layer, whereas in TEN the split occurs below the dermal-epidermal junction.

Treatment of SSSS is directed at the eradication of toxin-producing staphylococci, thus terminating toxin production. A penicillinase-resistant penicillin, first- or second-generation cephalosporin, or

clindamycin are all appropriate initial choices, with modification based on sensitivity testing. In patients with MRSA infection, parenteral vancomycin or other agents (as dictated by local resistance patterns) would be indicated. Because SSSS is usually a more mild disease in older children, ambulatory therapy may be an option in this population. In neonates or in infants or children with severe infection, hospitalization is mandatory, with attention to fluid and electrolyte management, infection control measures, pain management, and meticulous wound care with contact isolation. In particularly severe disease, care in an intensive care or burn unit is required. Neutralizing antibodies that inhibit the binding of ETs to desmoglein 1 are under investigation, given concerns about the development of antibiotic-resistant, exfoliative-toxin-producing staphylococci.<sup>127</sup>

### TOXIC SHOCK SYNDROME

TSS is an acute febrile illness characterized by fever, rash, hypotension, and multisystem organ involvement. Although classically described in menstruating women in relation to the use of superabsorbent tampons, TSS is now recognized in both menstrual and nonmenstrual forms, the latter now being more common.<sup>128</sup> Nonmenstrual TSS may occur in association with surgical procedures, nasal packing, the postpartum state, and a variety of *S. aureus* infections.

TSS is caused by toxin-producing strains of *S. aureus*. Manifestations of the disease are mediated primarily by the TSS toxin (TSST-1) and staphylococcal enterotoxins (SEA, SEB, SEC). These toxins are capable of widespread polyclonal activation of T cells, which results in massive cytokine release and in the clinical picture of TSS. Both TSST-1 and the SEs are considered "superantigens," given their ability to activate T cells without intracellular processing and via specific binding to major histocompatibility complex (MHC) class II molecules.<sup>129,130</sup> MRSA appears to account for a small percentage of TSS cases.<sup>131</sup>

A prodrome of mild constitutional symptoms including malaise, myalgias, and chills often precedes the symptoms of TSS. Eventually fever develops along with lethargy, diarrhea, chills, nausea, and altered mental status. Symptoms of hypovolemia including hyperventilation, palpitations, and orthostatic dizziness may be present.<sup>132</sup> Physical findings include high fever, hypotension, a diffuse rash, and pharyngitis with hyperemia of mucous membranes. The cutaneous eruption is a diffuse, macular erythroderma that is occasionally reminiscent of the rash of scarlet fever. Accentuation of the eruption in skin folds is a common finding, and in rare cases the inguinal or perineal regions may be the only skin surfaces involved.<sup>133</sup> Edema of the hands, feet, and face may be present, and desquamation of the affected skin surfaces (Fig. 14-28) eventually ensues. The nails may be shed, and telogen effluvium may occur up to several months later. Oral examination often reveals a strawberry tongue (Fig. 14-29), and palatal petechiae may be present. Diffuse myalgia is almost always present, and many patients complain of exquisite skin or muscle tenderness when they are touched or moved.

In addition to the fever, desquamating rash, and hypotension, evidence of multiorgan involvement is present. To meet the case definition of TSS, three or more of seven other organ systems must be involved (Box 14-3).<sup>134</sup> The diagnosis of TSS generally rests on clinical criteria, although isolation of *S. aureus* from a normally sterile site, especially if toxin production can be demonstrated, is supportive. Histopathologic findings on skin biopsy are not pathognomonic. The differential diagnosis of TSS includes streptococcal TSS (see below), Kawasaki disease, scarlet fever, drug reaction, atypical measles, Rocky Mountain spotted fever, and other exanthematous illnesses. The presence of shock and multiorgan involvement is unusual in the other entities, except for streptococcal TSS, which usually has some distinguishing features.

A neonatal TSS-like disease has been reported, and in some of these patients MRSA was recovered.<sup>135</sup> When studied, several of these MRSA isolates were positive for TSST-1 production. Most of the reported neonates had a mild course with a fairly rapid recovery.<sup>135</sup>

Since the late 1980s a disease similar to TSS yet with some distinguishing features has been recognized. This disorder is associated with toxin-producing GABHS and is referred to as *streptococcal TSS*. Although the pathogenic mechanisms are not entirely clear, streptococcal pyrogenic exotoxins (SPEA, SPEB, SPEC), mitogenic factor, and

**Figure 14-28** Desquamation in toxic shock syndrome. Mild perineal (A) and digital (B) desquamation in a 3-year-old female with toxic shock syndrome.

**Figure 14-29** Strawberry tongue in toxic shock syndrome. Hyperemia with prominent lingual papillae.

streptococcal superantigen appear to be associated with the clinical findings.

Streptococcal TSS is similarly characterized by the acute onset of shock and multisystem organ failure, but unlike staphylococcal TSS, patients usually have a focal, invasive tissue or blood infection with GABHS (Box 14-4). Most patients with streptococcal TSS have pain localized to an extremity in association with necrotizing fasciitis or myonecrosis. This pain is usually out of proportion to the clinical findings on physical examination. Varicella is a particularly important risk

### Box 14-3 Case Definition of Toxic Shock Syndrome

- Temperature  $>38.9^{\circ}\text{C}$  ( $102^{\circ}\text{F}$ )
- Diffuse macular erythroderma
- Desquamation, 1 to 2 weeks after onset, particularly of the palms and soles
- Hypotension
- Multisystem involvement (3 or more of the following):
  - Gastrointestinal (vomiting, diarrhea)
  - Muscular (severe myalgia, increased creatine phosphokinase level)
  - Mucous membrane (vaginal, oropharyngeal, or conjunctival) hyperemia
  - Renal (elevated serum urea nitrogen or serum creatinine level more than twice the upper limit of normal, or urinary sediment with  $>5$  WBC per field in absence of UTI)
  - Hepatic (total bilirubin, AST or ALT greater than twice the upper limit of normal)
  - Hematologic (platelet count  $\leq 100,000/\text{mm}^3$ )
  - Central nervous system (disorientation, altered consciousness without focal neurologic signs when fever and hypotension are absent)
- Laboratory criteria: negative results on the following tests (if obtained):
  - Blood, throat, or CSF cultures (except blood culture may be + for *S. aureus*)
  - Serologic tests for Rocky Mountain spotted fever, leptospirosis, or measles

Probable disease: meets laboratory criteria and 4 of the 5 bulleted (dark green) findings are present

Confirmed disease: meets laboratory criteria and all 5 of the bulleted (dark green) findings, including desquamation (unless patient expires before desquamation occurs)

<sup>†</sup>Probable case: from a nonsterile site and both bulleted (dark green) findings.

factor for invasive GABHS infections in children, and in the child with varicella who becomes febrile after having been afebrile or who has any fever beyond the fourth day of illness, GABHS infection should be considered.<sup>136</sup>

A prodromal illness with influenza-like symptoms is present in up to 20% of patients with streptococcal TSS. Subsequently shock

develops rapidly, and often the patients develop renal impairment, disseminated intravascular coagulopathy, and an adult respiratory distress syndrome-like illness. Physical examination reveals a diffuse macular erythroderma and mucous membrane findings similar to those seen in staphylococcal TSS. Examination of the site of primary infection (usually an extremity) reveals localized swelling and erythema with eventual development of vesicles and hemorrhagic bullae.<sup>137</sup> Laboratory aberrations include leukocytosis, anemia, thrombocytopenia, elevation of serum creatinine and creatine phosphokinase, hypocalcemia, abnormal liver function studies, and evidence of disseminated coagulopathy. Streptococcal TSS presenting with purpura fulminans has been reported.<sup>138</sup> In one series of pediatric streptococcal TSS, one-quarter of the patients succumbed to the disease as a result of refractory shock and multiorgan failure; in half of these, death occurred within 24 hours of hospital admission.<sup>139</sup>

Management of TSS is similar for both staphylococcal and streptococcal disease. Supportive therapy (including aggressive fluid management), vasopressors, and antibiotics are the mainstays of therapy. Identification of sites of infection is vital, with appropriate drainage or in the case of streptococcal TSS, aggressive and early surgical exploration and debridement as indicated. Many experts recommend combination antibiotic therapy that includes clindamycin, given its effects on protein (i.e., toxin) synthesis inhibition, although clindamycin should not be used alone.<sup>136</sup> IVIG may be beneficial when used in combination with antibiotics for TSS because IVIG blocks superantigen-induced T-cell activation. Use of IVIG should be considered in patients in whom there has been no clinical response within the first several hours of aggressive supportive therapy.<sup>134,140</sup>

### ERYTHRASMA

Erythrasma is a superficial bacterial infection of the skin caused by *C. minutissimum*. It is characterized by asymptomatic, well-demarcated, reddish-brown, slightly scaly patches in the groin, axillae, gluteal crease, or inframammary regions and less often the interdigital spaces of the feet. Involvement of the vulvar mucosae has been observed.<sup>141</sup> Some 15% of erythrasma cases occur in children between 5 and 14 years of age. Erythrasma is often confused with a dermatophyte infection (i.e., tinea corporis), with which it may occasionally coexist. However, it can be differentiated from tinea infection by the characteristic coral red fluorescence seen when viewed under Wood lamp illumination (because of the production of porphyrins by the corynebacteria). Erythrasma tends to be more common in patients who are overweight, the elderly, and patients with diabetes.<sup>142</sup> Culturing the organism is difficult and requires a special medium. Erythrasma may be treated with topical antibiotics including erythromycin or clindamycin, although there is some evidence of increasing antibiotic resistance to the former.<sup>143</sup> Antibacterial soaps may help prevent recurrence. Oral antibiotic therapy is very effective and classically includes erythromycin, tetracycline, or newer macrolide agents.<sup>144</sup> In one recent series of patients with erythrasma who had cultures and susceptibility testing performed, amoxicillin clavulanate was the systemic agent with the least demonstrated resistance and hence should also be considered as potential systemic therapy when indicated.<sup>143</sup> *C. minutissimum* has rarely been associated with more severe disease, including cellulitis and bacteremia.<sup>145</sup>

### TRICHOMYCOSIS AXILLARIS

Trichomycosis axillaris (trichobacteriosis) is a superficial infection of the axillary and less commonly pubic hairs that results in adherent white or yellow concretions distributed irregularly along the hair shafts. *C. tenuis* is the causative agent for this condition and hence the traditional name *trichomycosis axillaris*, which implies a fungal infection, is a misnomer. The disorder usually occurs after puberty owing to its association with axillary and pubic hair but then occurs with equal incidence in all postpubertal age groups. The most common sign of trichomycosis axillaris is the presence of red-stained perspiration on the clothing, and individuals with hyperhidrosis often complain of a particularly offensive axillary odor. The nodules of trichomycosis axillaris consist of bacterial elements embedded in an amorphous matrix, and Gram stain reveals thread-like Gram-positive bacteria.

**Figure 14-30** Pitted keratolysis. Shallow pits of the plantar great toes in this adolescent boy. Malodor was also present.

Affected areas only rarely fluoresce (as a pale yellow color) under Wood light examination. Treatment consists of shaving the hairs of the affected areas, using antiperspirants (to help decrease hyperhidrosis and growth of Gram-positive flora), and the application of topical antibiotics such as clindamycin or erythromycin. Benzoyl peroxide has also been demonstrated to be useful.

### PITTED KERATOLYSIS

Pitted keratolysis is another superficial corynebacterial infection, in this case involving the plantar feet, lateral aspects of the toes, and occasionally the palms. It is characterized by erythema with shallow round pits (Fig. 14-30), crateriform depressions, or shallow erosions most commonly involving weight-bearing portions of the feet. Malodor is common, and although the condition is usually asymptomatic, painful, plaque-like lesions have been reported in children.<sup>146</sup> Pitted keratolysis is caused by *Corynebacterium (Kytococcus) sedentarius*, which produces extracellular enzymes capable of degrading human keratins.<sup>147</sup> The disorder has worldwide distribution and occurs most commonly in hot, tropical climates and in populations (i.e., homeless individuals, elite athletes) who experience repeated skin exposure to moisture and environmental hazards.<sup>148,149</sup> The diagnosis is fairly straightforward and based on clinical findings, although Gram stain of stratum corneum shavings can be used if necessary. Culture is generally not helpful. Pitted keratolysis is treated with topical erythromycin, clindamycin, or mupirocin. Clindamycin-benzoyl peroxide combination topical gel was very effective in an open-label study of four patients.<sup>150</sup> Treatment of the hyperhidrosis component with prescription-strength aluminum chloride products or 40% formaldehyde in petrolatum ointment is also useful.

### ERYSIPEROID

Erysipeloid is an infection of traumatized skin, particularly the fingers, hands, or arms of individuals who handle meat, raw saltwater fish, shellfish, or poultry and in those who come into contact with certain animals, especially pigs, sheep, rabbits, chickens, turkeys, ducks, emus, pigeons, cows, guinea pigs, cats, dogs, fish, and shellfish.<sup>151</sup> As such, it is most commonly associated with occupations such as animal breeders, veterinarians, slaughterhouse workers, butchers, fishermen, fishmongers, cooks, and grocers.<sup>152</sup> It is caused by *Erysipelothrix rhusiopathiae* (*insidiosa*), a Gram-positive bacillus that can survive for months in soil or decomposed organic material. Human infection with this organism can take one of three forms: the mild cutaneous infection erysipeloid, which may be confused clinically with erysipelas; a diffuse cutaneous form; and a serious systemic infection, usually septicemia or endocarditis.<sup>153</sup> Erysipeloid presents 1 to 7 days after inoculation as a painful, violaceous-red, sharply demarcated patch, usually on the hand or a finger. Burning, pain, or pruritus may be reported by the patient, and constitutional symptoms may occasionally be present.

A diffuse, generalized eruption in regions remote from the site of infection, hemorrhagic vesicles, and regional lymphadenopathy may occasionally occur. Systemic complications are rare and include septicemia, endocarditis, septic arthritis, cerebral infarct, osseous necrosis, and pulmonary effusion. When endocarditis occurs, it tends to involve structurally damaged but native left-sided valves.<sup>154</sup>

The diagnosis of localized cutaneous erysipeloid can be difficult, because the organism does not grow well in culture and tissue biopsy findings are nonspecific. The yield in culture may be increased by using enriched blood culture and incubating with 5% to 10% carbon dioxide. Blood culture may be useful when systemic infection is present. PCR assays are also available to assist in the diagnosis. Although the vast majority of patients with untreated localized erysipeloid tend to recover spontaneously within 3 weeks, antibiotics such as penicillin, cephalosporins, erythromycin, and tetracyclines (among others) have been demonstrated to be effective.

## Nontuberculous (“Atypical”) Mycobacterial Infections

The nontuberculous mycobacteria (NTM), which have traditionally been referred to as *atypical mycobacteria*, include those species different from *Mycobacterium tuberculosis*. These slender, nonmotile, acid-fast organisms have a worldwide distribution and usually are nonpathogenic for humans. Infection tends to occur in immunocompromised individuals or when in the immunocompetent host, after an episode of skin trauma.<sup>155</sup> Six major clinical syndromes have been identified, including lung infection, lymphadenitis, SSTI, disseminated infection, catheter-related infection, and chronic granulomatous infection of bones, joints, and tendon sheaths.<sup>156</sup> Skin infection with NTM usually manifests as skin nodules, abscesses, papulopustules, or ulcers.<sup>157</sup> Systemic spread most often occurs in immunocompromised hosts. The diagnosis of NTM infection is usually confirmed by histology and tissue culture.

The NTM include *Mycobacterium marinum*, *Mycobacterium ulcerans*, *Mycobacterium fortuitum*, *Mycobacterium chelonae*, *M. abscessus*, *Mycobacterium kansassii*, *Mycobacterium avium-intracellulare* (*Mycobacterium avium* complex), and a variety of others that less commonly result in clinical infection. Those that will be discussed in this section are *M. marinum* (swimming pool granuloma), *M. ulcerans* (Buruli ulcer), and *M. fortuitum/M. chelonae/M. abscessus* (the “rapid growers”). Cervical lymphadenitis caused by NTM will also be briefly discussed.

*M. marinum* may result in a skin infection termed *swimming pool granuloma* or *fish-tank granuloma*. The organism resides in stagnant water and seawater as well as in natural pools and some heated pools in temperate climates. Exposure to fish-tank water is a more recently described source for inoculation and seems to be a fairly common mode of infection.<sup>158,159</sup> Abrasions from swimming pools or fish tanks and at times cuts sustained from cleaning fish may become infected with this NTM. *M. marinum* infections, sometimes unusually aggressive ones, are being increasingly reported in patients receiving anti-tumor-necrosis factor therapy, including etanercept and infliximab.<sup>160,161</sup> Most lesions begin on an extremity, hand, or foot after an incubation period of 2 to 3 weeks. In some studies the incubation period may be longer, up to 9 months after inoculation.<sup>162</sup> Infection begins with a nodule or pustule that eventually forms an ulcer or abscess. Multiple secondary lesions develop, often in a linear, lymphatic (sporotrichoid) distribution (Fig. 14-31). Without therapy, the skin lesions resolve over 1 to 3 years with scarring. Potential associated complications include tenosynovitis, arthritis, and osteomyelitis, and in immunocompromised individuals severe disseminated infection may occur. The differential diagnosis includes cellulitis, sporotrichosis, syphilis, cutaneous leishmaniasis, tularemia, foreign-body reaction, cat-scratch disease (CSD), neoplasia, and deep fungal infection. Skin biopsy reveals inflammation with tuberculoid granulomas, and culture of *M. marinum* from tissue confirms the diagnosis. Although purified protein derivative (PPD) skin testing may be positive, it is not diagnostic of *M. marinum* infection.

When a patient has cutaneous lesions suggestive of *M. marinum* infection, a thorough exposure history should be pursued and tissue biopsy performed. Although there is no completely satisfactory

**Figure 14-31** *Mycobacterium marinum* infection. This boy developed nodules that subsequently ulcerated on the dorsal foot (*superior lesion in photograph*) and the medial ankle (*inferior lesion in photograph*). The family had a large fish tank that they routinely cleaned in the bathtub used by the patient.

**Figure 14-32** Nontuberculous mycobacterial cervical lymphadenitis. This fluctuant, violaceous nodule developed in the inferior mandibular region of this otherwise-healthy 3-year-old girl. Occasional drainage had been noted by her parents, and the lesion improved gradually with clarithromycin therapy.

treatment for this infection, options that have been used with variable success include tetracycline, minocycline, doxycycline, clarithromycin, sulfamethoxazole-trimethoprim, linezolid, and rifampin, alone or in combination with ethambutol.<sup>155,158,163,164</sup> Excision, curettage, and warm compresses are traditional treatment modalities that may be helpful for early or small lesions, but recurrences are common.

*M. ulcerans* may result in an ulcerating skin condition called *Buruli ulcer*, which is most common in Africa, Central and South America, and Asia. Buruli ulcer usually begins after a scrape by grass or a thorn and presents initially as a painless nodule that progresses to abscess formation and eventually, a shallow ulcer. The favored site of distribution is a lower extremity. The ulcer persists for months to years and eventually heals spontaneously with scarring and lymphedema.<sup>155</sup> Surgery, hyperthermic therapy, and systemic antimicrobials have all been used with variable success.

*M. fortuitum*, *M. cheloneae*, and *M. abscessus* are all referred to as *rapid growers*, given their distinctive ability to produce colonies in culture as soon as 5 to 7 days. They may result in clinical disease after trauma, the most notable association being abscess formation after surgery, especially within postsurgical scars. Children are more likely to experience infection with *M. fortuitum* than the other two rapidly growing NTMs, which are more commonly isolated from older individuals.<sup>165</sup> There are increasing reports of *M. cheloneae* infection after tattooing, with culture of the organism originating from premixed tattoo inks.<sup>166–168</sup> Inflammatory skin lesions (papules, pustules, and nodules) involving primarily the palms and soles have been observed in children in association with *M. abscessus* infection acquired from public swimming pools. This presentation has been designated by some as “*M. abscessus* hand-and-foot disease,” and may have a prolonged latency (45 to 60 days) between exposure and onset, which is significantly longer than that typically seen with *Pseudomonas* hot foot syndrome (see earlier this chapter).<sup>169,170</sup> Lesions may occasionally occur in other sites including elbows, knees, and trunk, and although this condition is self-limited, recurrences may occur. This observation has led some to recommend therapy with an appropriate agent such as clarithromycin when this diagnosis is suspected or confirmed.<sup>170</sup>

Cervical lymphadenitis resulting from NTM should be mentioned, because it is the most common manifestation of infection with these agents in healthy, immunocompetent children. These patients usually experience nontender, unilateral cervical lymphadenopathy, although other sites may be involved including the inguinal region, axilla, and lower limb.<sup>171,172</sup> There may or may not be a history of preceding local trauma, and the area may reveal overlying erythema (Fig. 14-32), violaceous discoloration, fluctuance, or drainage. The most common of the NTM to cause cervical lymphadenitis is *M. avium-intracellulare*,<sup>171,173</sup> although *Mycobacterium haemophilum* appears to be increasing in incidence as another etiology in some areas.<sup>174,175</sup> Treatment options include surgery, incision and drainage, and antimicrobial therapy including ethambutol, rifampicin, and clarithromycin. Observation alone is another option given the complete resolution seen in most patients within 9 to 12 months.<sup>176</sup> Although surgical excision has long been considered the standard of care for NTM lymphadenitis, more diversified treatment strategies including the increased use of antimicrobial agents is being observed.<sup>177</sup>

## Tuberculosis of the Skin

The incidence of cutaneous tuberculosis was at one time declining owing to the availability of effective antimycobacterial therapy, improvement in living standards, and vigorous preventative and therapeutic programs. However, it has reemerged in areas with a high incidence of HIV infection and multidrug-resistant pulmonary tuberculosis.<sup>178,179</sup> Most published reports of childhood cutaneous tuberculosis are from developing countries, and the prevalence is high in India and Southeast Asia, although the highest prevalence is reported in Pakistan.<sup>180</sup> Cutaneous tuberculosis can be acquired either exogenously or via hematogenous spread of *M. tuberculosis* and may show a wide range of clinical presentations. The majority of cases of cutaneous tuberculosis are related to systemic involvement. In this section, several types of tuberculous skin lesions are reviewed. Of the lesions discussed, scrofuloderma and lupus vulgaris tend to be the most common types of cutaneous tuberculosis to occur in children.<sup>181,182</sup>

Primary tuberculous complex (tuberculous chancre) develops as a result of inoculation of *M. tuberculosis* into the skin (and occasionally the mucosa) of an individual who has not previously been infected or who has not acquired immunity to the organism. This disorder occurs on exposed surfaces at sites of trauma (i.e., abrasion, insect bite, puncture wound, ritual circumcision, ear piercing, tattooing). The cutaneous lesion develops 2 to 4 weeks after inoculation, and the earliest lesion is a brown-red papule that develops into an indurated plaque that may ulcerate. The edges of the ulcer are ragged and undermined, and thick adherent crusts may be present. When viewed through a

**Figure 14-33** Scrofuloderma. A discharging sinus is noted from the tuberculous focus in the underlying bone in this 4-year-old boy. (Courtesy of Venkatesh Ramesh, MD.)

glass slide producing pressure on the lesion (diascopy), these areas may have an “apple jelly” yellow-brown color. Marked regional lymphadenopathy may be associated with the skin lesion<sup>183</sup> and usually develops several weeks after the cutaneous lesion. Healing of the ulcer generally occurs over several weeks, but the regional lymphadenopathy may persist significantly longer and after weeks to months may soften and form sinuses that communicate with the skin surface (scrofuloderma).

*Scrofuloderma* refers to direct extension to the skin from underlying foci of tuberculous infection, and in addition to lymph nodes may occur overlying infection of the bone or joint. It is the most common form of cutaneous tuberculosis in children. Scrofuloderma is manifested most commonly as painless swelling in the parotid, submandibular, supraclavicular, or lateral regions of the neck.<sup>184</sup> As the lesions grow, they may develop ulcers and sinuses (Fig. 14-33). *M. tuberculosis* can be easily identified by Gram stain and culture of the draining exudate. Untreated lesions of scrofuloderma may persist with little change for years and eventually heal with cicatricial bands.

Tuberculosis verrucosa cutis (warty tuberculosis) is an externally acquired, relatively uncommon inoculation type of tuberculosis in individuals who have had previous contact with *M. tuberculosis* and thus have some degree of immunity. The inoculation usually occurs at sites of minor wounds or abrasions, and it occurs most often in adults with occupations that require the handling of patients with tuberculous infections or tuberculous tissues, including pathologists (“prosector’s wart”) and butchers (“butcher’s wart”). Lesions usually occur on the dorsal hands, fingers, or lower extremities. They begin as small violaceous papules that become hyperkeratotic and warty. Multiple lesions may occur, but the majority of lesions of tuberculosis verrucosa cutis are solitary.

Lupus vulgaris is the most common form of cutaneous tuberculosis. It is a chronic, smoldering form of the infection and usually occurs in individuals with a high degree of sensitivity. Although lupus vulgaris can arise at the site of a primary inoculation, in the scar of scrofuloderma, or at the site of a bacillus Calmette-Guérin (BCG) vaccination, it generally appears in previously normal areas of skin. The most common location of involvement is the head and neck, and regional lymphadenopathy may be present in over half of the patients.<sup>182</sup> In children in India, this form of cutaneous tuberculosis most often occurs on the lower extremities and gluteal region.<sup>180</sup> Lupus vulgaris presents as small, soft, brown-red papules that enlarge and coalesce to form larger patches with elevation and intensification of their brownish color. As in tuberculous chancre, the lesion shows a characteristic apple-jelly color on diascopy. The natural history of lupus

**Figure 14-34** Lupus vulgaris. This 7-year-old boy had an enlarging erythematous, infiltrative, scaly plaque of the nasal bridge, cheek, and periorbital region. Note the characteristic central scarring and peripheral activity. (Courtesy of Venkatesh Ramesh, MD.)

vulgaris is marked by slow and limited growth over years or occasionally decades. Ulceration and atrophy may occur.<sup>181,184</sup> When ulceration occurs, it may be complicated by scarring and disfigurement, especially with nose and nasal cartilage involvement (Fig. 14-34). The differential diagnosis of lupus vulgaris includes sarcoidosis, cutaneous lymphoid hyperplasia, lupus erythematosus, halogenoderma, leishmaniasis, leprosy, deep fungal infections, and cutaneous malignancy.

Oriificial tuberculosis is a rare manifestation of cutaneous tuberculosis occurring usually in individuals who are debilitated or immunocompromised. It affects the mucocutaneous junctions of the orifices (nose, mouth, anus, urinary meatus, and genital) and is caused by autoinoculation of tubercle bacilli from secretions. Lesions present as shallow, painful ulcers with a granulating base and undermined edges, with swelling, edema, and inflammation of the surrounding mucosa. Painful ulcers of the mouth or other mucosal membranes in patients with visceral tuberculosis should arouse suspicion of this disorder.

Miliary tuberculosis of the skin (tuberculosis cutis miliaris disseminata) is an extremely rare manifestation of fulminating pulmonary or meningeal tuberculosis. It is quite uncommon in children and in recent times is seen most often in the setting of adult HIV infection.<sup>185,186</sup> When present, the eruption is caused by hematogenous dissemination of *M. tuberculosis* to the skin in addition to multiple internal organs. Cutaneous lesions present as minute, symmetrically distributed, erythematous, red-brown macules, papules, or vesiculopustules. Purpuric lesions may occasionally be present. The course of miliary tuberculosis is usually fulminating, and the mortality rate high.

Diagnostic options for cutaneous tuberculosis include smears, stains, and cultures of skin swabs, aspirates, and biopsy tissue. The Mantoux intradermal tuberculin test is commonly positive, but the reactivity does not correlate with disease activity.<sup>182</sup> Another screening test is the QuantiFERON TB Gold test, which quantifies the release of interferon-γ in whole blood upon stimulation with *M. tuberculosis* antigens. PCR amplification of *M. tuberculosis* deoxyribonucleic acid (DNA) is a rapid, sensitive, and accurate technique for diagnosis and may be applied to paraffin-embedded skin-biopsy tissue.<sup>187,188</sup>

The treatment of all forms of cutaneous tuberculosis is similar to that used for active pulmonary tuberculosis. Current recommendations of the American Academy of Pediatrics include a 6-month regimen consisting of isoniazid, rifampin, ethambutol and pyrazinamide for 2 months followed by 4 months of isoniazid and rifampin (with ethambutol or streptomycin added if drug resistance is a concern) or a 6-month regimen (for hilar adenopathy only) of

isoniazid and rifampin.<sup>189</sup> Tuberculous meningitis is treated with a four-drug regimen for 2 months followed by isoniazid and rifampin for 7 to 10 more months.<sup>189</sup>

## The Tuberculid Disorders

The tuberculid disorders are hypersensitivity reactions to *M. tuberculosis* and classically include erythema induratum, papulonecrotic tuberculid, and lichen scrofulosorum. Originally felt to be related to toxins or an allergic response to tubercle bacilli, they are currently believed to be the result of hematogenous dissemination of organisms from an internal focus to the skin, where they incite a cutaneous inflammatory response. Lupus miliaris disseminatus faciei (formally described as a tuberculid) is probably more aptly described as a granulomatous disorder of the pilosebaceous units (see Chapter 8). A deep nodular form presenting on the lower extremities has been termed *nodular tuberculid* and seems to represent a hybrid between papulonecrotic tuberculid and erythema induratum.<sup>190</sup> Once a tuberculid disorder has been diagnosed, a thorough evaluation for subclinical active tuberculosis should be initiated.<sup>191</sup>

Erythema induratum of Bazin is a chronic, recurring panniculitis (inflammation of the fat) that typically occurs on the calves of girls and young women. Although the association with tuberculosis has historically been controversial, the clinical and histopathologic features, ability to identify *M. tuberculosis* on PCR studies, and response to antituberculosis therapy seem to support a tuberculous etiology.<sup>192–196</sup> Lesions present as symmetrical, tender, deep-seated nodules that develop into red-purple masses that tend to ulcerate. The ulcers are irregular and shallow and heal with an atrophic scar. Erythema induratum tends to be chronic and recurrent; many patients have a personal or family history of tuberculosis. The tuberculin skin test is positive, but mycobacteria are seldom recovered from lesions by standard culture techniques. PCR analysis of skin-biopsy specimens has been found to be rapid and sensitive in the diagnosis of this disorder.<sup>194–196</sup> Treatment of erythema induratum with combination antituberculous therapy is usually successful, although in untreated patients the lesions usually involute spontaneously over a period of years.

Papulonecrotic tuberculid is the most common tuberculid seen in children, although it is rarely seen in the United States. It is characterized by symmetric crops of dusky red, small papules and nodules with central necrosis or ulceration that heal with superficial scarring. Sites of predilection for papulonecrotic tuberculid include the extensor extremities (particularly the knees and elbows), the buttocks, and the lower trunk. Ear involvement may also be common, and pulmonary tuberculosis is usually present.<sup>197</sup> The lesions may clinically resemble those of varicella. As with erythema induratum, recovery of the organism from standard tissue culture is of low yield. Patients usually have a positive intradermal tuberculin skin-test reaction, and gene-amplification PCR performed on skin-biopsy tissue is useful in confirming the diagnosis.<sup>198</sup> Papulonecrotic tuberculid usually responds promptly to antituberculous therapy. Simultaneous occurrence of papulonecrotic tuberculid and erythema induratum has been reported.<sup>199</sup>

Lichen scrofulosorum is characterized by clusters of lichenoid papules on the trunk of children or young adults, usually in association with tuberculosis of lymph nodes and/or other organs. Lesions are firm, 1- to 5-mm, flesh-colored to reddish-brown flat-topped papules. They tend to be asymptomatic and slowly undergo spontaneous involution.

## Leprosy

Leprosy (Hansen disease) is a chronic infectious disorder of worldwide distribution in which the acid-fast bacillus *Mycobacterium leprae* has a special predilection for the skin and nervous system. Although the worldwide incidence of leprosy has decreased significantly, likely in response to multidrug therapy (MDT), widespread BCG vaccination, and public health initiatives, it is still somewhat prevalent in certain areas including India, China, and Southeast Asia. Leprosy is rare in

**Table 14-1** Classification of Leprosy (in Order of Decreasing Host Resistance)

Group	Clinical Features
Tuberculoid (TT) (mildest; high resistance)	A single or few localized anesthetic macules or plaques; hair loss within lesions; few if any organisms; peripheral nerve involvement common
Borderline tuberculoid* (BT)	Lesions similar to TT but more numerous; satellite papules around larger lesions (at times); hair and sensation diminished (but not absent) within lesions; peripheral nerve involvement common
Borderline borderline (BB)	Features of both TT and LL; more lesions than BT; borders more vague; nerve involvement and satellite lesions common; many bacilli usually present
Borderline lepromatos (BL)	Multiple nonanesthetic asymmetrically distributed annular plaques; may be surrounding papules; late neural lesions; leonine facies
Lepromatos (LL) (most severe; low or no resistance)	Generalized involvement (skin, mucous membranes, upper respiratory tract, reticuloendothelial system, adrenal glands, and testes); no neural lesions until late; no sensory or hair growth impairment; many bacilli in tissue
Indeterminate	Small number of hypopigmented macules; no thickened nerves or sensory impairment

\*The three intermediate forms (BT, BB, and BL) are clinically unstable and may pass from milder to more severe states and vice versa.

**Figure 14-35** Lepromatos leprosy. Erythematous, infiltrative patches and plaques that revealed many acid-fast bacilli in the skin-biopsy specimen.

the United States with around 85% of diagnosed cases occurring in immigrants, and the disease may mimic many common dermatological and neurological disorders.<sup>200</sup>

Although there is no universal agreement on the classification of leprosy, the disorder is usually divided into several clinical subtypes depending on the patient's degree of immunity to *M. leprae* (Table 14-1). At one end of the spectrum is the lepromatos (LL) form of the disorder, the disfiguring disease most familiar to the public. In this variant patients are anergic to *M. leprae* and develop widespread disease involving the skin (Fig. 14-35), upper respiratory tract, sensory and motor nerves, eyes (superficial keratitis), testes, lymph nodes, and bone. Many bacilli are present in the tissues. Nodules or diffuse infiltrates, especially on the face and earlobes, produce the characteristic "leonine facies." Loss of eyebrows and eyelashes may also occur. At the opposite pole is tuberculoid leprosy (TT), a form that occurs in patients with a very high degree of immunity against *M. leprae*. In this variant, patients have only a single (or occasionally a few) large

well-defined macule(s) or infiltrative plaques that show hypopigmentation and loss of sensation. The peripheral nerves, most commonly the ulnar, external popliteal, and great auricular nerves, are thickened and palpable, and patients may develop trophic disturbances and paryses. Between these ends of the spectrum, borderline forms of the disorder are seen. Patients with borderline lepromatous leprosy tend to have the most extensive involvement of nerves. Owing to the decreased sensation in affected areas, these patients are at risk for secondary infections and digital ulceration. Blindness occurs in around 5% of patients with leprosy.<sup>201</sup>

The incubation period of leprosy is typically very long and ranges from 3 months to 40 years (average, 2 to 4 years).<sup>200</sup> Early childhood disease often presents with solitary lesions that may occur on any exposed area of the skin, and childhood disease is most commonly indeterminate or at the tuberculoid end of the spectrum. The mode of transmission of leprosy remains unclear, although an upper respiratory route is suggested.

Leprosy should be suspected in any patient from a leprosy-endemic area (or immigrants from such regions) who has chronic hypopigmented or infiltrative skin lesions, skin anesthesia, thickened nerves, or eye complaints. The diagnosis is confirmed by the identification of acid-fast bacilli in skin smears or biopsy material, and the histologic picture reveals a granulomatous infiltrate containing large foamy histiocytes (lepra cells) in the epidermis. Treatment should be directed by a clinician experienced in the care of patients with leprosy and preferably in a Hansen-disease center where feasible. Although therapeutic recommendations of the past called for monotherapy with dapsone, given increasing resistance to this approach MDT is now recommended and includes other agents such as rifampin and clofazimine. In treated patients, 95% of all nerve function impairment develops within 2 years, supporting a decreased frequency for neurologic follow-up examination in patients without neurologic findings by that time.<sup>202</sup>

Leprosy reactions are fairly commonplace during treatment for the disease and are related to immune-mediated inflammation. These reactional states, which include reversal reactions and erythema nodosum leprosum (ENL), may result in worsening of neural and skin lesions and significant tissue damage. These reactions are often treated with systemic corticosteroids and in the case of ENL, thalidomide is a very effective agent.<sup>203</sup> Although there is no effective vaccination for leprosy, BCG vaccination has been demonstrated to be effective at protecting some populations from infection.<sup>200,204</sup>

## Anthrax

Anthrax, an infection caused by the Gram-positive *Bacillus anthracis*, is occasionally transmitted to humans through contact with infected animals or animal products such as hides or wool. Whereas this mode of infection usually results in cutaneous anthrax, inhalation disease ("woolsorters' disease") has occurred in settings such as factories where processing of these products takes place.<sup>205</sup> Anthrax has long been considered a potential agent of biologic warfare, the significance of which was magnified by the events of September 11, 2001, and the following apparent bioterrorism involving the spread of *B. anthracis* via bioengineered spore-containing letters within the US postal system. These events highlight the importance of adequate education in and recognition of this infection and other potential biologic weapons of mass destruction.

Clinical infection with *B. anthracis* usually takes one of three forms: inhalational, cutaneous, or gastrointestinal. The cutaneous form (malignant pustule) is responsible for 95% of the cases in the United States and is usually an occupational disease of farmers, butchers, veterinarians, and individuals who process animal products.<sup>206</sup> The spore is introduced via an abrasion or cut in the skin and develops into the primary lesion, which is a painless, pruritic papule. This papule progresses to develop small surrounding vesicles surrounded by a brawny, nonpitting edema. The vesicles rupture with the development of necrosis, and eventually a black eschar forms (Fig. 14-36) and overlies an ulcer. Nonnecrotic ulcerations may also be the presenting feature, as was observed in a patient affected by the 2001 terrorism attacks, and lesions may be solitary or multiple.<sup>207</sup> Low-grade fever,

**Figure 14-36** Cutaneous anthrax in a child. Erythematous plaque with necrosis and eschar formation in a 7-month-old male. Anthrax bacilli were detected in biopsy tissue. (Reprinted with permission from Roche KJ, Chang MW, Lazarus H. Images in clinical medicine: cutaneous anthrax infection. N Engl J Med 2001;345(22):1611. © 2001, Massachusetts Medical Society. All rights reserved.)

malaise, and headache are often present, and regional lymphadenopathy early in the course is common. Without therapy, this form is fatal in 20% of cases.<sup>208</sup> Cutaneous anthrax is rare in children and may be accompanied by anthrax meningitis or systemic spread of disease. Microangiopathic hemolytic anemia, hyponatremia, and coagulopathy were reported in a 7-month-old infant with cutaneous infection.<sup>209</sup>

Gastrointestinal anthrax forms after ingestion of undercooked meat from infected animals. In this case, the characteristic eschar forms in the gastrointestinal tract, usually the terminal ileum or cecum, and patients experience fever, nausea, vomiting, and anorexia. Severe abdominal pain (presenting as an acute abdomen), bloody diarrhea, sepsis, and death may ensue, with a mortality rate greater than 50%.

Inhalational anthrax is the most severe form of infection and is traditionally associated with a very high (>95%) mortality rate. Patients initially experience flu-like symptoms and progress to dyspnea, stridor, fever, and cyanosis. Meningitis, coma, and death may ensue.

The diagnosis of anthrax can be confirmed by Gram stain and culture of a skin lesion, CSF, or blood. Confirmatory studies are usually performed in a reference laboratory. Nasal swabs are used epidemiologically but are not a reliable method of diagnosis.<sup>205,208</sup> Serologic testing is useful only from a retrospective standpoint and requires acute and convalescent samples. A variety of real-time PCR assays exist for detection of *B. anthracis*.<sup>210</sup> Histopathologic examination of a skin-biopsy specimen may also be useful, especially with the concomitant use of a tissue Gram stain.

Penicillin has been the drug of choice for anthrax for many decades, with penicillin resistance found only rarely in naturally occurring strains. Other antimicrobials with good activity against *B. anthracis* include ciprofloxacin, tetracyclines, macrolides, clindamycin, and cephalosporins. Some of these other agents may be more concentrated in the phagocyte and therefore may be more desirable.<sup>211</sup> The treatment of choice for bioterrorism-associated anthrax, however, is ciprofloxacin, even in children.<sup>212</sup> Postexposure prophylaxis is recommended in situations where there is a credible threat of exposure to spores, and ciprofloxacin (alternative doxycycline) is recommended for a full 60 days in this setting.

## Cat-Scratch Disease

Cat-scratch disease (CSD) is an acute, self-limited infection of children and young adults caused by the pleomorphic Gram-negative bacillus *Bartonella henselae*. *Bartonella* species, which are Gram-negative bacilli,

**Figure 14-37** Cat-scratch disease. Axillary lymphadenopathy in a 2-year-old boy with a crusted red papule at the primary inoculation site on the chest.

result in a variety of diseases in humans, including Carrión disease, prolonged fever of unknown origin, encephalopathy, ocular disease, trench fever, and endocarditis. CSD is a benign cause of lymphadenitis in children and is usually transmitted from infected kittens to humans by means of a scratch or bite that is often recalled only in retrospect.<sup>213</sup> The domesticated house cat is the most important natural reservoir for *B. henselae*, and stray cats and kittens are more likely to be infected than are pet or adult cats, respectively.<sup>214</sup> It is estimated that up to half of domestic cats have antibodies to *B. henselae*, testing seropositive for the bacteria.<sup>215</sup> This organism has also been linked to bacillary angiomatosis (see Chapter 12), a vascular proliferative disease seen most commonly in individuals infected with HIV. CSD is most common in areas with warm climates and occurs most often in the fall and winter.<sup>216</sup>

The most common clinical presentation of CSD is lymphadenopathy. However, the infection usually begins with a small papule or nodule within the original cat-scratch line 3 to 10 days after the trauma. Over the following 1 to 2 weeks, the regional lymph nodes draining the region begin to enlarge (Fig. 14-37), reaching the point of maximal enlargement around 1 month after the initial injury.<sup>217</sup> Often the initial wound at the site of contact with the animal has resolved by the time the patient pursues medical care. The enlarged lymph nodes gradually decrease in size over a period of a few months in the absence of therapy. In up to 10% of patients, lymph nodes become erythematous and fluctuant, occasionally requiring needle aspiration.<sup>216</sup> In 85% of patients, there is only a single lymph node involved.<sup>215</sup> Common locations for the lymphadenopathy of CSD include the neck, axillary, and inguinal regions.<sup>218</sup> In one large series, the most common sites of lymphadenopathy (in order of decreasing incidence) were the axilla, epitrochlear region, cervical region, submandibular region, and groin.<sup>219</sup> Biopsy of lymph nodes, when performed, reveals granulomas with multiple microabscesses.

Other features that may be present in patients with CSD include fever, headache, and malaise. Parinaud oculoglandular syndrome consists of unilateral granulomatous conjunctivitis with concomitant ipsilateral preauricular lymphadenopathy at the site of inoculation and represents the most common form of atypical CSD. This presentation appears to occur as a result of indirect inoculation of the organism into the eye rather than by direct contact through a cat scratch as is typical of CSD. Other less common associations include neuroretinitis (presenting as acute-onset unilateral vision loss), encephalopathy, endocarditis, seizures, generalized lymphadenopathy, or prolonged fever. Bony involvement may present with osteomyelitis and may include lytic lesions of the cortex and/or inflammation of the marrow.<sup>220</sup> Immunocompromised individuals with *B. henselae* infec-

tion may develop a disseminated, invasive form of infection that involves multiple organs. *Bacillary peliosis* is the term used to describe reticuloendothelial organ involvement including the liver (peliosis hepatitis), spleen, abdominal lymph nodes, and bone marrow.<sup>216</sup>

CSD is usually diagnosed based on the characteristic clinical presentation in combination with a history of recent contact with a cat. Diagnostic confirmation is provided by positive serologic studies for antibodies to *B. henselae* (either >1:64 antibody titer or a fourfold titer elevation between acute and convalescent sera). Serology remains the most practical diagnostic tool for the laboratory detection of *B. henselae* infection.<sup>215</sup> Blood and tissue can be cultured, but the organism is slow growing and may be difficult to isolate. Identification of the organism in tissue samples stained with the Warthin-Starry silver stain lends further support to the diagnosis and may be useful in some settings. The most sensitive test available is *B. henselae* DNA sequence detection via PCR, but this modality is not readily available.<sup>217</sup>

Treatment of CSD in the immunocompetent host with uncomplicated disease is not always necessary, as it is a self-limited disease and studies demonstrating a significant advantage of therapy are lacking. However, treatment may shorten the period of symptomatic illness and may promote more rapid resolution of the clinical abnormalities.<sup>217</sup> *B. henselae* has been demonstrated to be susceptible to a variety of antimicrobial agents, including azithromycin (the recommendation of many clinician-researchers), clarithromycin, rifampin, doxycycline, ciprofloxacin, gentamicin, and trimethoprim-sulfamethoxazole. Disease in immunocompromised patients may be more serious, and thus therapy is usually recommended with a macrolide, rifampin, or doxycycline for at least 6 weeks.<sup>213</sup> Surgical removal of lymph nodes is generally not indicated except in rare patients in whom the diagnosis is in doubt, in whom repeated aspirations fail to relieve pain, or in whom the inflammatory process persists without involution.

## Disorders Resulting from Fungus-like Bacteria

Actinomycosis and nocardiosis are disorders caused by actinomycetes, which are Gram-positive organisms that may resemble fungi both microscopically and macroscopically. Although these infections can occur at any age, they most often occur in adults. Although primary skin infection is rare, involvement of the cutaneous and subcutaneous tissues may result from contiguous spread from other sites or secondary infection of traumatized or injured skin, particularly in debilitated or immunodeficient individuals.

### ACTINOMYCOSIS

Actinomycosis is a chronic suppurative infection caused by *Actinomyces israelii*, an anaerobic Gram-positive saprophyte of the tonsillar crypts, carious teeth, and female genital tract, and rarely by other *Actinomyces* species. Infection is often associated with dental procedures, trauma, or surgery.<sup>221</sup> This disorder is clinically characterized by the production of “sulfur granules” from multiple draining sinuses. It tends to occur in one of three areas: the cervicofacial region (most common), lungs, or intestinal tract. Some patients have mixed-organ involvement that may include the skin, brain, pericardium and extremities.<sup>222</sup> Cervicofacial actinomycosis, seen most often in individuals with poor oral hygiene and carious teeth, begins when the infecting organism invades a traumatized oral mucous membrane. This form presents as soft-tissue swelling, usually over the mandibular region. It increases to form a brawny, erythematous nodule that discharges serosanguineous or purulent material through multiple sinus tracts, from which the characteristic sulfur-yellow granules consisting of masses of organisms can be demonstrated. Destruction of bone with periostitis and osteomyelitis may occur, and absence of regional lymph node involvement is characteristic.

Aspiration of the organism causes pulmonary infection that progresses through the pleura, causing draining sinus tracts of the chest wall. It may occur after esophageal disruption during surgery or non-penetrating trauma or may occur as a manifestation of extension of cervicofacial infection.<sup>223</sup> The abdominal form develops from the ileum, cecum, or appendix (in association with appendicitis) and is

seen as draining sinuses, tracts, or subcutaneous abscesses extending to either the abdominal wall or the perineum. Primary infection of other body sites may affect the urinary tract, CNS, bones, and joints. A localized form, known as *mycetoma*, occurs most commonly on the feet or ankles of individuals who walk around barefoot (see Chapter 17).

Actinomycosis is diagnosed by isolation and identification of the causative organism in anaerobic culture. It may also be confirmed by observation of the highly characteristic sulfur granules (groups of delicate filaments, often with club-shaped ends) in purulent or biopsied materials. The course of actinomycosis is prolonged and characterized by closure of one sinus tract and the opening of another. Treatment is with intravenous penicillin G for 4 to 6 weeks followed by oral penicillin in high doses for 6 to 12 months.<sup>223</sup> Surgical incision and drainage of abscesses and excision of fibrotic, avascular tissue are occasionally necessary. Alternative antibiotics for patients allergic to penicillin include tetracyclines, erythromycin, or clindamycin.

## NOCARDIOSIS

Nocardiosis is a severe, primarily pulmonary infection caused by an aerobic Gram-positive, partially acid-fast fungus-like organism, *Nocardia asteroides*. It is less often caused by *Nocardia brasiliensis* or other species. Nocardiosis primarily affects men in the 30- to 50-year-old age group, although it has been increasingly recognized in infants and children. Disseminated disease has a significant morbidity and mortality and is more likely in immunosuppressed hosts.

Nocardiosis may occur with several different presentations, including pulmonary, systemic, CNS, and cutaneous/subcutaneous forms. It generally occurs through inhalation of contaminated dust, and the clinical picture is usually that of a primary pulmonary disease that resembles tuberculosis in its clinical and radiographic findings. These primary pulmonary infections may result in blood-vessel erosion with subsequent hematogenous dissemination to other organs, including the skin. In those instances in which the skin is involved (<15% of cases), the most common lesions are abscesses of the chest wall with granulomatous lesions surrounding draining sinuses.<sup>224</sup> Primary cutaneous or subcutaneous nocardiosis is usually the result of traumatic implantation of foreign objects into the skin and often presents in immunocompetent hosts.<sup>221,225</sup> Once inoculated into the skin, it may present in a lymphocutaneous syndrome mimicking sporotrichosis, as a cellulitis-like picture, or as a mycetoma (large, draining mass).<sup>226</sup> Disorders that may predispose an individual to invasive disease include chronic granulomatous disease, organ transplantation, HIV infection, or diseases requiring long-term systemic steroid therapy.<sup>227</sup>

Nocardiosis should be considered in obscure pulmonary and meningeal syndromes and chronic suppurative disorders of the bones or skin. The diagnosis is established by the presence of organisms in smears or cultures of sputum, aspirated material collected from lesions, or biopsy material. Unfortunately, the diagnosis is seldom established until the disease is far advanced. The cornerstone of therapy for nocardiosis is sulfonamides and trimethoprim-sulfamethoxazole. Imipenem, third-generation cephalosporins, amoxicillin clavulanate, amikacin, minocycline, and fluoroquinolones maybe other options.<sup>226</sup> The overall mortality rate of nocardiosis is around 25% and is highest in those patients who have pulmonary involvement and those with immunocompromise.<sup>228</sup>

## Treponemal Infections

### SYPHILIS

Syphilis is an infectious disease caused by the spirochetal organism *Treponema pallidum*. It is transmitted primarily by sexual contact, with the next most common mode being vertical transmission across the placenta, which may result in congenital syphilis (see Chapter 2). After a steady decline in the number of cases of syphilis in the early 1970s, the incidence of syphilis has fluctuated with peaks and troughs occurring in approximately 10-year cycles, with the overall trend being toward increasing rates, especially in men who have sex with men.<sup>229,230</sup> Syphilis continues to be an important health problem

throughout the world and left untreated may result in long-term neurologic, cardiovascular, and other systemic sequelae, as well as congenital syphilis in offspring of infected mothers. Some 15% to 40% of untreated patients develop recognizable late complications.<sup>229</sup> Currently more than 60% of new cases of syphilis occur in men who have sex with men, and the HIV coinfection rate is high (up to 60% in some geographic locations) among patients with syphilis in the United States.<sup>230–232</sup> Importantly, syphilis infection increases the likelihood of acquiring and transmitting HIV.

Untreated acquired syphilis is characterized by a series of clinical stages that are summarized in Table 14-2. There may be considerable overlap of symptoms in the various stages, and the early stages may pass by undiagnosed. The incubation period for syphilis ranges from 5 to 90 days. Patients with early syphilis (primary, secondary, and the first year of latent syphilis) are considered infectious. The late latent (after the first year) and late stages, conversely, are considered noninfectious, rarely relapse, and tend to be destructive and scarring.

Primary syphilis usually manifests as a single, painless genital papule or, more commonly, ulcer (chancre), occurring on the labia or vaginal wall in females and the glans penis (Fig. 14-38) in males. In

**Table 14-2** Clinical Stages of Syphilis

Stage	Clinical Manifestations	
<b>Primary</b>	Painless papule or ulcer at site of inoculation Regional lymphadenopathy	
<b>Secondary</b>	Generalized macular/papular rash, involves palms/soles Condyloma lata in intertriginous areas Mucous patches Constitutional symptoms Occasional aseptic meningitis	
<b>Latent</b>	No symptoms, but specific antibody tests positive	
<b>Tertiary</b>	Cardiovascular Neurosyphilis Gumma	Aortic aneurysm CVA, paresis, psychiatric symptoms, ataxia, autonomic dysfunction, cranial nerve palsies, optic neuritis Inflammatory infiltrates in multiple organs

CVA, Cerebrovascular accident.

**Figure 14-38** Primary syphilis. Eroded chancre of the glans penis in a male with primary infection.

**Figure 14-39** Secondary syphilis. Crusted, hyperkeratotic, erythematous papules and plaques on the palms.

homosexual men, anorectal ulcers are most common. Chancres may occasionally be multiple, painful, purulent, or destructive.<sup>233</sup> Painless regional lymphadenopathy is often present, although there may occasionally be tenderness to palpation. The differential diagnosis of the primary syphilitic chancre includes other sexually transmitted diseases, including herpes simplex virus infection and chancroid (caused by *Haemophilus ducreyi*), which both tend to be differentiated by painful ulcers. Extraprofessional ulcers occur rarely in primary syphilis and when present occur most commonly on the fingers, tongue borders, or anus. If left untreated, the ulcer of primary syphilis heals spontaneously over 4 to 6 weeks.

Secondary syphilis develops 2 to 8 weeks after exposure in untreated individuals and is more common in females given the increased number of asymptomatic or undiagnosed primary lesions compared to men.<sup>234</sup> The primary chancre may still be present at the time of diagnosis of secondary syphilis. The classic cutaneous findings of this stage are characterized by a widespread macular and papular skin eruption that may occasionally be follicular or pustular. Examination reveals pink to erythematous, slightly scaly macules and papules that often involve the palms and soles, as well as flanks and arms. In dark-skinned individuals the lesions tend to be hyperpigmented. The palm and sole lesions may appear as macular or hyperkeratotic red-brown papules or plaques (Fig. 14-39) and are often helpful in the differentiation between secondary syphilis and the primary differential diagnosis, pityriasis rosea. Other entities in the differential diagnosis include drug eruption, lichen planus, acute exanthems, tinea versicolor, sarcoidosis, Mucha-Habermann disease (pityriasis lichenoides), nummular eczema, and psoriasis.

Other mucocutaneous lesions seen in secondary syphilis include alopecia, mucous patches, and condyloma lata. Patchy alopecia may be present in up to 7% of patients and classically has a "moth-eaten" appearance. Mucous patches occur on the tongue, buccal mucosa, and lips and present as erythematous patches, often with associated erosion and a silvery-gray membrane. Condyloma lata are smooth, gray plaques found in warm and moist intertriginous zones in up to 20% of patients. These lesions are highly infectious and must be differentiated from genital warts (condylomata acuminata).

Systemic symptoms may also be present and include fever, headache, malaise, pharyngitis, and arthralgias. Ocular inflammatory conditions (including episcleritis, keratitis, and uveitis) may occur, as may aseptic meningitis, painless lymphadenopathy (especially epitrochlear), and hepatitis. A particularly aggressive form, termed *lues-maligna*, has been observed most often in the population infected with HIV.<sup>235</sup>

Cutaneous lesions of secondary syphilis usually heal without scarring, even in the absence of therapy, within 2 to 10 weeks. Residual hyperpigmentation or hypopigmentation may be present. Residual

hypopigmentation on the skin of the neck has been termed the *necklace of Venus* (leukoderma collis).

Latent syphilis is a stage of the disease during which there are no clinical signs or symptoms or during which there are mild but generally unrecognized nonspecific symptoms such as malaise, anorexia, headache, sore throat, arthralgia, and low-grade fever. A diagnosis of latent syphilis is usually established on the basis of a positive serologic test after other stages of syphilis have been ruled out by physical and CSF examination. This stage is arbitrarily divided into early latent syphilis (occurring within 1 year of infection) and late latent syphilis (occurring after 1 year). Patients with early latent syphilis are considered to be infectious.

Tertiary syphilis is divided into late benign syphilis (gumma), neurosyphilis, and cardiovascular syphilis (see Table 14-2). It appears in around 10% to 40% of untreated patients and after a latent period of 3 to 30 years or longer. Tertiary syphilis is extremely rare in children.

The hallmark lesions of late benign syphilis are the "gummas," and the skin is one of the most common organs of involvement, other common sites being the bone and liver. The cutaneous lesions present as superficial nodules or nodoulcerative plaques that may result in punched out ulcers. Common sites of involvement include the extremities, face, scalp, sternum, and the sternoclavicular joints. Upon healing, hyperpigmentation and atrophic scarring may persist. When the palate or nasal mucosa is affected, destruction is often pronounced and may lead to perforation of the affected areas. Large gummas may have several perforations, and as the intervening bridges of skin break down and necrose, lesions tend to produce arched or scalloped margins with arciform and geographic patterns. Bone lesions occurring in this stage are marked by periostitis involving the cranial bones, tibia, and clavicle and present with nocturnal pain and local swelling.<sup>229</sup>

The diagnosis of syphilis depends on the combined findings from history, clinical examination, tissue examination, and serologic studies. *T. pallidum* cannot be cultured. Dark-field microscopy is the gold-standard diagnostic method for primary syphilis, although it is not always readily available. Direct fluorescent antibody testing for *T. pallidum* has also been described for the diagnosis of primary syphilis. Both of these approaches, however, have been supplanted by serologic diagnostic methods, which are also the mainstay of laboratory diagnosis for secondary, latent, and tertiary syphilis.

Serologic tests, which provide only indirect evidence of infection, are divided into nontreponemal and treponemal categories. The nontreponemal tests detect an antibody against cardiolipin that is present in the sera of many patients with syphilis. These examinations include the Venereal Disease Reference Laboratory (VDRL) slide test and the Rapid Plasma Reagins (RPR) card test. These examinations are inexpensive, rapid, and convenient but may result in false-positive reactions (i.e., with advanced age, malignancies, Lyme disease, chronic liver disease, pregnancy, systemic lupus erythematosus, and some viral or bacterial infections) and are limited in their sensitivity. The treponemal tests include fluorescent treponemal antibody absorption (FTA-ABS), the microhemagglutination test for antibodies to *T. pallidum* (MHA-TP), the *T. pallidum* enzyme immunoassay (TP-EIA), and *T. pallidum* particle agglutination (TP-PA) tests.<sup>236</sup> Treponemal tests measure specific antibodies formed by the host in response to infection with *T. pallidum*. They have a higher sensitivity and specificity than nontreponemal tests and are used as confirmation of diagnosis. Treponemal tests establish the high likelihood of a treponemal infection either at the present time or at sometime in the past.<sup>237</sup>

Parenteral penicillin G is the mainstay of treatment for all forms of syphilis, with dosing regimens and duration of therapy varying based on stage of disease and the clinical manifestations that are present.<sup>236</sup> In patients with penicillin allergy, doxycycline or tetracycline are the preferred alternatives. Azithromycin has been investigated for its utility in treating patients with early disease.<sup>238</sup> The treatment of choice for congenital syphilis or neurosyphilis is aqueous crystalline penicillin G.<sup>236</sup> Patients under therapy for syphilis are generally assessed for response to therapy by serial quantitative nontreponemal tests. Patients with neurosyphilis require very close follow-up clinical and intermittent CSF examinations for at least the first 2 years after diagnosis.

## PINTA

Pinta, a nonvenereal treponemal infection caused by *T. pallidum* subspecies *carateum*, occurs almost exclusively among the dark-skinned population of Central and South America and Cuba. It is transmitted by direct contact and is often seen in children of affected parents. Although transmission by insects is possible, this mode of exposure is considered to be exceedingly rare. Pinta is the only spirochetal disease that results in purely cutaneous manifestations.

There are three basic forms of pinta, termed *primary*, *secondary*, and *late*. The primary stage, seen on uncovered areas such as the face, arms, and legs, begins 1 to 8 weeks after inoculation as red papules that enlarge into oval or round erythematous scaly plaques measuring up to 10 cm in diameter. Small papules often become surrounded by satellite macules or papules that coalesce to form configurative patterns. Regional lymphadenopathy is common. After several months to years, secondary lesions (referred to as *pintids*) appear as small, scaly papules that coalesce into large, scaly plaques. Their color is initially red to violaceous, with progression to a slate-blue, brown, gray, or black hue.<sup>239</sup> In this stage, widespread involvement is present with coalescence of lesions. The differential diagnosis may include psoriasis, eczema, tinea corporis, syphilis, or leprosy. Lesions of primary and secondary pinta are highly infectious.

The late phase develops in 3 to 10 years and is characterized by irregular pigmentation with a range of different shades (correlating with the site of deposition of melanin in the dermis), resulting in a spotted and highly characteristic appearance. These lesions have an insidious onset, usually during adolescence or young adulthood, and are eventually replaced by depigmented patches closely resembling vitiligo. The most common sites of involvement are the bony prominences including the wrists, elbows, and ankles. Periarticular skin atrophy and extensor surface hyperkeratosis is also common during this phase.<sup>240</sup>

The diagnosis of pinta is made by identification of *T. carateum* on dark-field examination or more commonly, serologic testing. The serologic studies utilized for the diagnosis of pinta are the same as those utilized for venereal syphilis, and these diseases are immunologically and serologically indistinguishable.<sup>241</sup> Penicillin is the treatment of choice, with options similar to those of syphilis for patients with penicillin allergy.

## YAWS

Yaws, caused by *Treponema pallidum* subspecies *pertunue*, is a nonvenereal treponemal disease endemic in many tropical regions that typically begins in childhood (usually before puberty). It is also transmitted by direct skin contact (nonsexual) and has been divided into primary, secondary, and tertiary stages. The primary stage is characterized by an erythematous papule that occurs within 2 to 4 weeks at the site of inoculation (the “mother yaw”), usually the legs, feet, or buttocks. It enlarges and becomes confluent with surrounding satellite nodules with eventual ulceration. This stage is occasionally accompanied by constitutional symptoms, arthralgias, and lymphadenopathy. Spontaneous healing of the skin lesion eventually occurs with scarring, although it may take up to 6 months.<sup>242</sup>

Weeks to months after the primary lesion, secondary yaws occurs, presenting as smaller, widespread cutaneous papules (“daughter” yaws or framboesias) that tend to occur adjacent to body orifices. These lesions ulcerate and secrete infectious treponemes. This stage is characterized also by palmoplantar lesions, bone involvement, lymphadenopathy, and occasional neurologic and ophthalmologic abnormalities. Hyperkeratotic involvement of the palms and soles with painful fissuring is common. The latter may cause patients to walk on the sides of their feet, producing a characteristic gait known as *crab yaws*. If not treated in its early stages, yaws may become a chronic infection with frequent relapses and severe disfigurement with permanent bony deformities.<sup>243</sup>

Although the disorder generally terminates with the secondary stage, 10% of patients develop a late tertiary stage in which gummatous lesions occur. These lesions, which present 5 to 10 years after inoculation, may be locally destructive and lead to skin ulceration as well as deforming bone and joint sequelae. Late neurologic or ophthal-

mologic manifestations may occasionally present during the tertiary stage but are not typical.

Yaws is usually diagnosed based on the characteristic clinical findings in an endemic region combined with dark-field microscopy or serologic studies. Again, the same serologic examinations used to diagnose venereal syphilis and pinta are utilized. Treatment options include long-acting penicillin (benzathine penicillin), azithromycin, and tetracycline.

## LYME DISEASE

Lyme disease is the most common vector-borne disease in the United States. It was first recognized in southeastern Connecticut in 1975 and is an immune-mediated multisystem disorder caused by the spirochete *Borrelia burgdorferi*. Lyme disease is transmitted by *Ixodes* species ticks, primarily *Ixodes scapularis* (the deer tick) in the United States. It occurs most commonly in areas where deer ticks are abundant and *B. burgdorferi* carriage is common, especially the coastal northeastern, mid-Atlantic, and northern central regions of the United States, as well as much of Europe and Northern Asia.<sup>244</sup> Lyme disease is rare in the Pacific states because of the low infection rate of *Ixodes pacificus* (the Western black-legged tick) with *B. burgdorferi*.<sup>245</sup> When cases occur in the western states, they are most common in northern California and Oregon. In Europe, the vector is most often *Ixodes ricinus*, and the pathogenic *Borrelia* species are *Borrelia afzelii* and *Borrelia garinii*.<sup>246</sup> There is a bimodal age distribution of Lyme disease, with the initial peak occurring in children between the ages of 5 and 14 years.<sup>247</sup>

There are several factors associated with the risk of transmission of *B. burgdorferi* from ticks to humans. Because organisms often remain dormant in the tick until multiplication and migration occur during feeding, the risk of transmission is low if the tick is removed within 24 hours of attachment. In addition, the proportion of infected ticks varies according to geographic location, and hence the risk of disease is low outside of endemic regions. The highest probability of transmission of infection occurs 48 to 72 hours after the onset of attachment.<sup>248</sup>

The clinical findings of Lyme disease were originally described as occurring in three stages, although now they are generally divided into two stages: early (divided into early localized or early disseminated) and late (Table 14-3). These correspond to the traditional stages I, II, and III. The onset of clinical manifestations usually occurs from 3 days to 4 weeks after the tick bite. However, because of the small pencil-point size of the *Ixodes* tick, only about 30% of patients recall having had a tick bite.

**Table 14-3** Clinical Manifestations of Lyme Disease

Stage of Disease	Clinical Findings
Early localized (stage I)	Erythema migrans (single) Constitutional symptoms (headache, myalgias, arthralgias, fatigue, fever) Lymphadenopathy
Early disseminated (stage II)	Erythema migrans (multiple) Lymphadenopathy Constitutional symptoms (headache, myalgias, arthralgias, fatigue, fever) Neurologic: facial palsy, meningitis, other neuropathies Cardiac: atrioventricular conduction defects, congestive heart failure, myocarditis Rheumatologic: arthritis
Late (stage III)	Neurologic: encephalopathy, encephalomyelitis, peripheral neuropathy Rheumatologic: arthritis Cutaneous: lymphocytoma cutis, acrodermatitis chronica atrophicans

**Figure 14-40** Erythema migrans of Lyme disease. Expanding, erythematous, annular patch of early localized Lyme disease. A small red papule is seen centrally at the site of the tick bite.

**Figure 14-41** Erythema migrans, multiple lesions. Multiple erythematous macules and patches were present in this child with early disseminated Lyme disease.

### Early Localized Lyme Disease (Stage I)

The earliest manifestation of Lyme disease is usually a single skin lesion termed *erythema migrans* (EM). It is felt that at this stage the spirochetal infection is restricted to the skin in most patients. EM begins with a red papule at the site of the bite and progresses to become a flat, erythematous patch. With peripheral expansion, there may be central clearing (although not always), resulting in an annular patch (Fig. 14-40). This lesion usually is nonpalpable, and it is most commonly asymptomatic. Occasional variations include vesicular, urticarial, scaly, and purpuric presentations.<sup>249</sup> Systemic symptoms may be present and include fatigue, fever, chills, headache, myalgias, and arthralgias. Lymphadenopathy may also occur. Although EM may occur anywhere on the cutaneous surface, the thighs, groin, and axillae are particularly common sites of involvement. The lesions can be differentiated from those of *tinea corporis* and *nummular eczema* by rapid peripheral expansion, lack of scaling, and lack of pruritus. The eruption of EM resolves spontaneously over several weeks even without therapy. Multiple EM lesions may be seen and usually correlate with spirochetemia and disseminated disease (see the following section).

### Early Disseminated Lyme Disease (Stage II)

As the organism disseminates, patients may show additional signs or symptoms, including multiple lesions of EM (Fig. 14-41). The individual lesions are similar to the original EM lesion, although they tend to be less inflamed and do not extend as aggressively.<sup>250</sup> Multiple EM lesions occur in around 25% of infected children in the United States.<sup>245</sup> Constitutional symptoms are common during this stage of infection. Neurologic manifestations of early disseminated Lyme disease include peripheral neuropathy (especially cranial nerve VII palsy) and lymphocytic meningitis. Facial palsy is the most characteristic neuropathy and is reported in 40% to 50% of patients with neurologic involvement. Bilateral facial palsy, a quite rare presentation, should be highly suspicious for Lyme disease, especially when occurring in an endemic area. The facial palsy of Lyme disease usually resolves in 2 to 8 weeks with or without treatment. Other cranial and peripheral mononeuropathies are possible, albeit more common in adults than children,<sup>249</sup> and a Guillain–Barré-like syndrome has been reported. Because Lyme meningitis is fairly common in endemic regions between April and December, clinicians should include this on the differential diagnosis for children presenting with undifferentiated aseptic meningitis and CSF pleocytosis in this scenario.<sup>251</sup> Migratory arthralgia or frank arthritis may also occur, as may cardiac involvement. The latter is marked by first-, second-, or third-degree atrioventricular conduction defects or bundle branch blocks and less commonly carditis or congestive heart failure.<sup>249</sup> In children with early disseminated Lyme disease, predictive variables for carditis include older age, presence of arthralgias, and cardiopulmonary symptoms.<sup>252</sup>

### Late Lyme Disease (Stage III)

The primary features of late Lyme disease, which occurs in 60% of untreated cases, are arthritis and neurologic disease. Fortunately, with better and earlier recognition of this disorder, manifestations of late disease have become much less common.<sup>244</sup> Cutaneous manifestations during late disease include lymphocytoma cutis and acrodermatitis chronica atrophicans (ACA) (see below). The arthritis is usually monoarticular or oligoarticular and tends to involve the knees most commonly, although migratory and small-joint involvement may be seen. The presentation may simulate that of juvenile rheumatoid arthritis or an acute septic arthritis, and confusion with the latter may be compounded by the finding of markedly elevated joint-fluid leukocyte counts.<sup>253</sup> The most common neurologic sequelae of late disease are encephalopathy, encephalomyelitis, and sensorineural peripheral neuropathy, although late neurologic disease tends to be rare in children.

Other cutaneous manifestations that have been potentially linked to *B. burgdorferi* infection include linear morphea, lichen sclerosis et atrophicus, and lymphocytoma cutis (cutaneous lymphoid hyperplasia). In Europe, *B. burgdorferi* infection has also been associated with Ban-nwarth syndrome (localized radicular pains accompanied by motor or sensory changes and occasionally lymphocytic meningitis), atrophoderma of Pasini and Pierini, eosinophilic fasciitis, and progressive facial hemiatrophy. ACA is reported primarily in Europe as a late manifestation of disease. It is characterized early by violaceous plaques followed by induration, hyperpigmentation, and atrophy of the skin on the distal extensor extremities and may be associated with concurrent arthritis and neuropathy.<sup>250</sup> This Lyme complication is associated primarily with infection by *B. afzelii*.<sup>254</sup>

Chronic Lyme disease (also known as *posttreatment chronic Lyme disease*) is a challenging and controversial entity from both a diagnostic and therapeutic standpoint. Two syndromes to occur in this context have been reported. The first consists of patients who continue to have symptoms similar to the pretreatment period despite appropriate therapy, especially joint complaints. The second syndrome to occur in this setting is similar to chronic fatigue syndrome or fibromyalgia, and patients present with complaints of extreme fatigue, myalgias, headache, polyarthralgias, and mood disturbances. Some patients are more symptomatic than others, possibly reflecting some sort of genetic influence, and although the disease does not tend to be destructive or progressive, its effects can be quite debilitating.<sup>255</sup> Chronic Lyme disease may be overdiagnosed as a result of equivocal test results, unreliable tests, or the misdiagnosis of associated psychiatric comorbidities.<sup>256,257</sup>

The diagnosis of Lyme disease relies upon clinical findings suggestive of the disease in combination with confirmatory laboratory testing. Antibody determinations are the most commonly utilized diagnostic examinations, and include indirect immunofluorescence

assays and enzyme-linked immunosorbent assays (ELISAs). Both can assess for IgM and IgG antibodies to *B. burgdorferi*. It must be remembered that patients with early localized Lyme disease are commonly seronegative for antibodies, and hence the diagnosis in that setting requires astute clinical judgment. Serologic studies may also be limited by cross-reactivities with other organisms and high rates of seropositivity among asymptomatic persons in endemic areas.<sup>258</sup> Immuno-blotting or Western blotting allows for more specific detection of antibodies and may be used in conjunction with the previously mentioned assays. Culture of *B. burgdorferi* is possible from tissue or fluid but it is slow and difficult and requires special media that are not readily available. PCR studies for Lyme disease have been applied to a variety of tissues and fluids but in general are neither approved nor widely available for this purpose and may result in false positive results. Lyme urinary antigen capture tests are unreliable and should not be used.

The treatment of Lyme disease depends on the type of presentation and the age of the patient. In patients in whom the diagnosis of early Lyme disease is strongly suspected, treatment is initiated based on clinical findings, given the potential delays in laboratory confirmation. Doxycycline for 14 to 21 days is the treatment of choice for early localized disease in children older than 8 years of age. For those younger than 8 years of age, amoxicillin or cefuroxime for the same period is indicated.<sup>259</sup> Alternatives include erythromycin or clarithromycin.<sup>249</sup> Early disseminated disease and late disease are treated with the same oral regimen but for 21 days. Persistent or recurrent arthritis, carditis, meningitis, or encephalitis are treated with parenteral ceftiraxone or penicillin for 14 to 28 days.<sup>259</sup> Occasionally, patients may develop intensification of symptoms during the first 24 hours of antibiotic therapy (a Jarisch–Herxheimer-like reaction), presumably caused by the host immune response to dying organisms. This reaction usually disappears in 1 to 2 days and is not an indication for discontinuation of therapy.

The hallmark of prevention for Lyme disease is tick avoidance. Simple measures to this end include avoidance of tick-infested areas, tucking pant legs into socks, and inspection for ticks after high-risk activities or exposures in endemic areas. The judicious use of chemical repellents such as N,N-diethyl-3-methylbenzamide (DEET), picaridin, or permethrin (see Chapter 18) on skin or clothing is also helpful. Because the *Ixodes* tick must be attached to the skin for at least 24 hours before infection is transmitted, daily inspection should be performed on individuals after exposure to potentially infested areas, and prompt tick removal by grasping the tick with a forceps, tweezers, or gloved fingers will help prevent transmission of the disease.<sup>260</sup> Removal should be performed without crushing the tick, and an effort should be made to leave no body parts behind. The bite site should be washed with soap and water to prevent secondary infection. Maintaining household pets as tick-free will also decrease the chance of transmission of tick-borne diseases.

Most experts recommend against serologic testing or prophylactic antibiotic therapy after a tick bite, especially for patients who have had ticks attached for less than 24 hours.<sup>244</sup> Most deer ticks, even in highly endemic areas for Lyme disease, are not infected with *B. burgdorferi*, and the overall risk of infection after a recognized deer-tick bite in such an area is only around 1.4%.<sup>261</sup> A vaccine for Lyme disease was available and approved by the US Food and Drug Administration for individuals between 15 and 70 years of age but was withdrawn in 2002 and is no longer available.

## Protozoal Disorders

### LEISHMANIASIS

The term *leishmaniasis* refers to three different diseases caused by the protozoan parasite of the genus *Leishmania*: cutaneous leishmaniasis (oriental sore, Delhi boil, Balkh sore), mucocutaneous leishmaniasis, and visceral leishmaniasis (kala-azar). These infections are characterized by diversity and complexity, and the majority of cases occur in Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, and Syria (in the “Old World”) and Brazil and Peru (in the “New World”).<sup>262</sup> *Leishmania* is present in most tropical and subtropical countries owing to characteristics of the sandfly vector (see below). In the United States,

leishmaniasis is primarily seen in foreign travelers, immigrants, and military personnel returning from countries where it is endemic.<sup>263</sup> Travelers can become infected even after short stays in *Leishmania*-endemic areas,<sup>264</sup> and the increase in travel to endemic regions of South and Central America has led to an increase in the number of cases diagnosed in the United States.<sup>265</sup> Although there may be overlap in clinical presentations caused by specific species, in general Old-World cutaneous leishmaniasis is caused by *Leishmania tropica* or *Leishmania major*; New World cutaneous disease by *Leishmania braziliensis* or *Leishmania mexicana*; mucocutaneous disease by *Leishmania braziliensis*; and visceral disease by *Leishmania donovani*. There are, however, multiple other less common species of *Leishmania* as well.

Leishmaniasis is transmitted by the sandfly (*Phlebotomus* or *Lutzomyia* species), which lives in dark and damp places. Sandflies fly silently and are most active in the evening and at night. The infection is transmitted to humans (an accidental host) by the bite of the sandfly, which itself becomes infected after a blood meal from infected mammals (primarily rodents and dogs).<sup>262,266</sup> An important epidemiologic observation of recent note is the increasing incidence of visceral leishmaniasis among patients with acquired immunodeficiency syndrome (AIDS) in southern Europe and a few other endemic areas.<sup>266,267</sup> *Leishmania* species are obligate intracellular parasites of macrophages, by which they are phagocytosed after inoculation into the skin. They subsequently replicate within macrophages and spread throughout the reticuloendothelial system of the host.

Cutaneous leishmaniasis has a variety of clinical presentations, although the most common is an indolent skin ulcer. There are an estimated 1.5 million new cases of cutaneous disease each year, and the incidence may be increasing.<sup>268</sup> The incubation period after the bite of the sandfly is usually 1 to 12 weeks, and occasionally the infection may remain subclinical. The initial lesion is a papule that enlarges to form a painless ulcer with a raised margin and necrotic base (Figs. 14-42 and 14-43). Most often there are one to two lesions, although multiple lesions have been observed, and some patients may show a lymphangitic distribution similar to that of sporotrichosis.<sup>264</sup> Regional lymphadenopathy and secondary bacterial infection may occur, the latter of which is often associated with pain.<sup>262</sup> Most lesions of cutaneous leishmaniasis heal over months to years, leaving an atrophic scar.

Other presentations of cutaneous leishmaniasis include a dry ulcerative form that appears as a brown nodule that ulcerates more slowly and reveals an adherent crust; leishmaniasis recidivans, which is manifested by red to yellow-brown papules that appear in or close to a scar of an old lesion of cutaneous leishmaniasis; and a nonulcerating generalized form that may resemble lepromatous leprosy. Patients

**Figure 14-42** Cutaneous leishmaniasis. An erythematous crusted plaque in a 4-year-old child. (Courtesy of William Burrows, MD.)

**Figure 14-43** Cutaneous leishmaniasis. Multiple erythematous papules and plaques with necrosis and crusting were present in this 2-year-old female. *Leishmania tropica* was confirmed by PCR analysis. (Courtesy of Ayelet Shani-Adir, MD.)

with this form of leishmaniasis present a public health hazard, because the skin is heavily infested and may act as a reservoir for transmission by the *Phlebotomus* fly.

The differential diagnosis of cutaneous leishmaniasis includes foreign-body reactions, tropical or traumatic ulcers, superinfected insect bites, myiasis, impetigo, fungal and mycobacterial infections, sarcoidosis, and neoplasms.<sup>262,264</sup> The diagnosis of leishmaniasis is usually made on the basis of the typical lesion(s) combined with a history of exposure or travel to an endemic region. Confirming the diagnosis can be challenging. Tissue biopsy for culture, smear, and histologic evaluation is useful. An impression smear is made by gently pressing the fresh biopsy tissue against a glass microscope slide, staining with Giemsa or hematoxylin and eosin (H&E) stain, and examining for amastigotes (intracellular organisms). Tissue specimens for culture must be plated on special culture, and the organisms can be typed by isoenzyme analysis in a reference laboratory, although the procedure is quite time consuming.<sup>268</sup> Alternative methods for diagnosis include needle aspirates, slit-skin smears, monoclonal antibody tissue stains, and molecular techniques based on kinetoplast (a small portion of extranuclear material) DNA analysis. Serologic studies, which may be helpful in visceral or disseminated cutaneous disease, are usually of no value for localized cutaneous leishmaniasis. PCR-based diagnosis is also possible and is particularly useful in cases with a low parasite load (i.e., mucosal leishmaniasis).

Mucocutaneous leishmaniasis results from hematogenous or lymphatic dissemination of organisms from skin to the nasopharyngeal mucosa. It often manifests years after resolution of cutaneous lesions of leishmaniasis.<sup>264</sup> Mucocutaneous leishmaniasis presents with chronic nasal symptoms and is followed by progressive nasopharyngeal destruction. Secondary bacterial infections with regional adenitis and lymphangitis are common, and occasionally the mucocutaneous lesions may be nodular and vegetative. Destruction of the nasal septum and nasopharynx may result in soft-tissue and cartilage erosion, with resultant deformities of the nose, lips, cheeks, pharynx, larynx, and palate that are often cosmetically debilitating.<sup>269</sup>

Visceral leishmaniasis may present with varied clinical findings and severity of illness. It infects an estimated 500,000 new individuals in

less-developed countries each year and may occur in large-scale epidemics, especially in east Africa and India.<sup>270,271</sup> The classic kala-azar syndrome, caused by *L. donovani*, results in fever, cachexia, hepatosplenomegaly, pancytopenia, and progressive deterioration. If left untreated, visceral leishmaniasis is often fatal. A common complication after therapy for kala-azar is "post-kala-azar dermal leishmaniasis." This disorder is characterized by macular, papular, and nodular skin lesions that usually begin around the mouth and subsequently generalize.<sup>272</sup>

Treatment of leishmaniasis depends upon the clinical presentation, and in fact there is no single optimal therapy for all forms. When considering treatment for cutaneous disease, it is important to remember that this form of leishmaniasis tends to heal spontaneously, but that *L. braziliensis* has the potential to progress to mucocutaneous disease.<sup>268</sup> Therefore any patient with *L. braziliensis* confirmed as the etiologic agent or with a history of contracting the infection in an area endemic for this organism should receive adequate systemic therapy. The goals of therapy are to reduce scarring and prevent parasite dissemination.

Pentavalent antimonial drugs such as sodium stibogluconate (Pentostam) and meglumine antimoniate (Glucantime) remain the mainstay of systemic therapy. These agents are generally administered in the hospital, although controlled outpatient management is an acceptable alternative in some situations. Pentostam is available in the United States from the Drug Service of the Centers for Disease Control and Prevention. Potential toxicities related to the antimonial agents include electrocardiographic abnormalities, hepatic toxicity, pancreatitis, and pneumonitis. Amphotericin B and its lipid formulations have shown efficacy in the treatment of leishmaniasis, especially in India where antimonial resistance has been an increasing concern.<sup>266,270</sup> Other treatments utilized with varying degrees of success have included cryosurgery, surgical excision, topical paromomycin ointment, intralesional sodium stibogluconate, and pentamidine. High-dose oral fluconazole was demonstrated useful in the treatment of cutaneous leishmaniasis caused by *L. braziliensis*.<sup>273</sup> Other potentially promising treatments for visceral leishmaniasis that have been studied include the anticancer alkylphosphocholines milt eosine, edelfosine, and ilmofosine.<sup>274,275</sup>

Viruses are ultramicroscopic organisms that grow only within living cells. The antigenic material responsible for viral immunologic reactions is present in the outer protein membrane (capsid) of the virus. The nucleoprotein core is composed of either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA). Lacking ribosomes, viruses depend on the use of the host cells' enzyme systems, blending with metabolic material of the host cell and often remaining undetected until some stimulus incites the production of new viral particles.

Viral infections of the skin may present with varied morphologies, including papules, vesiculobullous lesions, ulcers, and tumors. This chapter will include a discussion of herpes simplex virus (HSV) infections, herpes zoster (HZ), viral-like disorders of the oral mucosa, and warts. Some poxvirus infections will be discussed, including molluscum contagiosum (MC), cowpox, pseudocowpox ("milker's nodules"), orf, and smallpox. Although human immunodeficiency virus (HIV) infection does not result in primary skin disease, a brief discussion of acquired immunodeficiency syndrome (AIDS) in children and its skin disease associations is included. Neonatal herpes infection is discussed in Chapter 2.

## Herpes Simplex Virus Infection

The herpesvirus family includes HSV, Epstein–Barr virus (EBV), cytomegalovirus (CMV), varicella-zoster virus (VZV), and human herpesviruses (HHV) 6 through 8. Aside from HSV, the other herpesviruses are implicated primarily in exanthematous illnesses. HSV infections are quite prevalent in both children and adults. HSV-1 and HSV-2 are double-stranded DNA viruses that primarily infect the epidermis or mucosal surfaces. After acute infection, the virus rapidly replicates and establishes latent infection in regional nerve ganglia, from which it occasionally reactivates.<sup>1,2</sup> These viruses rely on the host-cell nucleus for DNA replication, and hence when microscopic evaluations are performed on samples with infection, the characteristic cytologic inclusions are located within the nucleus.<sup>3</sup>

HSV-1 is primarily associated with oral and labial lesions and HSV-2 with anogenital lesions, although the predilection of a specific viral serotype to a particular anatomic site appears to be changing.<sup>4</sup> Primary HSV-1 infection is largely a childhood disease that affects the oral mucosa, pharynx, lips, and occasionally the eyes.<sup>2</sup> HSV-2 is primarily implicated in genital-tract disease, with spread occurring via sexual contact or most commonly in neonates by passage through an infected birth canal (see Chapter 2). Although the mucocutaneous lesions caused by HSV-1 and HSV-2 are clinically indistinguishable, differentiation between the two serotypes can be made by viral culture, Western blot serologic testing, HSV-antigen detection with monoclonal anti-HSV antibodies, or polymerase chain reaction (PCR) studies. The Tzank smear is a rapid and cost-effective diagnostic test but is dependent on the experience of the examiner and cannot distinguish between HSV and VZV infections. Transmission of HSV is accomplished via exposure to infected mucous membranes or skin with active lesions or to mucosal secretions from an individual with active infection but can also be transmitted via exposure to secretions from an asymptomatic person who is shedding the virus.<sup>5</sup>

Infection with HSV is classified as primary or recurrent. Primary infections occur in individuals without circulating antibodies and result from direct contact with infected secretions or actual mucocutaneous lesions. After an incubation of days to weeks, they may present as subclinical infection, characterized only by the development of antibodies, as a localized or generalized cutaneous eruption,

or as a serious systemic infection with central nervous system or disseminated involvement. Most primary HSV infections are asymptomatic. Recurrent HSV infection occurs in individuals who were previously infected either clinically or subclinically. It is characterized by repeated episodes of mucocutaneous lesions at the same site or sites.

Topical and systemic antiviral agents commonly used to treat HSV infections are summarized in Table 15-1.

### HERPETIC GINGIVOSTOMATITIS

Herpetic gingivostomatitis most commonly occurs in children between the ages of 10 months and 5 years, although it may occur at any age. It presents with small vesicles on an erythematous base that evolve into painful, shallow gray erosions and ulcerations (Fig. 15-1). The lesions most often involve the palate, tongue, and gingivae. Gingival swelling and easy bleeding may occur. Perioral lesions involving the lips, cheeks, and chin (Fig. 15-2) occur in up to three-quarters of patients.<sup>6</sup> Other common features include fever, drooling, eating and drinking difficulties, foul breath odor, and irritability. Cervical and submandibular lymphadenopathy is also quite common. Secondary bacteremia with group A β-hemolytic streptococci, *Staphylococcus aureus*, or other organisms may occasionally be a complication.<sup>7</sup> Associated hepatitis has been observed, most often in neonates and immunosuppressed patients with acute primary HSV-1 infection, but also rarely in immunocompetent children.<sup>8</sup>

The differential diagnosis of herpetic gingivostomatitis in a child includes herpangina, hand-foot-and-mouth disease, aphthous stomatitis, Behcet syndrome, pemphigus vulgaris, and Stevens–Johnson syndrome. The diagnosis can be confirmed by viral culture or direct fluorescent antibody studies when necessary. Although gingivostomatitis is usually caused by HSV-1, HSV-2 may cause a similar syndrome that usually occurs in adolescents and young adults who engage in oral–genital contact.<sup>1</sup> Such primary HSV-2 infection results in similar symptoms of gingivostomatitis and pharyngitis, which in some patients may be difficult to differentiate from bacterial pharyngitis. Adolescents and young adults may also have primary HSV-1 gingivostomatitis.<sup>9,10</sup>

Although herpetic gingivostomatitis tends to be self-limited over 10 days to 2 weeks, dehydration may result from poor oral intake and excessive fluid losses, especially in younger children. In some patients, hospitalization may be required for intravenous hydration and pain control. Ambulatory treatment measures include supportive therapy with fluids and use of topical analgesics, anesthetics, or coating agents, including lidocaine, diphenhydramine, milk of magnesia, Maalox, or Kaopectate.<sup>11</sup> Specific antiviral therapy with acyclovir is advocated by some, seems most effective when started within 3 days of disease onset, and may reduce the number of oral lesions, prevent the development of new lesions, diminish difficulties with eating and drinking, and reduce the rates of hospitalization in young children.<sup>12–14</sup>

### OCULAR HERPES INFECTION

Primary HSV infection of the eye can result in a severe purulent conjunctivitis with edema, erythema, and vesiculation with superficial erosion or ulceration of the cornea (epithelial keratitis). Ocular HSV infection is a leading cause of recurrent keratoconjunctivitis with associated corneal opacification and one of the chief causes of corneal blindness in the United States.<sup>1,11</sup> This infection results from recurrent viral shedding from the trigeminal nerve reactivation and is more often caused by HSV-1. Patients with keratoconjunctivitis present

**Table 15-1** Topical and Oral Antiviral Medications Used for Herpes Simplex Virus Infections\*

Drug	Formulation	Regimen	Indication/Comment
<b>TOPICAL</b>			
Acyclovir	5% cream (2 g, 5 g) 5% ointment (15 g, 30 g)	Apply 5 times/day Apply 6 times/day	Recurrent HL; A: ≥12 years; 4 days; Rx Initial GH, localized HSV; A: adults; 7 days; Rx
Penciclovir	1% cream (1.5 g, 5 g)	Apply q. 2 h (awake)	Recurrent HL; A: ≥12 years; 4 days; Rx
Docosanol	10% cream (2 g)	Apply 5 times/day	HL; A: ≥12 years; treat until healed; OTC
<b>ORAL (ALL RX)</b>			
Acyclovir	200 mg capsule 400 mg, 800 mg tablet 200 mg/5 mL susp		A: ≥2 years
		200 mg 5 times/day 200 mg 5 times/day 400 mg 2 times/day	Initial GH; 10 days Recurrent GH; 5 days Suppression, recurrent GH; up to 12 months, then reevaluate
Famciclovir	125, 250, 500 mg tablet	1500 mg single dose 1000 mg 2 times/day 250 mg 2 times/day	A: ≥18 years Recurrent HL Recurrent GH; 1 day Suppression, recurrent GH; up to 12 months
Valacyclovir	500 mg, 1 g caplet	1 g 2 times/day 500 mg 2 times/day 500 mg–1 g once daily 2 g 2 times/day	A: adults, and ≥12 years for HL Initial GH; 10 days Recurrent GH; 3 days Suppressive GH HL; 1 day; both adults and children ≥12 years

A, Approved; GH, genital herpes; HL, herpes labialis; HSV, herpes simplex virus; Rx, by prescription; OTC, over-the-counter.

\*Approved indications and regimens listed; often used off-label.

**Figure 15-1** Herpetic gingivostomatitis. Multiple erosions with crusting. Note the associated lesions involving the chin.

**Figure 15-2** Herpetic gingivostomatitis. Lip erosions with multiple perioral herpetic lesions.

with pain, photophobia, lacrimation, and eye discharge. There may also be involvement of the eyelid (blepharitis). Deeper involvement of the cornea (stromal keratitis) or anterior uvea (iritis) may occur, and both are more serious and associated with a greater risk of visual loss. Children with HSV keratitis may have poorer visual outcomes than adults, are more often misdiagnosed, and are susceptible to amblyopia.<sup>15</sup> Ocular HSV infections may be unilateral or bilateral; patients with bilateral involvement tend to have a more protracted clinical course, and recurrences are more common.<sup>16</sup> Bacterial superinfection of herpetic keratoconjunctivitis is common. Acute retinal necrosis has rarely been reported in children.<sup>17</sup>

The diagnosis of herpetic keratoconjunctivitis can be confirmed with viral culture. Nested PCR studies, where available, seem to be superior to culture and can be performed on tear film or corneal scrapings.<sup>18</sup> The immunochromatographic assay (ICGA) kit utilizes a monoclonal antibody against HSV glycoprotein D and has high specificity (but lower sensitivity) when applied to corneal scrapings.<sup>19</sup> Ophthalmology referral is indicated, and treatment includes topical antiviral ophthalmic ointments or solutions and oral antiviral agents. Topical antiviral agents include trifluridine, vidarabine, and idoxuridine. In a series of 53 pediatric patients with HSV eye infections, 79%

of those with keratitis had corneal scarring and 26% experienced vision impairment, highlighting the importance of prompt referral and therapy.<sup>20</sup>

### HERPES LABIALIS

*Herpes labialis* refers to herpetic infections occurring on the lips, most often the vermillion border. This is the most common type of recurrent herpes infection and represents the classic “cold sore.” As with other types of recurrent infection, it occurs after reactivation of latent HSV in the cells of the trigeminal ganglia. Herpes labialis often presents initially with prodromal symptoms such as tingling, burning, or itching. After 1 to 2 days the cutaneous eruption appears as a localized cluster of small vesicles or erosions on an erythematous base (Fig. 15-3). Occasionally other areas of the face may be involved, and in immunocompromised individuals oral mucosal and/or severe involvement (Fig. 15-4) may be noted (see below). Topical and oral antiviral agents are useful in treating herpes labialis, especially when initiated within 1-2 days of the disease onset. Prophylaxis with oral agents is advocated by many for patients with a history of multiple recurrences of herpes labialis.

**Figure 15-3** Herpes labialis. Erythematous erosions clustered on the right lower lip in a patient with labial herpes. This young girl also had herpes-associated erythema multiforme (see Chapter 20).

**Figure 15-4** Herpes labialis. Severe crusting and lip edema in a patient receiving cancer chemotherapy.

## GENITAL HERPES

Genital herpes (herpetic vulvovaginitis, herpes progenitalis) is one of the most widespread sexually transmitted diseases (STDs) in the developed world and has an increasing incidence.<sup>21,22</sup> HSV-2 is primarily responsible for genital-tract herpetic infections, and seroprevalence studies reveal rates as high as 60% to 90% in developing countries and 20% to 22% of the general population in developed countries.<sup>2,23</sup> The proportion of HSV-1 isolates in genital herpes is also increasing, especially in young adults and college students.<sup>24</sup> Risk factors that directly correlate with HSV-2 infection include race (higher risk in African-Americans and Hispanics), age, years of sexual experience, lower family income, lower education level, number of sexual partners, and other STDs.<sup>2</sup> The diagnosis of genital HSV in a child should raise the suspicion of sexual abuse.<sup>25</sup> Maternal-fetal transmission of HSV may result in neonatal herpes, which is discussed in Chapter 2.

The majority of HSV-2 infections are subclinical and go unrecognized by the host.<sup>11</sup> Symptomatic primary genital herpes presents with lesions 2 to 8 days after contact with an infected individual. In distinction, first episode, nonprimary genital herpes (i.e., the initial episode

**Figure 15-5** Genital herpes. Vesicles on an erythematous base involving the right labia minora in a childhood victim of sexual abuse.

of genital herpes in a host with a past history of nongenital herpes) may not present with signs or symptoms for several months.<sup>22</sup> The lesions of primary genital HSV are painful vesicles clustered on an erythematous base (Fig. 15-5) and distributed on the vulva, labia, vagina, perineum, penile shaft, glans penis, urethra, and less often the scrotum. In females, cervical involvement, intense soft-tissue swelling, and severe pain may be present. The vesicles rupture rapidly, leaving behind painful erosions or ulcers that may be associated with pruritus, dysuria, vaginal and urethral discharge, and tender inguinal lymphadenopathy. Pustules may occasionally be present. Systemic signs and symptoms may include fever, malaise, headache, and myalgias. Herpetic sacral radiculomyelitis with urinary or fecal retention and neuralgias may occur, as may aseptic meningitis.<sup>1,11</sup> Less common features of HSV infection include endometritis and salpingitis in women and prostatitis in men. The symptoms of genital HSV usually improve over 5 to 7 days, and the cutaneous lesions heal over 2 to 4 weeks without therapy.

Genital herpes may show a heterogeneous clinical spectrum. Extra-genital involvement may be seen, with lesions most commonly involving the buttocks, anal region, thighs, mouth, and fingers (see below).<sup>2,21</sup> Atypical morphologies may also be present, including deep and tender ulcers, single erosions, erosive urethritis, vulvar fissure, and penile edema.<sup>21</sup> A high index of suspicion must be maintained, especially in the immunocompromised host or in patients with features of other STDs. The differential diagnosis for genital herpes includes syphilis, chancroid, lymphogranuloma venereum, condylomata acuminata, Behcet syndrome, HZ, erosive candidiasis, and lichen sclerosis. Acute infection with EBV may also present with acute genital ulceration (see Chapter 16).

Recurrent genital HSV infection is characterized by less severe cutaneous lesions that are usually preceded by a prodrome of pain, tenderness, itching, tingling, or paresthesia. The vesicles are fewer in number, and recurrent disease may be less common with HSV-1 versus HSV-2 disease. Triggering factors for recurrent disease may include physical or emotional stress, febrile illness, and menstruation. Recurrence rates tend to be highest for the first years after the initial infection.<sup>26</sup> Asymptomatic (subclinical) HSV shedding is another feature of genital herpes and among women with genital HSV-2 infection, occurs on an average of 2% of days.<sup>27</sup> The risk of subclinical shedding increases with the rate of symptomatic recurrences.

The diagnosis of genital herpes can be confirmed by viral culture, Tzanck preparation (cannot distinguish between HSV-1 and HSV-2), direct fluorescent antibody testing, Western blot serologic testing, or PCR. Treatments for genital herpes include supportive care and anti-viral therapy (see Table 15-1). Supportive measures include warm sitz baths, topical anesthetics, topical antibacterial ointments to prevent secondary infection, and oral analgesics. Education regarding the nature and risks of HSV infection and safe sex practices should be offered, and evaluation for other STDs should be considered when appropriate. An effective vaccine against HSV is highly desirable, and

research toward this end is ongoing. Experimental vaccines contain recombinant glycoprotein subunits, attenuated or replication-defective virus vaccines, and those composed of plasmids expressing glycoprotein subunits. Vaccine development has been challenging given the poor understanding of the mechanisms by which host immune responses fail to control HSV.<sup>28–30</sup>

The choice of antiviral therapy depends on the host immune status and the nature of the infection (primary or recurrent). Oral acyclovir, famciclovir, and valacyclovir may all help to speed healing, decrease symptoms, and decrease viral shedding. Long-term suppressive therapy in patients with frequent recurrences is useful in reducing both the rate and duration of flares. Although topical acyclovir ointment may offer some benefit for initial genital herpes infections, it offers little in recurrent infections.

### CUTANEOUS HERPES AND ECZEMA HERPETICUM

Cutaneous HSV infection can occur on any body surface area. Involvement of the finger (herpetic whitlow) is discussed in the next section. Nonorolabial, nongenital involvement presents in a similar fashion, with clustered vesicles or erosions on an erythematous base (Figs. 15-6 and 15-7). The lesions may be misdiagnosed as impetigo or HZ. Occasionally, recurrent cutaneous HSV may present only with prodromal symptoms followed by skin erythema and edema but without the characteristic vesiculation. In some instances, patients with recurrent cutaneous HSV may develop associated secondary bacterial infection or lymphangitis.

**Figure 15-6** Cutaneous herpes. Resolving vesicles and crusted papules overlying an erythematous base on the left cheek.

**Figure 15-7** Cutaneous herpes. Coalescing vesicles on a red base over the distal nose.

Eczema herpeticum (EH, or Kaposi varicelliform eruption; see Chapter 3) is a severe, disseminated HSV infection that occurs in individuals with atopic dermatitis or other chronic skin disease, including pemphigus, Darier disease, burns, and others.<sup>31</sup> Although the etiology of EH has not been clearly established, the impaired skin barrier associated with these diseases is believed to create a more permissive environment for viral invasion and binding to cellular receptors,<sup>31</sup> leading to a higher prevalence of EH with greater dermatitis severity.<sup>32</sup> Despite the high prevalence of atopic dermatitis in the general population and frequent exposure to HSV, EH is quite rare, possibly relating to a requirement for multiple additional host and environmental factors.<sup>33</sup> Single nucleotide polymorphisms in the interferon regulatory factor 2 (*IRF2*) gene have been demonstrated to confer a greater risk of EH, possibly reflecting an abnormal immune response to HSV.<sup>34</sup> Patients with EH usually experience an abrupt onset of fever, malaise, and a widespread eruption of monomorphous vesicles and erosions (Figs. 15-8 and 15-9; see Chapter 3, Figs. 3-28 and 3-29). The lesions are

**Figure 15-8** Eczema herpeticum. This toddler with chronic atopic dermatitis had an explosive onset of fever and widespread vesicles with crusting in eczematous areas. Note the monomorphic nature and clustering of these crusted papules with a few intact small vesicles on the dorsal hand.

**Figure 15-9** Eczema herpeticum. These coalescing vesicles progressed rapidly in this young girl with atopic dermatitis.

most prominent in areas of active dermatitis but especially tend to involve the head, neck, and trunk.

Complications of EH include keratoconjunctivitis, secondary bacterial superinfection, fluid loss, and viremia. The mainstay of treatment for EH is systemic antiviral therapy, which for the majority of patients is most appropriately administered via intravenous delivery in the hospital. Early initiation of therapy is preferable, and delays in starting acyclovir therapy appear to be associated with increased length of hospital stay.<sup>35</sup> Other treatment considerations include hydration with attention to electrolyte balance, antibiotic therapy for secondary bacterial infection, and pain control. Meticulous skin care should be performed, with bland emollients applied during the early phase of barrier recovery, as well as the application of anti-inflammatory agents for the underlying dermatitis. The timing of the latter remains controversial; although some have suggested that use of topical corticosteroids during active EH may adversely affect prognosis, a review of more than 1300 children admitted for treatment revealed no increase in length of stay when these agents were started at the time of admission.<sup>36</sup> Ophthalmologic evaluation is indicated when facial involvement is present. More extensive EH at presentation may be an indicator of an increased rate of repeated episodes.<sup>37</sup>

Erythema multiforme (see Chapter 20), an acute, self-limited reactive skin disease, has been associated with HSV infection in both children and adults. In prepubertal children with erythema multiforme, especially the recurrent type, HSV DNA was detected by PCR studies on skin biopsy specimens taken from the target lesions.<sup>38,39</sup> This finding was noted both in patients with a known history of HSV and in those without any such history. Prophylactic acyclovir may thus be useful in abrogating recurrences of erythema multiforme in children.

### HERPETIC WHITLOW

Herpetic whitlow is a unique form of HSV infection involving the pulp of the distal phalanx (or multiple phalanges). It is seen most often in physicians, dentists, dental hygienists, and nurses who have contact with the mouth or genital regions of patients with herpetic lesions. It may also occur as a result of autoinoculation in patients with herpes labialis, herpes stomatitis, or genital herpes.<sup>40</sup> The virus is inoculated onto the skin of one or more fingers, resulting in a deep-seated, painful vesicular or bullous eruption with erythema (Fig. 15-10). Spontaneous resolution usually occurs over 3 weeks if the condition is left untreated. The differential diagnosis of herpetic whitlow may include blistering dactylytis, burns, and impetigo. The diagnosis is confirmed by viral culture or direct fluorescent antibody testing, and treatment with oral acyclovir or other antiviral agents may result in alleviation of pain and more rapid healing.

**Figure 15-10** Herpetic whitlow. Clustered, tender, deep-seated vesicles of the distal phalanx.

### HERPES GLADIATORUM

*Herpes gladiatorum* is a term used to describe a widespread primary inoculation HSV infection occurring in contact sports enthusiasts such as wrestlers or rugby players. It may occur at some time in up to one-third of wrestlers and is characterized by grouped vesicles on an erythematous base. It has also been observed after shared use of boxing gloves believed to be contaminated by HSV-1, with lesions occurring over the knuckles.<sup>41</sup> The most common locations for herpes gladiatorum are the head, neck, and upper extremities.<sup>42,43</sup> In addition to widespread cutaneous lesions, affected individuals may have fever, malaise, sore throat, anorexia, headache, weight loss, and regional lymphadenopathy. The cutaneous lesions of herpes gladiatorum may occasionally lack classic vesicles, in which case the differential diagnosis may include tinea corporis gladiatorum, impetigo, and atopic dermatitis.<sup>43</sup>

Herpes gladiatorum can be effectively treated with oral acyclovir, famciclovir, or valacyclovir. The duration of therapy necessary before allowing the athlete to return to competition is controversial, and evidence-based recommendations do not exist. Sharing of equipment and towels should be discouraged and appropriate cleaning of wrestling mats encouraged. Seasonal antiviral prophylaxis has been advocated by some in an effort to suppress recurrent outbreaks and reduce the risk of spread to susceptible teammates or opponents.<sup>44,45</sup>

### HERPES IN THE IMMUNOCOMPROMISED HOST

Severe, chronic, and recalcitrant HSV infections may be seen in the setting of immunodeficiency. These settings include individuals with hematologic malignancy, those with a history of bone marrow or solid-organ transplantation, and those with HIV infection. Although these patients may develop common forms of HSV infection, their lesions may be more widespread and extensive. Persistent or recurrent ulcers are a common manifestation of HSV infection in patients with AIDS.<sup>1</sup> Large, persistent ulcers in patients infected with HIV should arouse suspicion for HSV, although the differential diagnosis may include syphilis and chancroid. Less common locations such as the buttocks and back are also more likely to be involved in these patients.<sup>21</sup> HSV lesions in immunocompromised hosts may also be verrucous, pustular, markedly crusted (Fig. 15-11), necrotic (Fig. 15-12), or exophytic.

In addition to cutaneous lesions, disseminated HSV may be noted in this patient population. Oropharyngeal involvement, esophagitis, tracheobronchitis, pneumonitis, hepatitis, pancreatitis, adrenal necrosis, and gastrointestinal-tract and bone marrow involvement may occur.<sup>1</sup> These severe and/or disseminated infections may be caused by either HSV-1 or HSV-2.

**Figure 15-11** Herpes in the immunocompromised host. This large, crusted plaque was culture-positive for *Herpes simplex* in this 6-year-old female receiving chemotherapy for leukemia.

**Figure 15-12** Herpes in the immunocompromised host. Vesicles rapidly progressed to necrotic plaques in this young girl status post-bone marrow transplantation.

**Figure 15-13** Herpes zoster. Confluent vesicles and crusted vesicles with erythema in a dermatomal distribution on the left thigh. This boy was otherwise healthy with no identifiable underlying predisposition.

**Figure 15-14** Herpes zoster. Edema with erythema and vesiculation, distributed in a V1 and partial V2 distribution. Corneal involvement may occur with this presentation.

## Herpes Zoster

HZ (also called *zoster* or *shingles*) is an acute vesicular eruption caused by reactivation of a latent infection with VZV in the sensory ganglia. Although it is most often seen in elderly or immunosuppressed individuals, it may also occur in children. Although pediatric zoster is most common in immunocompromised children or those who had a primary intrauterine infection or acute varicella within the first year of life,<sup>40</sup> it may occasionally occur in children without any of these risk factors. Neonatal HZ has rarely been reported, presumably in association with exposure to varicella zoster *in utero*. Due to licensure of the live attenuated Oka strain varicella vaccine, it has become clear that HZ may be caused by reactivation of the latent vaccine virus, even in children.<sup>47,48</sup> Studies of HZ incidence since implementation of the vaccination program in 1995 have yielded conflicting results, showing both increased incidence and no increase, and suggesting that there may be other unidentified risk factors for HZ that are changing over time.<sup>49</sup> In a review of 322 children with HZ, the incidence in vaccinated children (either wild-type or vaccine-strain) was 79% lower than in unvaccinated children (wild-type only).<sup>50</sup>

HZ is characterized by vesicles and erythema clustered in a dermatomal distribution of one or more sensory nerves (Fig. 15-13). The most commonly affected dermatomes are the second cervical to second lumbar nerves (C2 to L2) and the fifth (Fig. 15-14) and seventh cranial nerves. Patients often complain of hyperesthesia, pain, and tenderness to light touch in the affected area(s), usually before any cutaneous findings are present. Although the eruption is usually unilateral with a sharp demarcation at the midline, occasional contralateral involvement is seen. It is not unusual to see a few randomly scattered vesicular lesions beyond the primary dermatomal involvement, and such scattered lesions do not necessarily constitute disseminated zoster.

Successive crops of new lesions with extension of the process may occur for up to 1 week, followed by crusting of the vesicles and healing over 1 to 2 weeks. In children the disorder tends to be milder, and healing often occurs rapidly, within a few days to 1 week.<sup>51</sup> In addition, in otherwise healthy children, postherpetic neuralgia (PHN, a delayed phenomenon of chronic pain and paresthesias in an area previously affected by HZ) is rare. PHN is more common in elderly patients and in those with a history of ophthalmic HZ (see below).<sup>52</sup>

Immunocompromised children with HZ may have more extensive involvement with a higher risk of viremia and visceral dissemina-

tion.<sup>51</sup> This may include pneumonia, encephalitis, hepatitis, and disseminated intravascular coagulopathy.<sup>51,53</sup> These patients may also have disseminated cutaneous involvement that presents in a fashion more typical of acute varicella and with no obvious dermatomal component.<sup>53</sup> The intensity of chemotherapy may affect the risk of HZ; in one series, more than half of the children with acute lymphoblastic leukemia receiving chemotherapy on high-risk protocols developed HZ during their course of treatment.<sup>54</sup> *Abdominal zoster* refers to the presentation of HZ as severe abdominal pain that precedes the development of cutaneous lesions. These patients are often explored surgically, and the condition is associated with a high incidence of abdominal visceral involvement. Children infected with HIV may have chronic or relapsing HZ, or HZ with unusual cutaneous lesions (i.e., hyperkeratotic papules, ulcers, or necrotic plaques).

Infection associated with the ophthalmic branch of the fifth (trigeminal) nerve may involve the cornea with keratitis and uveitis and may lead to permanent damage. This presentation (termed *HZ ophthalmicus*) occurs when the nasociliary branch is involved and accordingly presents with cutaneous involvement of the nasal tip (Hutchinson sign).<sup>55</sup> This important sign should not be overlooked and should prompt rapid diagnosis, referral, and institution of therapy.

**Table 15-2** Systemic Antiviral Medications Used for Herpes Zoster\*

Drug	Formulation	Regimen	Indication/Comment
Acyclovir	200 mg capsule 400 mg, 800 mg tablet		A: ≥2 years
	200 mg/5 mL susp	800 mg 5 times/day	Adult dose; 7–10 days Pediatric HZ dosing: NE
	50 mg/1 mL IV	60 mg/kg per day	IC <12 years; divide every 8 hours; 7 days
		30 mg/kg per day	IC ≥12 years; divide every 8 hours; 7 days
Famciclovir	125, 250, 500 mg tablet	500 mg 3 times/day	A: ≥18 years; 7 days
Valacyclovir	500 mg, 1 g caplet	1 g 3 times/day	A: adults; 7 days

A, Approved; HZ, herpes zoster; NE, not established; IC, immunocompromised; IV, intravenous preparation.

\*Approved indications and regimens listed; often used off-label.

HZ of the maxillary division of the trigeminal nerve produces vesiculation of the palate, uvula, and tonsillar area. Involvement of the mandibular division produces vesicular involvement of the anterior aspects of the tongue, floor of the mouth, lips, and buccal mucous membranes. Involvement of the geniculate ganglion produces lesions on the tongue, ear, and skin of the auditory canal. When accompanied by Bell palsy and disturbances of hearing and equilibrium, it is part of the Ramsay Hunt syndrome.

The diagnosis of HZ is often a clinical one, and in typical cases further evaluations are generally unnecessary. In patients in whom diagnostic confirmation is indicated, direct detection with fluorescent antibody stains of vesicle-base scrapings is useful. Viral culture can be used, but VZV may take up to 1 week to induce cytopathic changes. PCR studies are not available on a widespread basis for clinical use, and serologic studies are generally not useful in this setting.

Treatment for HZ consists of symptomatic measures and specific antiviral therapy (Table 15-2). Symptomatic care includes wet compresses, drying lotions (i.e., calamine), antihistamines, and analgesics. High-dose acyclovir decreases vesicle formation, time to crusting, and days of pain when instituted within 72 hours of onset of the exanthem. Acyclovir should be administered via the intravenous route in immunocompromised patients, given their greater severity of disease, or in any patient with disseminated or severe infection. Other antiviral options in immunocompetent patients or those with uncomplicated HZ include valacyclovir and famciclovir. An HZ vaccine is approved for adults 50 years of age and older, with widespread vaccination desirable to help in the prevention of HZ and PHN in this population and in reducing the health and financial costs of HZ.<sup>56,57</sup> This vaccine is nearly identical to the varicella vaccine, except that the HZ vaccine contains 14 times as many virus particles.<sup>58</sup>

## Viral-Like Disorders of the Oral Mucosa

### APHTHOUS STOMATITIS

Recurrent aphthous stomatitis (RAS; aphthous ulcers, canker sores) is one of the most common painful diseases affecting the oral mucosa of children. It has been reported in 5% to 25% of the general population, and there may be a genetic predisposition.<sup>59,60</sup> The etiology is not well understood, and treatment has traditionally been symptomatic. Aphthous stomatitis presents with single or multiple shallow erosions

**Figure 15-15** Aphthous stomatitis. Multiple shallow erosions of the labial mucosa.

or ulcerations (Fig. 15-15) on the labial and buccal mucosae, gingivae, tongue, floor of the mouth, palate, or pharynx. Before the onset of the lesions, a tingling sensation may be present. After 24 to 48 hours, a focal erythema develops, followed soon thereafter by tiny, superficial gray-white erosions. Usually there are 1 to 3 lesions (minor RAS; 80% to 85% of cases), and the area of erosion increases and evolves into one or more sharply defined shallow ulcers covered by gray membranes and surrounded by sharp borders and slightly elevated, bright red areolae. Lesions usually measure 3 to 6 mm in diameter, and if left untreated, persist for 8 to 12 days (sometimes longer) and heal without scarring. Occasionally patients develop larger ulcerations, up to several centimeters in size with prolonged pain, fever, and healing with scarring. This variant has been termed *major RAS* (10% of cases; formally known as Sutton disease) and may be associated with dysphagia, malaise, and HIV infection.<sup>61</sup> Another form of aphthae, herpetiform RAS, occurs in 5% to 10% of patients with aphthous lesions and presents as clusters of pinpoint ulcers that simulate but are not caused by infection with HSV.<sup>62</sup>

Aphthous stomatitis is believed to be multifactorial in origin and may occur in response to a variety of triggering factors, including stress, trauma, hormonal changes, and infection. Cytokines are felt to play an important role, and polymorphisms in the genes for interleukins (ILs) 1b and 6 may increase a patient's individual risk of RAS.<sup>63</sup> Human leukocyte antigen (HLA) B52 and HLA-B44 antigens were found to be strongly associated with RAS in Israeli Arab youths.<sup>64</sup> Drug-induced RAS has also been suggested, especially in association with nonsteroidal anti-inflammatory drugs and β-blockers.<sup>65</sup> Both EBV and CMV have been hypothesized as potential infectious causes of RAS.<sup>66,67</sup> In the vast majority of cases, the etiology remains unknown.

The differential diagnosis (and/or potential associations) of RAS includes Behcet syndrome (see Chapter 25), inflammatory bowel disease (see Chapter 25), cyclic neutropenia, gluten-sensitive enteropathy, herpes simplex infection, candidiasis, vitamin/nutritional deficiencies (iron, folic acid, zinc, and vitamins B<sub>1</sub>, B<sub>2</sub>, B<sub>6</sub>, and B<sub>12</sub>), and the syndrome of periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA, Marshall syndrome) (see Chapter 25). PFAPA syndrome is characterized by high fevers (up to 41°C), aphthous ulcers, pharyngitis (which is usually culture-negative), and cervical adenitis. Associated symptoms include headache, nausea, vomiting, and abdominal pain.<sup>62,68</sup> The syndrome usually occurs in patients younger than 5 years of age, and flares recur at 21- to 42-day intervals. The fevers resolve over 24 to 48 hours spontaneously and often drop dramatically after even a single dose of oral corticosteroids. Other reportedly effective therapies have included cimetidine and tonsillectomy.<sup>68</sup> Overall, patients with PFAPA syndrome do well with spontaneous resolution of the episodes within 3 to 5 years and without any long-term sequelae.

Treatments for RAS include primarily topical corticosteroids and topical and/or oral analgesics. Topical clobetasol, a potent corticosteroid, in a denture paste or oral analgesic base and applied two to three times daily often results in remission and symptomatic relief.<sup>69</sup> Mixtures of diphenhydramine elixir and Kaopectate or Maalox have been

used successfully, as have a variety of medical mouthwashes (i.e., chlorhexidine [Peridex] antibacterial oral rinse). Patients with severe manifestations of RAS may respond to the oral corticosteroids (usually short course) colchicine, thalidomide, or dapsone. Multivitamin administration has not been demonstrated useful in reducing the frequency or duration of RAS episodes.<sup>70,71</sup>

### ACUTE NECROTIZING GINGIVITIS

Acute necrotizing gingivitis (acute necrotizing ulcerative gingivitis, trench mouth, Vincent stomatitis, Vincent angina) is a painful ulcerative disorder that chiefly affects adolescents and young adults. A related disorder termed *noma* (see Chapter 14) occurs when the infection spreads beyond the gingiva to involve other oral mucosal surfaces. Although acute necrotizing gingivitis was formerly common in schools and military establishments, it is quite rare in the United States and Western Hemisphere, perhaps owing to improved oral and dental care. The cause of acute necrotizing gingivitis is often a mix of bacterial pathogens, including *Fusobacterium*, *Prevotella*, *Actinomyces*, and *Bacteroides* species and spirochetes. The condition occurs most commonly in patients with predisposing conditions such as malnutrition, poor oral hygiene, ethanol or tobacco use, or immunosuppression.

Clinical findings consist of painful gingivae that bleed easily and an inflamed, eroded, hemorrhagic oropharynx. Ulcerations are most common at the gingival margins and interdental papillae. The ulcers are covered by a grayish-white slough or pseudomembrane that can be removed, leaving behind a raw bleeding surface. Single or multiple papillae may be involved, and the ulceration can be very extensive. Associated features include lymphadenopathy, pain, bleeding of the gums, fever, and a foul breath odor.<sup>72</sup> Treatment of acute necrotizing gingivitis consists of debridement by a dentist or periodontist and broad-spectrum antibiotic therapy, usually penicillin, clindamycin, or erythromycin. Chlorhexidine or saltwater oral rinses may help alleviate discomfort. Attention to good oral hygiene and nutritional rehabilitation (where indicated) are important steps in prevention.

## Warts

Warts (verrucae) are a common viral infection of the skin and mucosae caused by the human papillomavirus (HPV). These benign intraepidermal tumors most commonly occur in children and young adults, and their incidence has been estimated at 10%.<sup>73,74</sup> However, in a recent cross-sectional study of 1465 primary schoolchildren, 33% had warts, so this figure may be an underestimate.<sup>75</sup> Although harmless and often self-involving over years, warts are occasionally painful and may carry a negative social stigma. In addition, HPV may be associated with cutaneous and genital oncogenesis, particularly in immunosuppressed individuals.

There are four basic types of warts: verruca vulgaris, verruca plana, verruca plantaris, and condyloma acuminatum. Each of these will be discussed individually in the following sections. Most warts occur on the hands, fingers, elbows, and plantar surfaces of the feet. Patients with warts commonly autoinoculate themselves inadvertently with the subsequent appearance of multiple secondary lesions. A classic feature of cutaneous warts is that of koebnerization, whereby a linear constellation of lesions develops along the path of excoriation (Fig. 15-16).

HPV is transmitted via skin-to-skin contact or from fomites, where recently shed viruses may survive if the environment is warm and moist (i.e., locker room floors, pool decking, showers). The entry site is often an area of recent trauma or a skin region with subclinical abrasion or fissuring. Recently it has been shown that important environmental risk factors include having family members with warts and wart prevalence in classrooms, suggesting that preventive recommendations should perhaps focus on these sources more than public places.<sup>75,76</sup> The incubation period from inoculation to development of the wart may range from 1 to 6 months or more. Although the duration of warts is variable, one study documented that two-thirds of lesions resolve spontaneously within 2 years.<sup>77</sup> The most important mechanism in wart regression appears to be cell-mediated immunity, with cytokines released by keratinocytes or immune-system cells and inducing an immune response against HPV.<sup>78</sup>

**Figure 15-16** Warts with koebnerization. Multiple small, verrucous papules with a linear clustering (Koebner phenomenon) were present on this child's forehead.

Over 130 HPV types comprise this family of small double-stranded DNA viruses, and the various HPV types have been divided into two groups: cutaneous and mucosal.<sup>79,80</sup> Mucosal types are recovered mainly in the genital tract, although other mucosae may be infected, including the respiratory tract, nose, conjunctiva, and mouth. Although the same HPV virus can cause various types of warts, there is often a correlation between the virus type and the clinical/morphologic characteristics of the lesions it causes. For instance, HPV types 1, 2, 4, and 7 are often associated with common warts (verrucae vulgaris); type 1 with deep palmar and plantar warts; types 3, 10, 28, and 41 with flat warts; types 5, 8, 17, and 20 (among others) with the autosomal recessive disorder epidermodysplasia verruciformis (EV) (see later); and types 6 and 11 with respiratory, conjunctival, and genital infection.<sup>79</sup> In addition, HPV types associated with a high risk for cervical cancer include 16, 18, 31, 33, 35, 39, and 45, among others. HPV types 16 and 18 are the most common high-risk types found in the female anogenital system and are seen in up to 70% of women with cervical cancer. In a study of HPV types and their relationships to patient characteristics, the most distinct clinical profile was noted with HPV 1, which was associated with infection in children younger than 12 years of age, plantar location, a duration of less than 6 months, and patients with fewer warts.<sup>81</sup> Laboratory diagnosis of HPV skin infection is usually unnecessary, and the diagnosis usually straightforward. In instances where identification of the HPV type is necessary, options include nuclear-acid hybridization assays via Southern blotting, dot blots, RNA and DNA probes, and PCR studies. HPV genotyping on swabs of the overlying skin using a novel PCR assay was shown to be a simple and highly sensitive approach to typing.<sup>82</sup>

### VERRUCAE VULGARIS

Verrucae vulgaris (common warts) occur predominantly on the dorsal surface of the hands or periungual regions but may be seen anywhere on the cutaneous surface. Occasionally they may also occur on the oral mucosa. Common warts may occur as single or multiple lesions. They clinically present as flesh-colored, verrucous (rough surfaced) papules that may be dome-shaped (Fig. 15-17), exophytic (Fig. 15-18), or filiform (i.e., having a stalk; Fig. 15-19). Individual lesions may coalesce into larger plaques (Fig. 15-20). "Ring warts" may occur after overly aggressive therapies and are another example of koebnerization (Fig. 15-21). Oral lesions present as small, pink-white, soft papules and plaques of the labial, lingual (Fig. 15-22), buccal, or gingival mucosa. In Heck disease, multiple verrucous papules occur in a similar mucosal distribution (Fig. 15-23).

Periungual and subungual verrucae (Figs. 15-24 and 15-25) occur around and beneath nailbeds, particularly on the fingers of cuticle pickers and nail biters. These lesions, because of their location and susceptibility to trauma, often become irritated, infected, or tender

**Figure 15-17** Common warts. A dome-shaped lesion of the lateral nose and a filiform lesion of the columella.

**Figure 15-18** Common wart. This lesion demonstrates the exophytic type of *verruca vulgaris*.

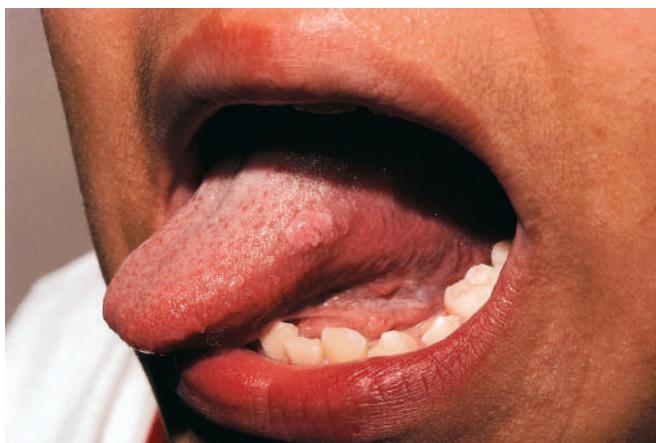

**Figure 15-19** Common wart. This lesion has a stalk, and is termed a filiform wart.

**Figure 15-20** Common warts. Multiple lesions coalesce into a mosaic plaque on the plantar surface.

**Figure 15-21** Ring warts. This annular plaque composed of small verrucous papules developed after a marked blister response to therapy of a single wart above the upper lip.

**Figure 15-22** Common warts affecting mucosa. This tongue lesion presented as a soft, verrucous papule.

**Figure 15-23** Heck disease. Multiple soft, pink verrucous papules of the inner lip mucosa.

**Figure 15-26** Wart with thrombosed capillaries. Note the multiple black dots within this large mosaic plantar wart.

**Figure 15-24** Periungual warts. Verrucous papules of the lateral nail-fold. Note adjacent subungual hemorrhage.

**Figure 15-27** Flat warts. Flat, verrucous papules.

**Figure 15-25** Subungual warts. Verrucous papules of the distal thumb and index finger with extension under the nail plate.

**Figure 15-28** Flat warts. Multiple disseminated flat papules in a patient infected with human immunodeficiency virus (HIV).

and are often more resistant to therapy. Satellite lesions may appear, particularly near warts that have been irritated, manipulated, or incompletely treated. When the diagnosis of *verruca* is in doubt, gentle paring with a number 15 scalpel blade will reveal characteristic punctate black dots that represent thrombosed capillaries (Fig. 15-26).

### VERRUCAE PLANA

*Verrucae plana* (flat warts) occur primarily on the face, neck, arms, and legs. They are usually seen as smooth, flesh-colored to slightly pink or brown, flat-topped papules measuring 2 to 5 mm in diameter (see Fig. 15-16; Figs. 15-27 and 15-28). They vary from a few lesions

**Figure 15-29** Flat warts with koebnerization. Flat papules on the forehead, with a linear configuration (Koebner phenomenon) at sites of autoinoculation.

**Figure 15-30** Plantar warts. Verrucous papules on the plantar surfaces.

to several hundred in any given individual. They may appear in the bearded areas of men and on the legs of women, because irritation from shaving tends to cause their spread. Contiguous warts may coalesce to form larger, plaque-like lesions. Again, linear arrangements of the papules in areas of scratching (koebnerization) are characteristic (see Fig. 15-16; Fig. 15-29).

#### VERRUCAE PLANTARIS

Verrucae plantaris (plantar warts) occur on the plantar surfaces of the feet and tend to be the most symptomatic type of warts as well as a therapeutic challenge. They usually occur on the weight-bearing areas of the heels, toes, and midmetatarsal areas (Fig. 15-30). Because of the pressure of walking, the lesions often develop an endophytic component and are very painful and tender. Coalescence of multiple lesions may result in mosaic warts (Fig. 15-31). It may occasionally be difficult to differentiate plantar warts from corns or calluses. Corns are localized hyperkeratoses that form over interphalangeal joints as the result of intermittent pressure and friction. Penetrating corns often appear at the base of the second or third metatarsal-phalangeal

**Figure 15-31** Plantar warts, mosaic. Multiple verrucous papules coalesced into this giant, painful verrucous plaque.

**Figure 15-32** Condylomata acuminata. Verrucous, brown papules in a perianal distribution.

joint. They can be distinguished from plantar warts by the lack of thrombosed capillaries after paring and by their characteristic hard core. Soft corns are macerated hyperkeratotic lesions that persist at points of friction and pressure in intertriginous areas. They are usually seen on the lateral aspect of the toes or in the web spaces between the fourth and fifth toes.

Black heel (talon noir, calcaneal petechiae) is a common condition that is often confused with plantar warts. In this disorder, superficial dermal capillaries are ruptured by the shearing action associated with sudden stops in athletic individuals, usually tennis, racquetball, or basketball players. Clinically it is characterized by clusters of brown or blue-black pinpoint petechial macules in the horny layer along the backs or sides of the heels or lateral edges of the feet. Gentle paring of the surface with a number 15 scalpel blade can help differentiate this condition from malignant melanoma, calluses, corns, and plantar warts.

#### CONDYLOMATA ACUMINATA

Condylomata acuminata (anogenital warts, anogenital HPV) are HPV-induced lesions of the anogenital tract and one of the most common STDs. The diagnosis of condylomata acuminata in a child is fraught with anxiety for parents and practitioners alike, and the implications regarding sexual abuse versus benign transmission are controversial and often unclear. Although condylomata often occur after sexual contact, other modes of acquiring the infection include vertical (perinatal) transmission, benign (nonsexual) heteroinoculation, and autoinoculation. In addition, fomite spread is another potential mode of transmission.<sup>83</sup>

Condylomata acuminata present most commonly in the perianal area as flesh-colored, soft, verrucous papules (Fig. 15-32) measuring 1 to 5 mm in diameter. The lesions are usually multiple, and "mirror image" lesions may be noted on each side of the anus. Other areas of involvement include the glans penis, penile shaft, scrotum, and vulva. Vaginal and cervical involvement are appreciable only with internal

**Figure 15-33** Condylomata acuminata. Verrucous papules of the labial surfaces, with a large, vegetative lesion protruding from the vagina. This toddler had been sexually abused.

**Figure 15-34** Infantile perianal pyramidal protrusion. Pyramidal-shaped, fleshy papule of the midline raphe.

examination. Occasionally, lesions may enlarge rapidly and present as large, exophytic, cauliflower-like masses (Fig. 15-33). Childhood condylomata are usually incidentally noted during diaper changes, toileting, bathing, or physical examinations.<sup>84</sup> The lesions are usually asymptomatic, but irritation, bleeding, and pain may occur. The differential diagnosis of condylomata acuminata includes MC, epidermal nevus, skin tag, and pseudoverrucous papules and nodules. Infantile perianal pyramidal protrusion is a pyramid-shaped, flesh-colored to pink soft-tissue swelling (Fig. 15-34) that appears in the medial raphe of girls and may represent a peculiar form of lichen sclerosus et atrophicus.<sup>85,86</sup> The distribution, appearance, and solitary nature of this lesion should distinguish it from condylomata.

The diagnosis of condylomata acuminata in a child should prompt consideration for the possibility of sexual abuse. In one large study of children with evidence of child sexual abuse, genital HPV infection was present in 13.7%.<sup>87</sup> However, it should be remembered that anogenital warts occur in large numbers of children as a result of innocent (nonsexual) or vertical transmission or from autoinoculation. Although HPV DNA typing is occasionally considered, it does not help in the differentiation between the various modes of transmission.<sup>83,84</sup> Although innocent autoinoculation or heteroinoculation from hand warts is common, and the finding of such hand lesions in an adult contact or caretaker might be reassuring, fondling is a form of sexual abuse commonly seen in younger children and thus the possibility of sexual abuse must still be considered.<sup>88</sup>

**Table 15-3** Findings in a Child with Condylomata that Should Prompt Referral to Child Protective Services

Finding	Comment
Abuse suspected by parent(s)	Includes history of access to the child by a known sexual offender
Abuse disclosed by child	If child appropriately aged for interview (usually 3 to 4 years)
Child's behaviors suggestive	Includes nightmares, advanced sexual knowledge for age, acting out sexually with peers
Suggestive physical examination	Acute or chronic trauma (petechiae, bruising to the hymen, anal tears, absent hymen, anogenital scarring)
Findings of other sexually transmitted infection	May include gonorrhea, <i>Chlamydia</i> , <i>Trichomonas</i> , human immunodeficiency virus, hepatitis B and C, syphilis
Child older than 4 years	Some experts recommend routine referral

Modified from Sinclair KA, Woods CR, Sinal SH. Venereal warts in children. *Pediatr Rev* 2011;32(3):115–21.

When a child is diagnosed with anogenital condylomata, a directed history should include the age of onset, history of maternal infection (genital warts or abnormal Papanicolaou [Pap] smear), and personal or family history of warts, as well as inquiries about the child's social environment and all caregivers.<sup>88</sup> Physical examination should be focused on findings suggestive of sexual abuse, and laboratory evaluation for other STDs should be performed if noninnocent HPV transmission is suggested. A behavioral and social assessment by a skilled professional should be considered. A summary of findings that should prompt referral to child protective services is shown in Table 15-3. The literature contains significant disagreement with regard to the prevalence of sexual abuse in children with condylomata, with estimates ranging variably from 4% to 91%.<sup>84</sup> Although sexual transmission of HPV may occur at any age, the risk seems greater in children over 3 to 4 years of age.<sup>89,90</sup> The Committee on Child Abuse and Neglect of the American Academy of Pediatrics (AAP) considers the presence of anogenital warts in children “suspicious” and recommends reporting to a child protective agency.<sup>25</sup>

The authors' personal approach is to consider nonsexual transmission of HPV if the child is under 3 years of age; if lesions developed within the first year of life; if the patient has other nongenital warts; if warts are present in close contacts, especially genital warts (or history of abnormal Pap smear) in the mother; and when there are no findings to suggest sexual abuse. If there is any suspicion of sexual abuse, referral to child protective services is initiated. In patients in whom there is uncertainty or where the situation is ambiguous, a social worker from the protective-services team should be enlisted early on in the evaluation for a formal structured interview. Although the diagnosis of sexual abuse must never be missed, “reflexive reporting” to child welfare authorities should be avoided given the emotional devastation and destruction that may result. Practitioners need to balance the risk of missing a case of sexual abuse (if they do not report) against the decision to report the family, with the parents or caregivers potentially suffering false accusation and its ramifications, which in some cases may include losing parental custody.<sup>91</sup> If the practitioner evaluating the patient is uncomfortable in performing such an evaluation, referral should be made to a clinician with expertise for further evaluation.<sup>84</sup>

Treatment of condylomata acuminata in children (see the following section) is challenging for many reasons. In an interesting study of the natural history of these lesions in children, spontaneous resolution occurred in 54% of patients within 5 years of the diagnosis, suggesting that nonintervention is a reasonable initial approach to managing this condition.<sup>92</sup> Precise identification of the rate of spontaneous involution is challenging, however, because the majority of infected children receive some form of therapy.<sup>93</sup>

**Table 15-4** Treatments for Warts and Condylomata Acuminata in Children

Treatment	Comment
<b>WARTS</b>	
Watchful waiting	Especially appropriate in young children
Topical salicylic acid	Available OTC; may be more effective when combined with duct-tape occlusion
Cryotherapy	Both in-office and OTC available
Manual paring or filing	May minimize pain from plantar warts
Immunotherapy:	
Oral	Cimetidine; OL use (see text)
Topical	Imiquimod (home use; OL); SADBE, DCP
Laser therapy	Pulsed dye laser potentially useful; CO <sub>2</sub> laser useful but scarring may result
Photodynamic therapy	Rarely utilized in children
Injection therapy	<i>Candida</i> /mumps antigens, bleomycin, interferon; rarely utilized in children
Curettage, electrocautery	Rarely utilized in children
Topical retinoids	May be useful for flat warts; OL
Topical chemotherapy:	
5% 5-fluorouracil	OL use; may be useful for facial flat warts
2% 5-fluorouracil + 17% salicylic acid	Available OTC from compounding pharmacy; useful for plantar warts; applied nightly with tape occlusion
Antiviral therapy:	
Cidofovir	OL use; typically used IV to treat CMV retinitis in immunocompromised patients; has been compounded as 1% topical cream for refractory warts
<b>CONDYLOMATA</b>	
Watchful waiting	Especially appropriate in young children
Chemovescicants	Podophyllin, TCA, podofilox
Immunotherapy:	
Oral	Cimetidine; OL use (see text)
Topical	Imiquimod; OL if <12 years
Cryotherapy	
Sinecatechins	Green tea extracts; 15% ointment approved for anogenital warts ≥18 years
Laser therapy	Rarely used for this indication in children
Surgery	Rarely used for this indication in children

CMV, Cytomegalovirus; CO<sub>2</sub>, carbon dioxide; DCP, diphenylcyclopropenone; IV, intravenous; OL, off-label; OTC, over-the-counter; SADBE, squaric acid dibutylester; TCA, trichloroacetic acid.

### Treatment of Common Warts and Condylomata Acuminata

No specific antiviral therapy exists for HPV infections, and most wart treatments rely on destruction of the affected area of epidermal proliferation. Some newer methods of therapy are immunomodulatory in nature. Because spontaneous involution of warts may occur, watchful waiting is an appropriate consideration, especially in younger patients in whom destructive therapies are traumatic and poorly tolerated. When considering therapy for warts, every effort should be made to avoid overly aggressive or scarring therapies. **Table 15-4** lists some of the treatment options for common, plantar, and planar warts and for condylomata acuminata. Several are discussed here in more detail.

Patients and parents must be reminded that even with apparent “cures” of warts or condylomata, latent HPV infection in grossly normal appearing squamous epithelium beyond the areas of treatment may persist and results in a fairly high risk of recurrence.

Whether warts should be treated depends on the patient's and parents' desires and the nature of the lesions. Those patients with warts that are painful, extensive, enlarging, subject to trauma, or cosmetically objectionable are most likely to be interested in therapy. If treatment is to be given, it should be harmless to the child, and if a painful therapy is being utilized, the child should be old enough to consent to the therapy. Parents occasionally request painful therapies (i.e., cryotherapy) for young children; this decision should be made only after a thorough discussion of the therapy, the pain involved, and its risk-to-benefit ratio. It should be emphasized that some modalities used for the treatment of warts in adults are neither feasible nor desirable for the treatment of warts in children. The choice of therapy will depend on the age, personality, and developmental status of the patient and the number, size, and location of the lesions.

Salicylic acid is available commercially under a variety of brand names and generics. It comes as liquids, gels, plasters, and pads. Salicylic acid preparations are applied directly to the wart surface and may be left on continuously or overnight. An effective form of combination therapy is to apply a salicylic acid liquid to the wart(s) and after drying occurs (5 minutes) to occlude the surface with duct tape. This treatment is placed on at bedtime, and the duct tape is removed the next morning. With removal of the tape, gradual debridement of the wart is performed, and the application is repeated nightly until the warts have resolved. Salicylic-acid therapy may take from 2 to 12 weeks for complete wart resolution. A potential side effect of this therapy is maceration and irritation of the skin surrounding the wart. If this occurs, therapy should be held for 2 to 3 days to allow for resolution and then it is resumed. A compounded product of 17% salicylic acid and 2% 5-fluorouracil (Wart PEEL, NuCara Pharmacy, Coralville, IA) is available and quite effective when applied to plantar warts nightly under tape occlusion.

Cryotherapy is a highly effective therapy for warts, albeit one that is painful and that may be unacceptably traumatic for younger patients. The most effective cryogen appears to be liquid nitrogen, which has a vaporization temperature of -196° C.<sup>88</sup> Other agents such as dimethyl ether and propane (Histofreezer) and chlorodifluoromethane (Verruca-Freeze) achieve temperatures in the range of -40 to -80° C and appear to be less effective.<sup>94</sup> Liquid nitrogen is applied to the wart with a cotton-tipped applicator or via a spray gun, for 10 to 20 seconds. The number of applications per treatment session depends on multiple factors, including the size of the wart, its location, past responses, and the style of the physician. The goal is to induce blister formation above the dermal–epidermal junction without causing a deep ulcer or significant necrosis to surrounding tissue. Therapy is often repeated at 3- to 4-week intervals and may be more effective when preceded by gentle debridement of warty tissue with a number 15 scalpel blade. Cryotherapy may be extremely uncomfortable, and some children will not accept this mode of therapy. Although the child can be held down for the procedure, this is an undesirable approach in most instances, and alternative treatments should be considered. Several over-the-counter cryotherapy wart removal products (i.e., Wartner, Compound W Freeze Off, Dr Scholl's Freeze Away) are available and use the combination of dimethyl ether and propane to freeze to -57° C. The cryogen is delivered by a foam pad attached to an applicator, and held on the wart for 10 to 20 seconds.

Immunologic forms of wart therapy rely on the host immune system to mount a response against the HPV-induced lesions. Although these forms of therapy are not uniformly efficacious, they offer another option in the treatment of patients with warts. The most common form of oral immunotherapy is treatment with cimetidine, which is believed to possess immunomodulatory activity including the ability to inhibit suppressor T-cell function, activate T helper (Th) 1 cells, and stimulate production of IL-2 and interferon-γ.<sup>95,96</sup> In one study, 32 children with warts were treated with cimetidine, 25 to 40 mg/kg per day divided into three or four doses, with an 81% clearance rate after 2 months of treatment.<sup>95</sup> Other studies of cimetidine and warts have shown conflicting results.<sup>97–100</sup> When utilized, most experts recommend 30 to 40 mg/kg per day divided into twice daily doses. However, the treatment is usually well tolerated with few if any side effects, and when effective, recurrences are rare.

Imiquimod is a topical immune-response modifier approved for the treatment of genital and perianal warts in patients 12 years of age or

older. It is marketed in a 5% and 3.75% creams (Aldara and Zyclara, respectively) and is applied to those lesions thrice weekly (on nonconsecutive days) to daily. Imiquimod has its therapeutic effect via induction of interferon- $\alpha$  and other cytokines in the skin.<sup>101,102</sup> Studies have suggested that the off-label use of this agent with more frequent application schedules (once daily for 5 weeks to twice daily applications), may be useful in the treatment of common warts.<sup>103,104</sup>

Topical immunotherapy with squaric acid dibutylester (SADBE) is another option in the treatment of recalcitrant warts. Topical immunotherapy was initially described with dinitrochlorobenzene (DNCB) and subsequently with diphenylcyclopropenone (DCP). These agents are less desirable because of mutagenicity associated with the former and local side effects associated with the latter.<sup>105</sup> With SADBE immunotherapy, sensitization of (unaffected) skin is followed by the application of the solution to nonfacial warts. The therapy is painless and often effective, with complete clearance rates ranging from 58% to 84% in open-label studies.<sup>105–107</sup> Although in-office application has been traditionally utilized for topical immunotherapy, experience with at-home application of SADBE has demonstrated safety and high patient acceptance.<sup>105</sup>

Side effects of this treatment include allergic contact dermatitis (at either sensitization or treatment sites) and rarely urticaria. The hypothesized mechanism of action of this form of immunotherapy is generation of a delayed-type hypersensitivity reaction at the site of the wart and possibly a systemic antiviral effect, because even untreated lesions at distal sites may occasionally resolve.<sup>105</sup>

Pulsed-dye laser therapy is another option for the treatment of recalcitrant warts. This laser, which is most often utilized in the treatment of vascular birthmarks, works by selectively destroying the blood vessels found within warts.<sup>108</sup> This therapy has a large advantage over carbon-dioxide laser therapy in that it is nonscarring and the period of postoperative recovery is significantly shorter. Pulsed-dye laser therapy has been demonstrated to be quite effective in the treatment of warts including common, plantar, and periungual types.<sup>73,108,109</sup> Its use, however, is best limited to lesions that are recalcitrant and have failed other therapeutic modalities.

Flat warts may be treated with a variety of modalities, although their small size, common location on the face, and occurrence in groups make aggressive therapies impractical. Treatment options for these lesions include light cryotherapy, imiquimod, topical retinoids (i.e., tretinoin or adapalene cream), oral cimetidine, topical chemotherapy (i.e., 5-fluorouracil cream) or topical immunotherapy.

Therapies for condylomata acuminata have been poorly studied in children. As mentioned, a significant portion of anogenital warts in the pediatric population may spontaneously involute over several years, and thus watchful waiting is an appropriate consideration. When therapy is desired, a commonly used regimen is that of either podophyllin or trichloroacetic acid (or the two in combination), which are applied in the office. These agents cause cytotoxic effects with resultant necrosis of the affected cells, and their use may be limited by local irritation. Podofilox solution or gel (Condylx) is a closely related compound marketed for application in the home setting. Podofilox, which is approved for use in adult patients, is applied twice daily for three consecutive days, although more limited regimens (i.e., once daily) are often recommended for children to try and avoid local irritation. Self-treatment with podofilox has shown greater efficacy and cost-effectiveness than office therapy with podophyllin.<sup>110</sup> Imiquimod, applied three times weekly on nonconsecutive days, is another option that has been demonstrated effective in the treatment of external genital and perianal warts.<sup>111</sup> This treatment is also occasionally limited by local irritation. Other treatments used occasionally for condylomata acuminata include cryotherapy, laser therapy,<sup>112,113</sup> oral cimetidine, topical immunotherapy,<sup>114</sup> 5-fluorouracil cream, and surgical ablation. The pain of cryotherapy often precludes its use for warts in this location for children.

Prevention of anogenital HPV infection is the goal of HPV vaccination. Two vaccines are available in the United States, including a quadrivalent (types 6, 11, 16, and 18; Gardasil, Merck & Co) vaccine initially approved for use in females 9 to 26 years of age and a bivalent (types 16 and 18; Cervarix, GlaxoSmithKline) vaccine initially approved for use in females 10 to 25 years of age.<sup>115</sup> These vaccines have subsequently been demonstrated useful in preventing related

cervical precancerous lesions in females, anal precancerous lesions in males, and genital warts in both males and females.<sup>116</sup> The current recommendation of the AAP and the Advisory Committee on Immunization Practices is for routine immunization (with either vaccine) of females 11 or 12 years of age and those 13 to 26 years of age not previously immunized. The quadrivalent vaccine is also recommended for routine immunization of males 11 or 12 years of age and those 13 to 21 years of age not previously immunized.<sup>117</sup> Vaccination is also recommended for men who have sex with men and those who are immunocompromised through 26 years of age.<sup>115</sup> It is important to emphasize that these vaccines do not provide benefit for established HPV infections, and they are most effective when administered before the first sexual contact.<sup>118</sup>

## EPIDERMODYSPLASIA VERRUCIFORMIS

EV is a rare autosomal recessive disorder characterized by a genetically determined susceptibility to widespread and persistent infection of the skin with specific HPV types.<sup>119</sup> Infections begin in early childhood, and malignant transformation (nonmelanoma skin cancer) occurs in approximately half of patients during adulthood. The predisposition to HPV infection is believed to be the result of an immunogenetic defect associated with generation of cytokines, which downregulate cell-mediated immunity, and possibly with low levels of IL-10.<sup>120</sup> The role of environmental factors (most notably UV irradiation) also appears to be important in the pathogenesis of the HPV-associated malignancies.<sup>121</sup> EV has been found to be caused by inactivating mutations in two adjacent, related genes, EVER1/TMC6 and EVER2/TMC8. These genes encode transmembrane proteins located in the endoplasmic reticulum.<sup>122,123</sup> EV may represent a primary deficiency of intrinsic immunity to the EV-specific HPVs ( $\beta$ -papillomaviruses), in innate immunity, or in both.<sup>123</sup> There is also an acquired form of EV, which has been rarely reported, usually in the setting of HIV infection or other forms of immunosuppression.<sup>124–126</sup>

Patients with EV seek treatment during childhood with widespread tinea versicolor-like, hypopigmented macules and/or flat verruca plana-like papules. These papules are red to red-brown and may coalesce into larger plaques. The most common locations for the warty lesions are the hands, extremities, and the face, whereas the tinea versicolor-like lesions occur predominantly on the trunk.<sup>121</sup> When skin malignancy (usually squamous cell carcinoma) develops during adulthood, it is most often at sun-exposed sites, and these tumors are most often associated with HPV types 5 and 8. There is no specific therapy for EV. Protection from UV radiation with protective clothing and sunscreens and sun avoidance are vital. Close clinical surveillance for squamous cell carcinoma is recommended, with early surgical excision as needed. Experimental therapies have included interferon, imiquimod, cimetidine, photodynamic therapy, and systemic retinoids.<sup>121,127</sup>

## RECURRENT RESPIRATORY PAPILLOMATOSIS

Recurrent respiratory papillomatosis (RRP; laryngeal papillomatosis) is a disorder of HPV-associated benign tumors of the larynx and at times other portions of the aerodigestive tract. RRP is the most common benign neoplasm of the larynx in children and is usually caused by HPV types 6 and 11, which are both common genital-tract HPV types.<sup>128</sup> Although the exact method of HPV acquisition in patients with RRP is not well established, it is most likely caused by maternal-fetal transmission (ascending *in utero* infection or direct contact in the birth canal), and less likely via postnatal acquisition.<sup>129,130</sup> However, even given the potential links among cervical HPV, vaginal delivery, and RRP, the utility of elective cesarean sections in mothers with genital-tract HPV infection as a preventive measure remains controversial.<sup>130–132</sup> A maternal history of condylomas during pregnancy appears to be a risk factor for more severe RRP.<sup>133</sup> Fortunately, very few children overall who are exposed to genital HPV at birth develop symptoms of RRP.

Although the tumors of RRP are benign, significant morbidity may result from obstruction of the airway and potential malignant degeneration. RRP is usually diagnosed before the age of 5 years, and the clinical presentation often includes the triad of stridor, progressive

hoarseness, and respiratory distress.<sup>128</sup> Other symptoms may include dyspnea, chronic cough, recurrent upper respiratory infections, pneumonia, dysphagia and failure to thrive.<sup>134</sup> Patients may be initially diagnosed with asthma, croup, or bronchitis. In some, the condition may go undiagnosed until frank respiratory distress develops with the resultant need for emergent tracheotomy. The condition is diagnosed with direct airway endoscopy, and the mainstay of therapy for RRP is surgery or laser therapy. Adjuvant treatments include interferon, photodynamic therapy, and antiviral therapy. Intralesional cidofovir in combination with surgery has been advocated as an effective therapeutic combination, although efficacy has been questioned by some, and weight-based dosing limits are recommended.<sup>135–138</sup> It also appears that aggressive control of gastroesophageal reflux disease, when present, is vital, because it may contribute to the severity of RRP.<sup>128,139</sup>

## Molluscum Contagiosum

MC is a common cutaneous viral infection in children caused by a member of the poxvirus family (*Molluscum contagiosum* virus, or MCV). Although MC is often an STD or associated with immunodeficiency (especially HIV infection) in adults, childhood disease tends to lack these associations. There has been a dramatic increase in MC over recent decades in the United States, with an 11-fold increase in patient visits for the disorder reported for one 18-year period.<sup>140</sup> In children, the infection is also becoming more prevalent, because the spread of virus through skin-to-skin contact and fomites is rapid and easy. MC occurs most often in school-aged children and especially those under 8 years of age. Although controversy still exists, epidemiologic data suggest that MC may be transmitted via swimming pools as well as via fomites such as sponges and towels and in beauty parlors.<sup>141–144</sup>

Autoinoculation of the virus is a common mode of spread in affected patients. MC lesions tend to spread more rapidly in children with atopic dermatitis, possibly related to suppressed Th-cell responses. Congenital MC have been reported and likely represents vertical transmission of MCV.<sup>145</sup>

MC presents as pearly, flesh-colored to pink papules that often appear translucent (Figs. 15-35 through 15-37). The range in size is from 2 to 8 mm. A small central dell or depression may or may not be evident, and occasionally excrescences protrude from this central region (Fig. 15-38). Although single lesions may occur, MC most often presents with numerous clustered papules, and linear configurations (from koebnerization) may be present (Fig. 15-39). Although MC lesions may occur on any area of the skin surface, they are most common in areas of skin rubbing or moist regions, including the axillae, popliteal fossae, and groin. Genital and perianal lesions are also common, even in children, in whom the disorder is nearly always transmitted in a benign (nonsexual) fashion. Lesions may develop significant erythema (Fig. 15-40), which usually represents a host immune response against MCV and often heralds spontaneous involution. Occasionally, childhood MC may be marked by very high numbers

**Figure 15-35** Molluscum contagiosum. Solitary, dome-shaped pearly papule. Note the capped white plug.

**Figure 15-36** Molluscum contagiosum. Multiple pearly, translucent papules in the popliteal fossa. Note erythema and flattening of some lesions, representing the host immune response and early involution.

**Figure 15-37** Molluscum contagiosum. Pearly, umbilicated papules around the knee.

**Figure 15-38** Molluscum contagiosum. This solitary lesion with surrounding dermatitis demonstrates the central excrescence that may be present in some mollusca.

**Figure 15-39** Molluscum contagiosum with koebnerization. Linear configuration of lesions along a line of autoinoculation.

**Figure 15-41** Molluscum contagiosum in an immunocompromised host. This young boy receiving cancer chemotherapy had disseminated mollusca contagiosa, including multiple recalcitrant lesions in the groin.

**Figure 15-40** Molluscum contagiosum with host immune response. The bright red appearance of several of the lesions is typical once an immune response is being mounted by the host. The inflamed lesions usually resolve over 2 to 3 weeks.

**Figure 15-42** Giant molluscum contagiosum. These two nodular plaques of the scalp turned out to be giant molluscum lesions. This pattern of presentation may be confused with other causes of cutaneous pseudolymphoma (see Chapter 10).

of lesions (Fig. 15-41) or a giant size (Fig. 15-42). The latter may occasionally be confused with cutaneous pseudolymphoma (see Chapter 10), although MC is also considered to be one potential cause of pseudolymphomatous skin infiltration (and may be associated with CD30-positive lymphoid infiltrates).<sup>146</sup>

Surrounding dermatitis around MC lesions (“molluscum dermatitis”) is common (Fig. 15-43), is considered one form of an id reaction, and may be misdiagnosed as eczema.<sup>147</sup> Importantly the presence of molluscum dermatitis, if untreated, may propagate the cycle of infection when the patient scratches and subsequently autoinoculates the virus onto other regions. Complications of MC are rare but include secondary bacterial infection (Fig. 15-44), which is often secondary to scratching-induced impetiginization. In some patients with eyelid lesions, chronic conjunctivitis or superficial punctate keratitis may develop. Gianotti-Crosti syndrome-like reactions have been observed in some patients with MC and present with an eruption of monomorphic papules on the extensor extremities primarily and occasionally on the face, buttocks, or trunk. When this pattern presents, the papules are distinct from the underlying molluscum lesions (Fig. 15-45).<sup>148</sup>

Spontaneous clearing of MC often occurs over years, but parents and patients may request therapy for several reasons. These include the cosmetic significance of the lesions, pruritus, and epidemiologic concerns of other parents, teachers, or school nurses. In addition, in

patients with an underlying atopic diathesis, the lesions may be more extensive and autoinoculation more significant given the extensive pruritus. Traditional therapies (and those utilized in adults), such as curettage or cryotherapy, rely on destructive measures and may be traumatic for pediatric patients. Although curettage is not a preferred method of the authors, the pain of the procedure may be reduced by pretreatment of the lesional areas with topical anesthetic (lidocaine or lidocaine/prilocaine) cream. Care must be exercised, however, given reports of the latter (lidocaine/prilocaine, eutectic mixture of local anesthetics [EMLA]) cream in association with adverse events including methemoglobinemia, hypoxemia, and seizures.<sup>149,150</sup> In these reports, however, the topical anesthetic had been applied in excess of the recommended use. The maximum dose and application area recommendations suggested by the manufacturer of EMLA cream are listed in Table 15-5.

A highly effective and well-tolerated therapy for MC is the in-office application of cantharidin. Cantharidin is an extract from the blister beetle, *Cantharis vesicatoria*, and is known to induce vesication of the epidermis upon application to human skin.<sup>151</sup> Although concerns regarding the safety of cantharidin therapy have tempered its use for some, with appropriate application and patient education it is usually very well tolerated and effective.<sup>151–153</sup> Among pediatric dermatologists surveyed, 92% reported satisfaction with cantharidin’s efficacy in treating MC.<sup>154</sup> Although a prospective, blinded, placebo-controlled

**Figure 15-43** Molluscum contagiosum with molluscum dermatitis. Note the intensely erythematous, scaly plaque surrounding multiple mollusca in the antecubital fossa.

**Figure 15-44** Molluscum contagiosum with secondary bacterial infection. This patient with mollusca developed an associated dermatitis and eventual secondary infection with *Staphylococcus aureus*.

study of cantharidin did not demonstrate superiority of cantharidin over placebo during a 2-month observation period,<sup>155</sup> favorable results are often noted clinically, and this therapy continues to be a top choice for practitioners who treat these lesions.

A concentration of 0.7% or 0.9% cantharidin is usually used, and guidelines for the safe and effective use of this agent for treatment of MC are listed in Box 15-1. Treatment results in blister formation within 24 to 48 hours, with healing over several days to 1 week. The extent of blistering is minimized by having the patient (or parent) rinse treated areas after a specified time after application, usually 2 to 6 hours.<sup>153</sup> Treatment of perioral or periocular facial lesions, mucosal

**Figure 15-45** Molluscum contagiosum and Gianotti–Crosti syndrome-like reaction. This 2-year-old boy had numerous lesions of molluscum, several of which were becoming inflamed (**A**) in conjunction with monomorphic papules on the extensor surfaces of the upper (**B**) and lower (**C**) extremities, suggestive of Gianotti–Crosti syndrome.

sites, or occluded areas (i.e., diaper region) with this agent is not generally recommended. Cantharidin should be applied in the office only and by a physician or other qualified and well-trained health professional and should never be dispensed for home application.<sup>156</sup> If molluscum dermatitis is present, it should be cleared by use of a topical corticosteroid ointment before commencing with cantharidin therapy. Access to cantharidin is difficult in some regions of the United States given recent critical reevaluation of pharmacy-compounding practices by the US Food and Drug Administration. When available, however, cantharidin is considered by many practitioners to be a first-line treatment for this common condition.

**Table 15-5** Maximum Recommended EMLA Dose and Application Areas

Age and Body Weight*	Maximum Total Dose of EMLA (g)	Maximum Application Area (cm <sup>2</sup> )	Maximum Application Time (h)
0–3 months or <5 kg	1	10	1
3–12 months and >5 kg	2	20	4
1–6 years and >10 kg	10	100	4
7–12 years and >20 kg	20	200	4

EMLA, Eutectic mixture of local anesthetics, lidocaine/prilocaine.

\*If patient is older than 3 months of age and does not meet minimum weight requirement, the maximum total dose of EMLA should be based on the patient's weight.

### Box 15-1 Guidelines for Treatment of Molluscum Contagiosum with Cantharidin

Patient and parent education (handouts useful)

Avoid treating lesions in the following sites:<sup>\*</sup>

- Facial
- Mucosal
- Occluded

Treat 20 to 30 lesions maximum per treatment session

Application of cantharidin (0.7% or 0.9%):

- Vigorously shake bottle several times before opening to ensure even dispersal of cantharidin crystals within collodion base
- Use applicator stick or blunt (wooden) end of cotton-tipped applicator
- Apply single small droplet (sufficient to cover lesion) to each molluscum
- Avoid "painting"
- Let area dry for 3 to 5 minutes before patient gets dressed
- Do not occlude treated sites
- Treat initial lesion in a location that can be easily visualized by patient (to calm anxiety about the therapy)
- Have patient bathe/rinse off all treated sites in 2 to 6 hours (may vary based on past response; 4 hours good starting point with first treatment; may rinse sooner if significant discomfort or if vesiculation is noted)
- Acetaminophen or ibuprofen may be administered by parent, if needed, for pain
- Bacitracin ointment applied to blisters twice daily until areas heal
- Therapy repeated at 3- to 4-week intervals as needed

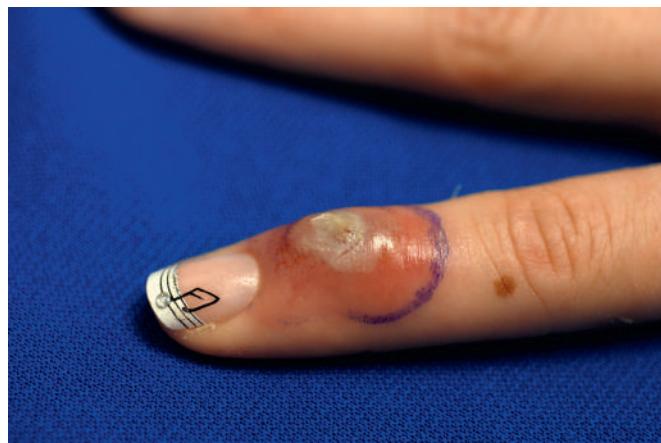

\*Treatment of facial (but not periorbital) lesions can be considered on a case-by-case basis once the patient's initial response to cantharidin application has been assessed.

Other methods of therapy that have been reported for MC include imiquimod cream, topical tretinoin cream, salicylic acid,  $\alpha$ -hydroxy acids, tape stripping, pulsed-dye laser therapy, 5% potassium hydroxide, topical cidofovir, oral cimetidine, and silver nitrate paste.<sup>103,141,151,157–166</sup>

Imiquimod cream has been used off-label with different treatment regimens, from three times weekly to application on a daily basis, with variable results. Two unpublished randomized controlled trials failed to show superiority of imiquimod over vehicle, although some smaller trials and observational studies have suggested potential efficacy.<sup>167</sup> Topical tretinoin cream is a commonly used method (also off-label) for treating facial MC, although its use may be limited by its irritation potential.

## Cowpox and Pseudocowpox

Cowpox is a rare zoonotic infection caused by a DNA orthopoxvirus that is similar to the vaccinia and smallpox viruses. It is transmitted by contact with infected animals, which may include cattle (from whom it may be transmitted as an occupational infection) and wild

**Figure 15-46** Orf. An inflammatory nodule with superficial vesiculation and oozing on the distal index finger of a 16-year-old female. She had been bitten by a goat 3 weeks before while visiting a petting zoo.

rodents, which serve as its natural reservoir.<sup>168</sup> After an incubation period of 1 to 3 weeks, a localized crusted nodule with ulceration or vesiculation forms and evolves through several stages to ultimately heal with a scar over several weeks. Flu-like symptoms may occasionally be present, and lymphadenopathy is common. Immunocompromised hosts may develop severe generalized infection. Although there is no accepted standard for therapy, cidofovir and some novel antiviral agents have been studied for patients with severe involvement, and measures to prevent secondary bacterial infection (i.e., wound care, topical and oral antibiotics) are recommended.<sup>168</sup>

Pseudocowpox (milker's nodule, paravaccinia) is a parapox virus infection seen worldwide and usually occurring in dairy farmers and new milkers. The infection is acquired from contact with the teats of cattle infected with the virus, and children may occasionally acquire it. Clinically, pseudocowpox is characterized by a single or several papules on the hands or fingers that progress through several stages: a macular or papular lesion becomes a vesicular lesion; then subsequently it progresses to a nodular stage with weeping; then it moves to a papillomatous or verrucous (warty) stage; and finally a dry crust develops, and healing occurs over 4 to 8 weeks. Typically, no scarring results. Secondary bacterial infection may occur in some patients. Occasionally, an erythema multiforme-like secondary eruption may occur.<sup>169</sup> Treatment is similar to that discussed for cowpox.

The diagnosis of cowpox or pseudocowpox is usually made by the combination of the history of exposure and clinical examination. The differential diagnosis may include herpetic whitlow or other poxvirus infections (i.e., orf). If confirmation of the diagnosis is necessary, virus isolation and serologic studies may be useful. In addition, light or electron microscopic examination of skin biopsy tissue is useful, the latter showing characteristic brick-shaped viral particles.<sup>168,170</sup>

## Orf

Orf (ecthyma contagiosum, contagious ecthyma) is another parapox virus infection that normally infects sheep and goats (scabby mouth, sore mouth, contagious pustular dermatosis) and occasionally humans. Transmission is via contact with infected lesions in animals or fomites, including barn doors, fences, troughs, and shears.<sup>170</sup> More recently, human orf has been associated with household meat processing and animal slaughter, often in the setting of ethnic religious celebrations.<sup>171</sup> Clinically, orf usually presents with a solitary lesion (Fig. 15-46), although several lesions may be present. The onset usually follows a 3- to 7-day incubation period after exposure. The clinical stages of the skin lesions are identical to those described previously for cowpox and pseudocowpox. Associations include secondary bacterial infection, lymphadenopathy, lymphangitis, erythema multiforme-like eruptions, and recurrences in immunocompromised hosts.<sup>172,173</sup> Giant lesions of orf are occasionally reported.<sup>174</sup>

**Figure 15-47** Smallpox. Multiple, tense pustules of the face in a patient from Ghana with smallpox. (Courtesy of the CDC, Dr J Noble Jr.)

Diagnostic modalities are the same as those for discussed above, and in addition, a PCR method for diagnosis has been described<sup>175</sup> (see **Cowpox and Pseudocowpox** section) and is available through the Centers for Disease Control and Prevention (CDC) or state health departments. Treatment is supportive, and the lesions involute spontaneously over 4 to 8 weeks without scarring. Antibiotics should be given if secondary bacterial infection is present.

## Smallpox

Smallpox (variola major) is an exanthematous disease but is included here with other poxvirus infections. The last case of endemic smallpox occurred in Somalia in 1977, and the disease was declared eradicated in 1980.<sup>176</sup> Variola virus, the etiologic agent of smallpox, has been maintained since that time in two high-security laboratories, the CDC in Atlanta and the Vektor Institute in Novosibirsk, Russia. However, concerns that some virus may exist outside of these laboratories and that it could potentially be used for a widespread bioterrorism attack remain. Routine vaccination for smallpox ended after the eradication declaration in 1980, and as such, a large population of susceptible persons now exists. The remaining protection of individuals who have received vaccination is unclear.

Smallpox begins with entry of the virus from respiratory droplets via the respiratory tract. It then travels to regional lymph nodes, where replication occurs. Viremia develops, and after an incubation period of 7 to 17 days, symptoms develop. These include high fever, malaise, severe headache, and backache. The temperature may be as high as 40°C. An enanthem precedes the exanthem and presents as erythematous macules on the oral mucosae, including the palate, tongue, and pharynx. The characteristic exanthem begins 1 to 2 days later with erythematous macules that progress to papules, then vesicles, and eventually pustules (Fig. 15-47) over 4 to 7 days. All lesions tend to be in the same stage of development, which is a useful feature in distinguishing smallpox from varicella (see Chapter 16) (Table 15-6). Skin lesions begin on the face and extremities with subsequent spread to the rest of the body and eventual widespread involvement. Crusting then begins around day 8 or 9 and is followed by healing with scarring. Complications of smallpox include secondary bacterial infection (usually associated with a second fever spike during the exanthem phase), pneumonia, arthritis, encephalitis, and death. Mortality in the past was as high as 30%, although it would probably be lower in developed countries with the availability of modern-day medical

**Table 15-6** Distinguishing Features of Smallpox and Varicella

	Smallpox	Varicella
Prodrome	High fever, headache, backache, malaise	Mild fever, constitutional symptoms
Skin examination	Centrifugal distribution; pustules all in same stage of development; deep involvement	Central distribution; vesicles and crusted papules in different stages at one time; superficial
Scarring	Common; often severe	Occasional; usually mild (unless secondary bacterial infection)
Complications	Bacterial infection, pneumonia, arthritis, encephalitis, blindness, death	Bacterial infection; rarely pneumonia, encephalitis, arthritis

intervention. In survivors, blindness may occur because of viral keratitis or bacterial eye infection.

Variants of smallpox include hemorrhagic and malignant forms. In the hemorrhagic form, which is uniformly fatal, patients have high fever, abdominal pain, and then petechiae and hemorrhage of skin and mucous membranes.<sup>177</sup> The malignant form is similar but without progression of the rash from vesicles to pustules. Variola minor (alastrim) is a less severe variant of smallpox with fewer lesions and a milder course occurring in individuals with partial immunity.<sup>177</sup> These patients have a longer incubation period, milder prodrome, and lower mortality rate.<sup>178</sup>

Rapid diagnosis of smallpox is vital, because a single confirmed case could result in an international epidemic. State health officials should be contacted, and the tissue should be submitted to a Biological Safety Level 4 laboratory for processing.<sup>176</sup> The CDC should also be notified. Airborne and contact precautions should be strictly followed. Vesicular or pustular fluid, crusts (scabs), blood samples, and throat swabs should be collected as directed by regional or national health authorities. Methods for confirming the diagnosis of smallpox include cell culture, PCR, electron microscopy, serologies, and immunohistochemical stains. Collection of epidemiologic data is vital, and contacts must be identified so that a vaccine can be administered. The administration of a vaccine within 4 days of exposure may diminish the severity of the illness.

Therapy for smallpox consists first and foremost of isolation of the patient, who will remain infectious until approximately 10 days from the onset of the rash. Vaccination should be given, and meticulous skin and eye care, as well as hydration and nutrition support, is vital. No specific antiviral therapy exists for smallpox, although cidofovir has shown some benefit in the postexposure prevention of other poxvirus infections.<sup>179,180</sup>

The issue of smallpox vaccination has received much attention with the resurgence of interest in this disease. A vaccinia virus (*Orthopoxvirus vaccinia*) vaccine has been used to prevent infection with the smallpox virus. Concern about the variola virus potentially being used as a biological weapon has resulted in the United States and some other countries deciding to stockpile live vaccinia virus vaccine (ACAM2000) and to vaccinate military personnel. There is also an attenuated vaccine (IMVAMUNE) that has been investigated for individuals who cannot safely receive ACAM2000.<sup>181</sup> In light of world events in the twenty-first century, several groups of individuals have received smallpox vaccination, including physicians from the CDC and eligible first responders and healthcare workers. New production of a smallpox vaccine has again been initiated, this time in tissue-cell culture. The current recommended vaccination strategy is known as *ring vaccination* and also is referred to as surveillance and containment. In this strategy, if a single case of smallpox occurs, infected patients would be immediately isolated, and contacts would be identified and immunized by specially trained (and vaccinated) healthcare teams.

**Figure 15-48** Eczema vaccinatum. Extensive umbilicated papulopustules involving the chest and nipples of a 2-year-old hospitalized male. He had a history of atopic dermatitis and was exposed to vaccinia virus via household contact with a relative who had recently received the smallpox vaccination. (Courtesy of Sarah Stein, MD.)

Complications of smallpox vaccination include local vaccination-site reactions and more widespread reactions such as fever, generalized vaccinia, urticaria, erythema multiforme, encephalitis, and rarely death. Local reactions are common and include pustules at the vaccination site, bacterial superinfection, and lymphadenitis. In addition, pustular reactions at sites distant from the vaccination site occasionally occur from autoinoculation.

Eczema vaccinatum is a serious, potentially life-threatening side effect of smallpox vaccination occurring in individuals with atopic dermatitis or less commonly other skin disorders. It is caused by widespread dissemination of vaccinia and can occur in patients with either active or quiescent dermatitis.<sup>182</sup> The barrier disruption in these patients permits viral implantation with subsequent spreading from cell to cell and occasionally a viremic phase.<sup>183</sup> The lesions are similar in appearance to those associated with primary vaccination, but with extensive involvement they may become confluent (Fig. 15-48). Bacterial superinfection, shock, and death may occur, especially without the prompt administration of vaccinia immunoglobulin (VIG). Scarring is common. Because of the risks of eczema vaccinatum, individuals with atopic dermatitis should not receive elective vaccination if there is no risk of exposure to smallpox, and individuals who have regular contact with persons with atopic dermatitis should not receive vaccination unless they can avoid person-to-person contact until the scab separates from the vaccination site.<sup>183</sup> In addition to administration of VIG, patients with eczema vaccinatum may require treatment with cidofovir, ST-246, or other potent antivirals. Importantly, patients with eczema vaccinatum may shed large amounts of virus, and viable vaccinia virus may be present on inanimate objects in their environment, potentially causing inadvertent infection in other susceptible individuals exposed to those items.<sup>184</sup>

Childhood smallpox vaccination is a topic that has received considerable attention as part of the “pre-event” vaccination program. Of concern is the fact that children under the age of 5 years have historically had the highest rates of complications, especially for the most severe reactions.<sup>176</sup> In response to this and other data, the Advisory Committee on Immunization Practices does not recommend routine smallpox vaccination for children and adolescents younger than 18 years of age, and the Committee on Infectious Diseases of the AAP has strongly endorsed further vaccine development and testing in children as well as adults.<sup>178,185</sup>

## Acquired Immunodeficiency Syndrome in Children

Infection with HIV type 1 occurs worldwide in adults and children, with the majority of new pediatric cases occurring in children living

in sub-Saharan Africa (up to 2000 new cases per day). The number of children with AIDS is decreasing in the United States, owing to better prevention of perinatal transmission and the availability of effective therapies.<sup>186</sup> HIV-1 is an RNA retrovirus that infects CD4+ T lymphocytes as well as other cells of the immune system. With the subsequent depletion of CD4+ T cells, progressive immunocompromise occurs, leaving the patient at risk for a wide variety of infections, inflammatory conditions, and malignancies. AIDS is diagnosed when an infected patient has an opportunistic or other unusual or persistent infection as well as a CD4+ T cell count lower than 200 cells/ $\mu$ mL.

More than 90% of infant and childhood HIV-1 infections in the United States are the result of perinatal (mother-to-child) transmission. The remaining children acquire the infection from blood-product exposure, sexual abuse, or unknown sources. It is estimated that in the absence of antiretroviral therapy, approximately 30% of women infected with HIV-1 transmit the virus to their infants.<sup>187</sup> This can occur *in utero*, during delivery, or via breastfeeding after delivery. Maternal plasma viral load is one of the strongest predictors of perinatal transmission.<sup>188</sup> Infection with HSV type 2 or other STDs resulting in cervical or vaginal ulcers also increases the risk of transmission.<sup>189</sup> When infants acquire the infection via breastfeeding, it tends to occur within the first several months of life.<sup>190</sup> Formula feeding, therefore, is a desirable choice in this setting. The availability of treatments and the global commitment to prevent mother-to-child transmission have positively impacted the epidemiology of childhood HIV infection. In the United States, the number of infected infants per year has decreased from approximately 1800 to fewer than 100.<sup>191</sup> Combination antiretroviral drugs administered during pregnancy and labor have drastically reduced transmission rates to under 2%.<sup>192</sup>

Adolescents, on the other hand, are a population with an increasing rate of HIV-1 infection. Some of these patients acquired the infection perinatally and because of improved medical care are living longer than in the past. The number of vertically infected adolescents will increase dramatically in numbers over the years to come.<sup>193</sup> In others, high-risk behaviors such as intravenous drug abuse and unprotected sexual intercourse place them at increased risk. Those at highest risk are homeless youth and those living in poverty, as well as young minority men who have sex with men. Victims of sexual abuse are another population of adolescent youth at high risk for HIV-1 infection. A high index of suspicion of HIV-1 infection should be maintained when an at-risk adolescent presents with a mononucleosis-like illness or persistent adenopathy.<sup>186</sup>

HIV-1 infection may present differently depending upon the child's age. Although a detailed discussion of the clinical features is beyond the scope of this section, a brief review is included. Importantly, cutaneous and/or mucosal findings are often significant in the patient with HIV-1 infection or AIDS. These are listed in Table 15-7.

Acute HIV-1 infection may present with several nonspecific features, known as *acute HIV infection syndrome*. Symptoms may include fever, myalgias, fatigue, pharyngitis, weight loss, and headache, and because of the nonspecific nature of many of these, the infection often goes unrecognized.<sup>194</sup> Dermatologic features that may be seen during acute HIV infection syndrome include a mononucleosis-like, erythematous eruption, desquamation of palms and soles, urticaria, and alopecia. In addition, gastrointestinal symptoms are common during this acute illness and include abdominal pain, vomiting, and diarrhea.

In infants with HIV-1 infection, the most common features include *Pneumocystis carinii* pneumonia (PCP), lymphoid interstitial pneumonitis (LIP), failure to thrive, recurrent infections (especially bacterial and candidal), and encephalopathy.<sup>186</sup> LIP occurs in the setting of EBV infection with chronic lymphoid pulmonary infiltrates and a “honeycomb” pattern on chest radiography. It may represent a unique immune response to coinfection with EBV and HIV,<sup>195,196</sup> and it usually responds to therapy with oxygen and steroids. Patients with LIP have a better prognosis than those with PCP, the latter of which is the most common AIDS-defining illness in children. The acute HIV infection syndrome may be absent in infants with HIV-1 infection.<sup>193</sup> Infants infected with HIV-1 are prone to gastrointestinal infections, enteropathy, and malabsorption. They may also have hepatosplenomegaly and lymphadenopathy. Primary infection with CMV may result in hepatitis, bone marrow failure, pneumonitis, or encephalitis. Perinatal HIV

**Table 15-7** Mucocutaneous Manifestations of HIV-1/AIDS

Class	Type	Comment
Infections	Bacterial	Syphilis <i>Staphylococcus aureus</i> : impetigo, folliculitis, ecthyma, abscess <i>Pseudomonas aeruginosa</i> : folliculitis, ecthyma gangrenosum, abscess <i>Bartonella</i> : bacillary angiomatosis
	Mycobacterial	MAC: nodules, ulcers, pustules, folliculitis TB: scrofuloderma, papules, vesicles, ulcers, nodules, pustules, abscess Atypical mycobacteria: various skin findings
	Viral	HSV: typical or atypical (deep ulcers, thick crusts) VZV: primary varicella, herpes zoster CMV: perianal ulceration, vesicles, purpura, nodules EBV: oral hairy leukoplakia HPV: common warts, condylomata acuminata Molluscum contagiosum: often genitals/face or widespread; recalcitrant <i>Candida albicans</i> : cutaneous, oral, esophageal, vulvovaginal
	Fungal	<i>Pityrosporum ovale</i> : tinea versicolor Dermatophytes: tinea infections, onychomycosis Deep fungal infections: histoplasmosis, cryptococcosis, sporotrichosis, coccidioidomycosis <i>Penicillium marneffei</i> : various skin findings <i>Pneumocystis carinii</i> : occasional skin lesions
	Protozoal	
Infestations	Scabies	Classic findings or severe, crusted (Norwegian) form
	Amoeba	<i>Acanthamoeba</i> , <i>Naegleria</i> species: papules, nodules, ulcers
	Demodicidiosis	<i>Demodex folliculorum</i> : folliculitis (often facial)
Inflammatory	Psoriasis	May be severe, widespread
	Reactive arthritis	NG urethritis, arthritis and skin changes: keratoderma blennorrhagicum, balanitis, oral ulceration
	Seborrheic dermatitis	More severe, more widespread
	Eosinophilic folliculitis	Sterile, pruritic follicular papules and pustules
	Drug eruption	May be severe; most often secondary to trimethoprim/sulfamethoxazole, penicillins, antituberculous medications; include morbilliform eruption, erythema multiforme, SJS; may also develop in response to HAART
	Aphthous ulcers	
Idiopathic	Pruritus	Absence of primary cutaneous findings; may be severe
	Papular eruption	Pruritic, nonfollicular papules
	Ichthyosis	An acquired form of the disorder
	Xerosis	Severe skin dryness
Malignant	Kaposi sarcoma	Skin and mucosal nodules, plaques; may metastasize; mainly homosexual/bisexual men; association with HHV-8
	Cutaneous lymphoma	Usually T-cell, less commonly B-cell, non-Hodgkin lymphoma
	Other skin cancers	Basal cell, squamous cell carcinoma; malignant melanoma

Data from references 194–202 and 204–206.

AIDS, Acquired immunodeficiency syndrome; CMV, cytomegalovirus; EBV, Epstein–Barr virus; HAART, highly-active antiretroviral therapy; HIV-1, human immunodeficiency virus type 1; HHV, human herpesvirus; HPV, human papillomavirus; HSV, herpes simplex virus; MAC, *Mycobacterium avium* complex; NG, nongonococcal; SJS, Stevens–Johnson syndrome; TB, *Mycobacterium tuberculosis*; VZV, varicella zoster virus.

infection may also result in endocrine dysfunction with growth failure and pubertal delay.<sup>197</sup>

In children (i.e., those between 2 and 6 years of age), the most common features of HIV-1 infection are recurrent episodes of otitis media and sinusitis, recurrent bacterial infections, LIP, and encephalopathy. Other serious infections, including meningitis and osteomyelitis, may occur. Invasive disease caused by *Streptococcus pneumoniae* may occur, although this may become less common with the advent of routine pneumococcal immunization. Again, hepatomegaly and lymphadenopathy are common, and problems with weight gain and linear growth may be seen.

In older children and adolescents with HIV-1 infection, the most common signs and symptoms include *Candida* infections (i.e., oral thrush, vulvovaginitis, esophagitis), HZ, recurrent herpes simplex infection, parotitis, cryptosporidiosis, and infections with CMV and atypical mycobacteria. Nonspecific signs after acute HIV infection are common and may simulate those of EBV infection. Poor growth, pubertal delay, and HIV-associated wasting may all occur.

There are multiple other associations with HIV-1 infection. Metabolic disturbances may result in hyperlipidemia, body-fat redistribution (with resultant lipodystrophy or lipoatrophy), insulin resistance, and hyperglycemia. Lipodystrophy appears to be propagated by the use of combination antiretroviral therapy (cART) (see below), which contributes to altered lipid metabolism.<sup>198</sup> Ocular manifestations include retinopathy, keratoconjunctivitis, keratitis, iridocyclitis, and retinal

microvasculopathy. Infectious retinitis may be caused by CMV, VZV, *Toxoplasma*, or other agents. Cardiac manifestations of HIV-1 infection include effusion, myocarditis, endocarditis, dilated cardiomyopathy, and pulmonary hypertension. In addition to HIV-associated encephalitis, or AIDS encephalopathy, other neurologic complications include aseptic meningitis, peripheral neuropathy, Guillain–Barré-like syndrome, and myelopathy. Patients may also have genitourinary, rheumatologic, gastrointestinal, and hematologic manifestations and have an increased risk of malignancy, especially non-Hodgkin lymphoma. Tuberculosis occurs with increased incidence in patients infected with HIV-1 and has important epidemiologic significance both within the community and for the world at large. In fact, the incidence of tuberculosis worldwide has been increasing, owing primarily to the incidence of HIV infection.<sup>198</sup> Psychological effects of HIV infection can be profound and may relate to the degree of illness, the threat of death, the association with substance abuse, and the social stigma associated with the disease.<sup>199</sup>

The diagnosis of HIV infection is based on clinical, immunologic, and serologic findings, and the exclusion of other causes of immunodeficiency. Antibody-based tests include enzyme-linked immunosorbent assays (ELISAs), second-generation ELISAs, and confirmatory Western blotting. Direct detection assays include p24 antigen capture ELISA and DNA/RNA assays via PCR, *in situ* hybridization, or other hybridization assays. In infants under 18 months of age, anti-HIV antibody may be transplacental and therefore is not diagnostic of HIV

infection (although a negative result suggests that the infant is uninfected). The diagnostic method of choice in infants, therefore, is HIV DNA PCR on peripheral blood lymphocytes.<sup>193</sup> Other laboratory tests that may be useful in the evaluation for HIV infection include complete blood cell counts with platelets, CD4+ lymphocyte counts, serum chemistries, and urinalysis. Plasma HIV RNA (viral load) studies are useful in monitoring response to therapy and are the best indicator of risk for disease progression in children.<sup>200</sup>

The mainstays of therapy for patients with HIV infection are a combination of medications encompassing one to three main categories. These categories include nucleoside analog reverse transcriptase inhibitors (NRTIs) and nucleotide analog reverse transcriptase inhibitors (NtRTIs) including zidovudine or ZDV (formerly azidothymidine [AZT]), didanosine (ddI), stavudine (d4T), lamivudine (3TC), abacavir (ABC), emtricitabine, and tenofovir; nonnucleoside analog reverse transcriptase inhibitors (NNRTIs) including nevirapine, efavirenz, delavirdine, and etravirine; and HIV protease inhibitors (PIs) including atazanavir, darunavir, fosamprenavir, nelfinavir, ritonavir, indinavir, saquinavir, tipranavir, and lopinavir.<sup>186,201</sup> Fusion inhibitors (enfuvirtide, maraviroc) interfere with the penetration of HIV into the target cells (maraviroc via binding to the chemokine receptor [CCR] type 5 receptor on CD4 Th cells), and integrase inhibitors (raltegravir) block the viral integrase and insertion of the DNA copy of the viral genome into the host-cell chromosome.<sup>201</sup> In addition, HIV vaccines intended to boost immunity toward the virus have been studied,<sup>202</sup> and adjunctive therapies such as intravenous immune globulin and cytokine therapy are occasionally utilized. The challenge of developing an HIV vaccine has been compounded by the poor host immune response to HIV infection.<sup>203</sup>

Special considerations in treating young children infected with HIV include differences in body size, composition, and drug metabolism, distribution, and elimination. (Updated treatment guidelines for pediatric HIV infection can be found at [www.aidsinfo.nih.gov/guidelines](http://www.aidsinfo.nih.gov/guidelines).) In infants the best outcome is seen when antiretroviral therapy is

immediately initiated after diagnosis. In older children or adolescents, the decision to start therapy is based on the viral load, CD4+ lymphocyte count, and clinical status. Survival in children infected with HIV has improved notably with the introduction of cART, with a decrease in disease progression and mortality.<sup>204</sup> However, children seem to be more likely than adults to develop metabolic side effects of therapy, including lipodystrophy, dyslipidemia, insulin resistance, mitochondrial toxicity with lactic acidemia, and decreased bone-mineral density. Interestingly, HIV-associated growth retardation, manifested by muscle wasting and decreased linear growth, appears to be minimized with the use of cART in children, although the long-term significance of these findings is unclear.<sup>205</sup>

# 16 Exanthematous Diseases of Childhood

Several viral and bacterial illnesses may be accompanied by localized or generalized skin eruptions called *exanths*. These eruptions may be the first manifestation of a disorder and often are the reason for parents and patients to pursue medical evaluation. Prompt recognition and diagnosis of exanths is desirable and may dictate that other examinations be performed to assess for systemic associations. Although identification of the exact infectious agent is not always practical or possible, knowledge of the most common causes of the various exanths is important from an epidemiologic perspective. For instance, when diagnosing a child with a parvovirus B19-related exanthematous disease, consideration of at-risk contacts (i.e., gravid females, individuals with hemolysis or conditions resulting in decreased red blood cell production) is vital.

The majority of childhood exanths are caused by viruses and less often by bacterial or rickettsial agents. Most childhood exanths are diagnosed and managed by primary care providers, and thus a thorough familiarity with both classic and atypical exanths is desirable for the pediatric primary care practitioner. When evaluating the patient with an exanthem, several features should be considered, including the morphology of individual lesions, the distribution pattern, prodromal and concurrent symptoms, known exposures, associated exanthem (eruption of the mucous membranes), local epidemiology, and the findings of a thorough review of systems and physical examination. Whereas some exanthematous processes present with a characteristic patterning of lesion morphology and distribution, others may reveal no pathognomonic features, and the cutaneous findings must be taken into consideration along with the overall presentation of the patient. Exanths may be divided into erythematous, vesicular, and papular forms and have also been invariably described as *morbilloform* ("measles-like"), *rubelliform* ("rubella-like"), *scarlatiniform* ("scarlet fever-like"), or urticarial.<sup>1</sup> Pustular and petechial changes may occasionally be noted.

The classic childhood exanths are listed in Table 16-1. These disorders were originally classified with a numeric designation in the early 1900s. Since then much has been learned about the etiologic agents of the classic exanths, and several newer exanthematous disorders have been described. This chapter includes a discussion of the classic exanths: varicella, infectious mononucleosis (IM), and exanths caused by enteroviruses, *Mycoplasma*, and rickettsial agents. In addition, nonspecific viral exanths are discussed, as are some atypical exanths including papular acrodermatitis of childhood, unilateral laterothoracic exanthem (ULE), and papular-purpuric gloves-and-socks syndrome (PPGSS). Kawasaki disease, which may have clinical overlap with multiple exanthematous disorders, is discussed in Chapter 21. Acute generalized exanthematous pustulosis (AGEP), another exanthematous disorder, is discussed in Chapter 20.

## Varicella (Chickenpox)

Varicella-zoster virus (VZV) is a member of the herpesvirus family, and the causative agent of both varicella (chickenpox) and herpes zoster (shingles, see Chapter 15). Varicella results from primary infection with VZV and is a highly communicable human disease. Once acquired, VZV becomes permanently established in the sensory ganglia in a latent form with intermittent reactivation in a dermatomal distribution, resulting in herpes zoster.<sup>2</sup> Although acute varicella is usually a self-limited infection, before extensive use of the varicella vaccine most children had upward of 250 to 500 skin lesions,

approximately 9000 to 11,000 children were hospitalized annually, and up to 100 individuals per year died of the disease or its complications.<sup>3,4</sup>

VZV is found worldwide, and annual epidemics occur most often during late winter and spring.<sup>5</sup> Varicella is highly contagious and is usually spread between the prodrome and the first 3 days of the skin eruption.<sup>6</sup> VZV is transmitted via respiratory droplets, then enters regional lymph nodes, and eventually a viremia ensues with more widespread dissemination. Primary infection elicits a humoral immune response with production of immunoglobulin (Ig)A, IgM, and IgG anti-VZV antibodies, the latter of which help protect against reinfection.<sup>5</sup> Patients are considered contagious until at least 5 days after onset of the rash or until all existing lesions are dry and crusted.

A live attenuated varicella vaccine (Oka strain) was introduced in 1995, and in 1996 the Advisory Committee on Immunization Practices (ACIP) recommended universal one-dose vaccination of all children at age 12 to 18 months, with catchup vaccination of all susceptible children before age 13 years.<sup>4</sup> The ACIP and the American Academy of Pediatrics (AAP) have expanded their recommendations to include use of the vaccine for postexposure prophylaxis and for some immunocompromised children.<sup>3</sup> The vaccine is also indicated in adults who are susceptible to varicella. The vaccine has been quite effective in decreasing the overall incidence of varicella, and in vaccinees who develop breakthrough disease, the disease tends to be milder with fewer lesions that may remain papular rather than becoming vesicular.<sup>3</sup> In a 6-year case-control study of the effectiveness of the varicella vaccine over time, the effectiveness in the year after vaccination (97%) was greater than in years 2 through 8 after vaccination (84%), although most cases of breakthrough disease in vaccinees were mild.<sup>7</sup> Another study of the effectiveness of a one- versus two-vaccination regimen revealed high vaccine efficacy over 10 years for both groups (94.4% and 98.3%, respectively), and again, breakthrough disease was mild.<sup>8</sup> A decline in varicella-related hospitalizations for invasive group A  $\beta$ -hemolytic streptococcus (GABHS) infections has been documented between the period of the prevaccine era and that of widespread vaccine use.<sup>9</sup> Although some studies have demonstrated lower effectiveness of the varicella vaccine than expected, overall the data appear to support its universal use. In 2006, because of insufficient population immunity to prevent community transmission, the ACIP and AAP changed the varicella vaccine policy, recommending a universal two-dose vaccination program.<sup>10</sup>

The varicella vaccine is available as a monovalent vaccine (Varivax, Merck & Co, Kenilworth, NJ) and as part of a quadrivalent measles-mumps-rubella-varicella vaccine (MMRV; ProQuad, Merck & Co). Postlicensure studies have suggested a slightly increased risk of febrile seizures among children aged 12 to 23 months who received MMRV for their initial dose (versus separate MMR and varicella vaccines). A personal or family history of seizures is considered a precaution for use of MMRV, and unless a parent expresses strong preference for this vaccine, it is recommended that the first dose be administered as separate measles-mumps-rubella (MMR) and varicella vaccines.<sup>11</sup> For the second dose at any age or the first dose at ages 48 months and older, the combination MMRV vaccine is recommended.<sup>12</sup>

Primary varicella begins with a prodrome of fever, chills, malaise, headache, arthralgia, and myalgia. After 24 to 48 hours, the earliest skin lesions become evident, initially as red macules or papules (Fig. 16-1) that progresses rapidly to a vesicular phase. The fully developed lesion has been likened to a "dewdrop on a rose petal" (Fig. 16-2). Varicella lesions present initially on the scalp, face, or trunk and then spread to the extremities. Older lesions crust over, and new lesions

**Table 16-1** Classic Childhood Exanthems

Numerical Designation	Name(s)	Agent(s)	Comment
1	Measles, rubella	Measles virus (paramyxovirus)	Declining incidence with vaccination; occasional epidemics of imported cases and cases in unimmunized individuals in United States
2	Scarlet fever, scarlatina	GABHS	Toxin-mediated
3	German measles, rubella	Rubella virus (togavirus)	Rare with vaccination
4	Filatow-Dukes disease	?SA	No longer considered a distinct entity
5	Erythema infectiosum, fifth disease, slapped cheek disease	Parvovirus B19	Patients not contagious once rash is present
6	Exanthem subitum, roseola infantum, sixth disease	HHV-6 and HHV-7	Diffuse rash appears after abrupt defervescence

GABHS, Group A  $\beta$ -hemolytic streptococcus; HHV, human herpesvirus; SA, *Staphylococcus aureus*.

**Figure 16-1** Varicella. Note the early lesions consisting of erythematous macules and papules and the well-developed vesicular lesion.

**Figure 16-3** Varicella. Various stages are present in this patient with human immunodeficiency virus (HIV) infection and varicella, including vesicles and crusted papules.

**Figure 16-2** Varicella. These well-developed lesions demonstrate why they have been likened to "dewdrops on a rose petal."

**Figure 16-4** Varicella scarring. Hypopigmented macules and scars are present in this patient with a history of varicella.

continue to develop, resulting in the pathognomonic finding of lesions in various stages being present at the same time (Fig. 16-3). New lesions continue to develop for 3 to 4 days, and by day 6, most lesions have crusted over. Patients with sunburn or dermatitis may develop a more severe exanthem. An associated enanthem may be present and consists of painful erosions in the oropharynx, conjunctivae, or vaginal mucosae. The lesions of varicella heal with hypopigmentation (Fig. 16-4) and scarring (Fig. 16-5), especially at sites of the initial lesions.

Varicella tends to be a mild, self-limited disease in most immunocompetent hosts. Complications, however, may occur. The most

common complication is secondary bacterial superinfection, usually the result of *Staphylococcus aureus* or GABHS.<sup>13</sup> Invasive GABHS infections, including streptococcal toxic shock syndrome and necrotizing fasciitis, may rarely occur. Secondary bacterial infection usually presents as isolated secondary fever or localized symptoms, such as bulla (large blister) formation or cellulitis. Varicella gangrenosa is diagnosed when an area reveals rapidly progressing erythema, induration, and pain.<sup>5</sup> Peripheral gangrene may occur in the distal extremities.<sup>14</sup> Other skin-related complications include deep ulcerative lesions (Fig. 16-6), subcutaneous abscesses, and regional lymphadenitis. Patients under the age of 5 years who live in a household with older children seem

**Figure 16-5** Varicella scarring. Large, deep scars are present in this patient who had secondary bacterial infection of her primary varicella lesions.

**Figure 16-6** Varicella, complicated. Deep, ulcerative lesions occurred in this young girl with underlying immunodeficiency and secondary infection of the skin with *Streptococcus pyogenes*.

to be at greatest risk for bacterial complications.<sup>13</sup> In patients who develop secondary bacterial infection, bacteremia may occur, as may pneumonia, arthritis, or osteomyelitis.

Second to bacterial superinfection, the most common complication in patients with primary varicella is neurologic involvement. This may present as encephalitis, meningoencephalitis, cerebellar ataxia, transverse myelitis, or Guillain–Barré syndrome. Reye syndrome was a fairly common complication of varicella before the association with salicylates was identified. Reye syndrome (acute encephalopathy and fatty degeneration of the viscera) presents with decreased level of consciousness, vomiting, and abnormalities in liver function. The incidence of this complication has fallen dramatically over recent years. Varicella pneumonia is the most common serious complication in adults but is rare in healthy children.<sup>2,5</sup> When it occurs during the course of childhood varicella, it is usually bacterial in origin. Severe pulmonary deterioration may occur, and it may occasionally be

fatal.<sup>15</sup> Thrombocytopenia, arthritis, uveitis, nephritis, myocarditis, pancreatitis, and hepatitis may also occasionally occur. When arthritis occurs in this setting, it may be bacterial (*Streptococcus pyogenes* or *S. aureus*) or aseptic ("varicella arthritis") in origin. The latter is typically confined to a single joint, most commonly the knee, ankle, shoulder, or foot.<sup>16</sup> Purpura fulminans is a rare and life-threatening complication of varicella, and disseminated intravascular coagulopathy may occasionally occur.<sup>17</sup>

Immunocompromised hosts with varicella, including those with leukemia, lymphoma, or human immunodeficiency virus (HIV) infection; those receiving corticosteroids; and those with a history of organ or bone marrow transplantation may have more serious disease and a higher incidence of complications. These individuals have an increased risk of disseminated varicella, lung disease, thrombocytopenia, and other organ involvement. Bacterial superinfection may also occur with increased incidence, and hemorrhagic complications of the disease are more common. Varicella during pregnancy poses an increased risk of serious disease to both the mother and the fetus (see Chapter 2). Pregnant females have a higher incidence of varicella pneumonia, and mortality from the disease is increased.

The diagnosis of primary varicella is usually based on the history and clinical findings. Laboratory confirmation, when desired, can be performed by either virologic or serologic methods. Virologic methods include direct and indirect immunofluorescence studies, which are performed on tissue (i.e., cells scraped from the base of a fresh vesicle or organ biopsy tissue in patients with disseminated disease). These studies have the advantages of being both rapid and sensitive.<sup>18,19</sup> Tzanck smears on skin scrapings identify multinucleated giant cells and confirm the diagnosis of herpesvirus infection but are not specific for VZV. Cell culture is unequivocally confirmatory but not ideal for VZV given the prolonged time necessary for cytopathic effects to appear. Other virologic methods include hybridization and polymerase chain reaction (PCR) assays. Serologic studies for diagnosing VZV infection include acute and convalescent IgM and IgG antibody titers.

The treatment of varicella in otherwise-healthy children is usually symptomatic, with the goals being control of pain and pruritus and prevention of secondary superinfection. Supportive therapies include oral antihistamines for pruritus, acetaminophen for fever or pain, and topical care. Useful topical regimens may include cool compresses, oatmeal baths, and application of topical products such as bacitracin ointment, calamine lotion, pramoxine-containing preparations, or menthol-camphor (Sarna) lotion. Antibiotics should be given if secondary bacterial infection is present.

The decision regarding the use of antiviral therapy for primary varicella depends on several factors, including host immune status, the extent of the infection, and timing of the diagnosis. In general, routine use of antiviral agents for varicella in otherwise-healthy children is not recommended. Acyclovir, famciclovir, and valacyclovir are antiviral agents licensed for treatment of VZV infections, although famciclovir is not approved for primary varicella. Oral acyclovir has been suggested in some studies to decrease the severity of primary VZV infection, including a decrease in the days of fever, number of days of new lesion formation, total number of lesions, and pruritus. In a review of published studies on acyclovir treatment of varicella in otherwise-healthy children and adolescents, a reduction in the number of days with fever was noted, but the results were inconsistent with respect to the number of days to no new lesions, maximum number of lesions, and number of days to relief of itching.<sup>19</sup> In addition, no differences in the incidence of varicella complications between acyclovir and placebo groups were consistently noted.<sup>20</sup> Oral antiviral therapy should be considered, however, for healthy individuals who are at risk for moderate or severe disease, such as those over 12 years of age (especially unvaccinated), those with chronic skin or lung disorders, and those receiving therapy with salicylates (long-term courses) or corticosteroids (short, intermittent, or aerosolized courses).<sup>21</sup> When used in the treatment of varicella in otherwise-healthy patients, antiviral therapy should be started within 24 hours of the appearance of the rash. The use of oral antivirals for pregnant females with uncomplicated varicella remains controversial, although some experts recommend its use for those who develop it during the second or third trimesters. Intravenous acyclovir is recommended for pregnant females with serious complications of varicella.<sup>21</sup>

### Box 16-1 Indications for Varicella-Zoster Immune Globulin (VarizIG)

- Types of exposure to varicella-zoster:
- Residing in same household as infected patient
  - Playmate: face-to-face indoor play
  - Hospital: varicella in roommate; face-to-face contact with infected staff member or patient; visit by a person deemed contagious with varicella; intimate contact with person deemed contagious with zoster
  - Newborn: onset of varicella (not herpes zoster) in mother from 5 days or less before delivery or within 48 hours after delivery
- Candidates for VarizIG:
- Immunocompromised child without history of varicella or varicella immunization
  - Susceptible pregnant female (no evidence of immunity)
  - Newborn infant whose mother develops varicella (see above)
  - Hospitalized premature infant:
    - ≥28 weeks' gestation, if mother lacks reliable history of varicella or serologic evidence of antibodies
    - <28 weeks' gestation or birthweight 1000 g or less, regardless of maternal history of varicella or serologic status

Modified from American Academy of Pediatrics, et al. Varicella zoster infections. In: Pickering LK, Red book. 29th ed. 2012 Report of the Committee on Infectious Diseases. Elk Grove Village, IL: American Academy of Pediatrics; 2012. p. 774-89.

In immunocompromised children, intravenous antiviral therapy with acyclovir should be administered and is most effective when initiated early in the course of the disease (preferably within 24 hours of the onset of the rash). Some experts endorse high-dose oral acyclovir in selected immunocompromised individuals who are perceived to be at a lower risk for severe disseminated varicella. In 2008 valacyclovir was also approved for treatment of primary varicella in children 2 to under 18 years of age; some experts have used this agent for treating selected immunocompromised patients.<sup>21</sup> In susceptible individuals with a known exposure to VZV, options include administration of varicella-zoster immune globulin (VarizIG) or varicella vaccine. VarizIG is a high-titer preparation of VZV IgG that is given via the intramuscular route. It is recommended for susceptible individuals at high risk for infection and pregnant females who have been exposed to VZV (Box 16-1). VarizIG is best given within 48 hours of the exposure, but the United States Food and Drug Association (FDA) recently extended the approved period for which it can be given to up to 10 days.<sup>5,21,22</sup>

## Rubeola (Measles)

In the prevaccine era, more than 500,000 cases of measles, or rubeola, were reported annually in the United States. After introduction of a live-virus vaccine in 1963, a significant reduction in the incidence of infection was noted. The MMR vaccine has been distributed in excess of 575 million doses and is one of the most widely used combination viral vaccines in the world.<sup>23</sup> However, a dramatic resurgence occurred from 1989 to 1990, and during this period the highest mortality since 1977 was noted.<sup>24,25</sup> Those affected most during the measles resurgence were preschool-age children from the inner-city areas, especially those who were unvaccinated and from low-income families. A majority of the deaths occurring from measles infection during this period occurred in children aged 5 years or younger.<sup>25</sup> Other target populations during the measles resurgence included vaccinated school-age children and college students, probably owing to the insufficiency of a single vaccine dose and waning immunity.

In response to the measles resurgence of the 1980s, the Committee on Infectious Diseases of the AAP and the ACIP recommended an amendment to the previous vaccination schedule and suggested two doses of measles vaccination rather than one.<sup>25,26</sup> The current recommendation for measles vaccination calls for a two-dose schedule, with the first given at 12 to 15 months and the second at 4 to 6 years of age, and revaccination of children 11 to 12 years of age or older who received only one previous dose of measles vaccine.<sup>27</sup> Changes in

**Figure 16-7** Koplik spots. Gray-white papules of the buccal mucosa in a patient with measles.

the measles vaccination strategy resulted in a markedly diminished incidence of the disease in the United States, with 100 cases reported in 1999.<sup>28</sup> Although the incidence in the United States declined to extremely low levels compared with the prevaccine era, measles continues to be a major health problem worldwide, with the World Health Organization estimating around 700,000 deaths per year from the disease.<sup>29</sup> Of the 100 cases reported in the United States in 1999, 33% were imported from other countries.<sup>28</sup> In developing countries, infants under 9 months of age who are too young to have received vaccination have a high incidence of measles with more multisystem involvement and a greater risk of death.<sup>29</sup> Importantly, sporadic epidemics of primarily importation-associated measles in the United States continue to occur. During January through July 2008, 131 measles cases were reported to the Centers for Disease Control and Prevention (CDC), and these occurred primarily in unvaccinated school-aged children.<sup>30</sup> The majority of these children were eligible for vaccination but had parents who chose not to have them vaccinated. In 2011, 222 measles cases were reported to the CDC, the majority of which were associated with importations from other countries and more than 85% of cases occurring in individuals who were unvaccinated or had unknown vaccination status.<sup>31</sup> In 2014, measles cases in the United States had risen to 644.<sup>32</sup> In early 2015 the United States experienced a large, multistate outbreak of measles infection linked to an amusement park in California. Among 110 of the earliest patients in this outbreak, 45% were unvaccinated, 5% had received only one dose of the vaccine, and 43% had unknown or undocumented vaccination status. Of the unvaccinated patients, 67% were intentionally unvaccinated because of personal beliefs (65% of these were children under the age of 18 years).<sup>33</sup> Given such observations, maintaining high vaccination coverage and index of suspicion for measles and ensuring a rapid public-health response at times of outbreaks are critical in the attempt to maintain measles elimination in the United States.<sup>34,35</sup>

Measles is caused by a single-stranded ribonucleic acid (RNA) virus in the family *Paramyxoviridae*. Infection begins in the nasopharyngeal epithelium and less commonly through the conjunctivae. Transmission of measles is primarily via respiratory droplets and less commonly by small particle aerosols.<sup>36</sup> The incubation period is around 10 to 14 days. From the initial site of infection, the virus enters the lymph nodes and lymphatics and multiplies within the reticuloendothelial system with a subsequent viremia.<sup>29</sup> The virus is then disseminated to multiple lymphoid tissues and other organs, including the skin, liver, and gastrointestinal tract.<sup>37</sup> Measles immunity includes cell-mediated, humoral, and mucosal responses. Measles antibodies are responsible for protection from future infection or reinfection.<sup>29</sup>

Measles classically presents with fever and the three Cs: cough, coryza, and conjunctivitis. The pathognomonic enanthem, Koplik spots, usually occurs during this prodromal period and presents with punctuate, gray-white to erythematous papules distributed on the buccal mucosa (Fig. 16-7). These lesions were recently found to be

**Figure 16-8** Rubeola (measles). Erythematous macules and patches of the face early in the course of the disease.

**Figure 16-9** Rubeola (measles). Intensely erythematous patches of the face with cephalocaudal spread onto the trunk and extremities.

highly predictive of confirmed measles.<sup>38</sup> The skin eruption of measles usually begins 2 to 4 days after the prodrome, which may intensify several days before the onset of rash. It begins on the face (Fig. 16-8), especially the forehead, hairline, and behind the ears, and spreads downward onto the trunk (Fig. 16-9) and extremities. The lesions are erythematous to purple-red macules and papules that may become confluent and fade in the same order as their appearance, leaving behind coppery macules and desquamation.

Complications of measles include pneumonia, laryngotracheobronchitis, otitis, gastroenteritis, myocarditis, and encephalitis. Pneumonia may be caused by the measles virus itself or be related to secondary bacterial or viral infection. Keratoconjunctivitis is common, especially in children with vitamin A deficiency, in which case it may result in blindness.<sup>36</sup>

Modified measles is measles occurring in a previously vaccinated individual. In this situation the prodrome is milder and of shorter duration, the exanthem is less prominent, and Koplik spots may be absent.<sup>39</sup> This presentation of measles may pose a diagnostic challenge given the nonpathognomonic presentation. Atypical measles occurs rarely in contemporary times and is seen in individuals exposed to natural measles after vaccination with the killed measles vaccines. These vaccines were utilized for a short period in the 1960s in the United States and for more variable periods of time in other countries including Canada and Sweden.<sup>39</sup> It has occasionally been reported in children who received the live attenuated vaccine.<sup>40</sup> Atypical measles presents with high fever, headaches, and myalgias and eventually the measles rash and often pneumonia. Hemorrhagic features may be present, and the exanthem may be confused with Rocky Mountain spotted fever (RMSF). Subacute sclerosing panencephalitis (SSPE) is a delayed neurodegenerative disease characterized by seizures, personality changes, coma, and death within 5 to 15 years of the measles diagnosis. It classically occurs many years later in 1 in 100,000 patients with measles but fortunately has been dramatically decreased in incidence with widespread vaccination strategies.<sup>36,41</sup>

The diagnosis of measles is traditionally made based upon clinical presentation with laboratory confirmation. Acute and convalescent serologic studies documenting a fourfold increase in titer confirm the diagnosis of measles.<sup>42</sup> PCR and semiquantitative real-time PCR assays have been developed, the latter being quite sensitive and specific and potentially useful in situations where early and rapid diagnosis is vital.<sup>43</sup> The treatment of uncomplicated measles is largely supportive, because specific antiviral therapies do not exist. Ribavirin, a synthetic nucleoside analog useful in the treatment of other paramyxovirus (i.e., respiratory syncytial virus) infections, has been utilized in severely ill or immunocompromised patients.<sup>41,44</sup> Antibiotics are useful in patients with secondary bacterial infections such as otitis media or bacterial pneumonia. Vitamin A supplementation has been recommended by the World Health Organization and the United Nations International Children's Emergency Fund for children with measles who reside in areas where vitamin A deficiency is a recognized problem or where the measles case fatality rate is 1% or greater.<sup>45</sup> In these instances, vitamin A appears to reduce mortality and ameliorate the severity of diarrhea, possibly through a protective action on the epithelial lining of the gastrointestinal tract, increased mucus secretion, and enhanced local barriers to infection.<sup>46</sup> Hospitalized patients with measles should be kept in respiratory isolation for 4 days from the onset of the rash. Most patients will recover completely without sequelae and have lifelong immune protection against reinfection.

## Scarlet Fever

Scarlet fever (scarlatina) is a bacterial exanthem that may at times be confused with a variety of viral exanthematous diseases. It is caused by GABHS and is primarily a disease of children between the ages of 1 and 10 years. It is very rarely diagnosed in infants. Transmission of GABHS is usually via respiratory secretions. Epidemiologic changes over time in the types of streptococcal pyrogenic exotoxin (SPE) produced by the organism have been associated with changes in the severity of this disease. The shift from SPE-A- to SPE-B- and SPE-C-producing strains, which was seen early in the twentieth century, has paralleled the decrease in morbidity and mortality from scarlet fever, as well as the decline in incidence and severity of rheumatic fever (RF) in the United States.<sup>47</sup> However, RF and rheumatic heart disease (RHD; progressive valve damage) continue to burden many low- and middle-income countries, as well as some populations in higher-income countries. Immigration from countries where RF and RHD are endemic to higher-income areas have resulted in an increased prevalence in some regions where they were once believed to be eliminated.<sup>48</sup> In the United States, the incidence of RF is generally lower than in developing countries, but there have been some regional outbreaks, including an outbreak in Utah in the 1980s whereby the incidence in children aged 3 to 17 years approached 12 per 100,000.<sup>49</sup>

**Figure 16-10** Scarlet fever. Diffuse erythema with small, punctate papules. This eruption has a sandpapery texture to palpation.

**Figure 16-11** Scarlet fever in dark-skinned patient. The rash in this patient resembles "goose flesh." Note the early desquamation at some sites.

Scarlet fever presents with fever, throat pain, headache, and chills along with cutaneous findings. It is less commonly associated with streptococcal skin infection rather than pharyngitis. The primary distinction between streptococcal pharyngitis and scarlet fever is the accompanying exanthem present in the latter. Oropharyngeal inspection reveals tonsillopharyngeal erythema, exudates, and petechial macules of the palate. During the first few days of illness, the tongue may reveal a white coating with red and edematous papillae projecting through (white strawberry tongue). By the fourth or fifth day, the coating peels off, leaving behind a red, glistening tongue studded with prominent papillae (red strawberry tongue).

The differential diagnosis of streptococcal pharyngitis includes infection with viral agents (especially mononucleosis), *Mycoplasma*, *Chlamydia*, and *Arcanobacterium haemolyticum*. In adolescents the differential diagnosis should include groups C and G *Streptococcus* species and *Neisseria gonorrhoeae*,<sup>50</sup> and in developing countries *Corynebacterium diphtheriae* may be implicated. *A. haemolyticum*, formerly known as *Corynebacterium haemolyticum*, is a Gram-positive bacillus that most often infects adolescents and young adults and may result in a syndrome of pharyngitis and a scarlatiniform exanthem.<sup>51</sup> The pharyngitis in these patients is usually severe (occasionally mistaken for diphtheria), and the exanthem may also occasionally mimic toxic shock syndrome, measles, urticaria, or erythema multiforme.<sup>52,53</sup> Infection with *A. haemolyticum* can occasionally be associated with bacteremia, severe sepsis, and soft-tissue infections (especially in patients with concomitant diabetes mellitus).<sup>54,55</sup> Lemierre syndrome, a condition characterized by pharyngitis, bacteremia (usually with anaerobic organisms including *Bacillus* and *Fusobacterium*), and thrombophlebitis of the internal jugular vein, has also been reported in association with this organism.<sup>56</sup>

Tender anterior cervical adenopathy is commonly present in patients with scarlet fever, and rhinorrhea and cough are usually absent. Some experts argue that presence of the latter two findings is a negative factor for the diagnosis of GABHS infection.<sup>50</sup> The exanthem of scarlet fever presents as a fine, erythematous, macular and papular eruption (Fig. 16-10) that has been described as "sandpaper." It involves the trunk and extremities and may be accentuated in flexural areas with a petechial component (Pastia lines). In darker-skinned individuals, the exanthem of scarlet fever may be more difficult to recognize and may consist only of punctate papules resembling cutis anserina ("goose flesh") (Fig. 16-11). Circumoral pallor may be a useful clinical sign and is visualized as a rim of pallor encircling the perioral area. The exanthem generally resolves over 4 to 5 days and may heal with thick sheets of desquamation, especially over the hands, feet, toes, and fingers (Fig. 16-12). An interesting observation is that the SPEs produced by GABHS contribute to the exanthem by their ability to stimulate a delayed-type hypersensitivity response that requires prior exposure of the host to the organism.<sup>57</sup>

**Figure 16-12** Post-scarlet fever desquamation. Extensive peeling of the hands and digits occurred in this patient after treatment for scarlet fever.

Scarlet fever is diagnosed based on the clinical presentation in conjunction with results of laboratory testing. The gold standard laboratory examination is throat culture with growth of GABHS. Rapid antigen detection (rapid strep testing), when properly performed, has a high sensitivity and specificity.<sup>50</sup> In addition, antistreptococcal serologies may occasionally be useful. Complications of scarlet fever include pneumonia, pericarditis, meningitis, hepatitis, glomerulonephritis, and RF. Although the symptoms of streptococcal pharyngitis and scarlet fever will often improve spontaneously, treatment more rapidly alleviates symptoms and more importantly is the primary mode of prevention for the subsequent occurrence of RF. The prevailing theory regarding RF prevention is that antimicrobial therapy should be started within 9 days from the onset of symptoms of GABHS pharyngitis.<sup>50,58</sup>

The drug of choice for treatment of scarlet fever is penicillin V. Although amoxicillin and ampicillin are commonly used, they have no microbiologic advantage over penicillin.<sup>58</sup> In patients allergic to penicillin, erythromycin or another macrolide (i.e., clarithromycin or azithromycin) or clindamycin may be utilized. Other options include a first-generation cephalosporin (although the possibility of cross-reaction in patients with penicillin allergy must be considered) or intramuscular penicillin G, which has the advantage of not being compliance-dependent but the disadvantage of being painful during administration.<sup>58</sup>

## Rubella (German Measles)

Rubella, or German measles, is a viral exanthematous disease with a worldwide distribution. The incidence of rubella has greatly decreased since widespread rubella vaccination began in the United States in 1969. Before that time, epidemics occurred every 6 to 9 years, and major epidemics or pandemics occurred every 10 to 20 years.<sup>59</sup> The primary goal of the rubella vaccination program was to prevent fetal infection, which may have various effects including miscarriage, stillbirth, and congenital rubella syndrome (CRS) (see Chapter 2). Although reported rubella cases in the United States are now quite low, outbreaks still occur, primarily among Hispanic adults, most of whom were born outside of the country and are unvaccinated.<sup>60</sup> As of 2013, goals for rubella elimination had been established in two World Health Organization regions, the Americas (by 2010) and the European region (by 2015), and accelerated control of rubella and prevention of CRS have been established for the Western Pacific region.<sup>61,62</sup> In Japan, rubella outbreaks significantly increased in 2012 and 2013 with a corresponding increase in CRS. The effects of such outbreaks can be far-reaching given the possibility of disease importation into other countries and serves as a reminder of the need to maintain high levels of vaccination coverage and infectious-disease surveillance.<sup>61</sup>

Rubella is caused by an RNA virus in the *Togaviridae* family. Humans are the only source of infection, and postnatal disease is spread through direct or droplet contact from nasopharyngeal secretions. Up to 50% of cases of rubella are asymptomatic, and mild, self-limited disease is common. The incubation period ranges from 14 to 23 days.

Prodromal symptoms may occur, especially in adolescents and adults, and include low-grade fever, headache, malaise, eye pain, myalgias, sore throat, rhinorrhea, and cough. The prodrome usually presents 2 to 5 days before the exanthem appears. The skin eruption consists of erythematous to rose-pink macules and papules (Fig. 16-13) that tend to become confluent and most commonly involve the face and trunk. The eruption spreads in a cephalocaudad manner and begins to involute after 1 to 3 days, fading in the same order in which it appeared. After severe rubella eruptions, a fine flaky desquamation may be observed in areas of maximum involvement.

Generalized lymphadenopathy often occurs, especially in the suboccipital, postauricular, and cervical regions. Although this pattern of lymph node enlargement is highly characteristic of rubella, it is not pathognomonic and may occur in other disorders including measles, varicella, adenovirus infection, and mononucleosis. Arthralgias and arthritis are common, especially in females in whom they occur up to 52% of the time.<sup>63</sup> The most common joints affected are those of the fingers, wrists, and knees. Complete resolution of the joint symptoms may take up to several weeks, and chronic arthritis occasionally develops. A characteristic exanthem, Forschheimer spots, may be present in patients with rubella and presents with erythematous and petechial

**Figure 16-13** Rubella. Nonspecific rose-pink macules and papules on the trunk of an adolescent male with German measles.

macules on the soft palate.<sup>64</sup> Other complications of rubella include encephalitis (which occurs in 1 in 6000 patients), myocarditis, pericarditis, and hepatitis.<sup>42</sup> Anemia, neutropenia, and thrombocytopenia may also occur, as may hemolytic uremic syndrome.

A clinical diagnosis of rubella is difficult to make given the potential overlap with multiple other exanthematous diseases. Serologic tests are most useful in confirming the diagnosis of rubella. The presence of rubella-specific IgM antibody indicates recent infection, as does a fourfold or greater increase in titer between acute and convalescent serum taken 1 to 2 weeks apart.<sup>42,65</sup> The virus can be isolated from nasal specimens plated onto appropriate cell-culture media. The treatment of postnatal rubella is generally supportive. Hospitalized patients require contact isolation (and nonhospitalized children should be excused from school or day care) for 7 days after onset of the rash.

The ongoing efforts of global rubella eradication campaigns will hopefully result in eventual worldwide elimination of the disease. Continued efforts to ensure the immunity of women of child-bearing age will help to decrease the incidence of vertical transmission and CRS.

## Filatow–Dukes Disease

In 1900, Dukes described what was believed to be a unique exanthem and contrasted it from rubella and scarlet fever.<sup>66</sup> This disorder was termed *fourth disease* and subsequently became known as Filatow–Dukes disease given a similar description by Filatow 15 years earlier. The exanthem was described as bright red papules with a diffuse distribution, skin tenderness, and fever, and there was significant overlap with other exanthematous diseases, including staphylococcal scalded skin syndrome, scarlet fever, and rubella. Significant controversy followed the initial descriptions of fourth disease, and some authors propose that a distinct disorder never existed.<sup>67</sup> The possibility that epidermolytic toxin-producing staphylococci were the etiologic agent for the disorder described in the original reports has been suggested.<sup>68</sup> In general, researchers and practitioners alike have abandoned the idea of Filatow–Dukes disease representing a distinct entity.

## Erythema Infectiosum

Erythema infectiosum (EI; fifth disease) is a common childhood exanthematous illness caused by parvovirus B19 (referred to as *B19*). Although parvoviruses are ubiquitous in nature and may cause significant disease in a wide range of animals, B19 is the only one resulting in human disease.<sup>69</sup> Several disorders have been linked to B19 infection in humans (Box 16-2), including EI, arthritis, aplastic crises, and fetal hydrops. B19 infection is common in most countries, and in the United States 60% of adults are seropositive for the virus.<sup>70</sup> Infection is most common in school-age children. In immunocompromised hosts, persistent bone marrow suppression may occur, resulting in

### Box 16-2 Clinical Associations with Parvovirus B19 Infection

- Asymptomatic infection
- Exanthematous disorders
  - Erythema infectiosum (fifth disease)
  - Poplar-purpuric gloves-and-socks syndrome
  - Asymmetric periflexural exanthem
  - "Bathing trunk" exanthem
  - Petechial exanthems
- Other disorders
  - Arthritis
  - Transient aplastic crises
  - Chronic anemia
  - Refractory anemia after solid-organ or stem-cell transplantation
  - Hemophagocytic lymphohistiocytosis
  - Myelodysplastic syndrome
  - Fetal hydrops
  - Vasculitis
  - Neurologic disease
  - Rheumatologic disease

**Figure 16-14** Erythema infectiosum. Erythema of the bilateral cheeks, which has been likened to a "slapped cheeks" appearance.

severe cytopenias that may be misinterpreted as being related to malignancy relapse or drug reactions.<sup>71</sup>

In patients with classic EI, B19 infection is transmitted via the respiratory tract and is followed by a viremia that ends after 5 to 7 days with the production of IgM anti-B19 antibody. Prodromal symptoms such as headaches, fever, and chills are common during the viremic phase.<sup>72</sup> Respiratory symptoms may also be present. IgG antibody appears during the third week of illness and coincides with the appearance of the rash and arthralgias, and hence patients with the cutaneous findings of EI are not considered infectious. Outbreaks of EI occur primarily during the winter and spring.

EI is the most recognizable B19-associated manifestation. It is also known as "slapped cheek" disease given the characteristic fiery-red facial erythema (Fig. 16-14) that occurs 2 to 3 days after the prodromal symptoms. The cheeks are most prominently affected, with the nasal bridge and perioral areas usually being spared. This phase of the illness has been termed the *first stage*, and is subsequently followed by stages two and three. The differential diagnosis of the initial eruption of EI includes phototoxic reaction and systemic lupus erythematosus.

During stage two, the patient develops a lacy, reticulated eruption on the extremities and trunk 1 to 4 days after the facial rash. This eruption may be pruritic and is often evanescent. It often begins with a confluent pattern followed by central clearing, which results in the lacy and reticulated appearance (Figs. 16-15 and 16-16). The palms and soles are usually spared. The rash of the second stage of EI tends to fade over 2 to 3 weeks but may intermittently recur in response to environmental stimuli including sunlight, warm temperatures (i.e., a hot bath), or physical activity. This intermittent waxing and waning represents the third stage of EI, and the duration is variable, usually 1 to 3 weeks.

Joint symptoms occur in 8% to 10% of children with EI but in up to 60% of adults with primary B19 infection, especially females.<sup>69,73,74</sup> The most commonly involved joints include the metacarpophalangeal joints, proximal interphalangeal joints, knees, wrists, and ankles. For most patients, the joint symptoms are transient and self-limited. Occasionally, affected children develop a chronic arthritis.<sup>75</sup> Some experts have suggested a potential association between B19 infection and rheumatic arthritis or other connective tissue diseases, although the strength of this association remains unclear.

B19 has a remarkable affinity for erythroid precursors, binding to a receptor known as *P antigen (globoside)*.<sup>76</sup> Direct infection of the red blood cell precursors results in a transient arrest in red blood cell production and resultant transient anemia. Transient aplastic crises may occur in patients suffering from disorders of decreased red blood cell production or increased red blood cell destruction or loss. Predisposing disorders include iron-deficiency anemia, spherocytosis, sickle cell disease, thalassemia, glucose-6-phosphate dehydrogenase defi-

**Figure 16-15** Erythema infectiosum. Reticulate erythema on the upper arm of a patient with erythema infectiosum.

**Figure 16-16** Erythema infectiosum. Patchy erythema with reticulate changes of the inner thigh in a patient with erythema infectiosum.

ciency, and pyruvate kinase deficiency. Although these episodes may be asymptomatic with spontaneous recovery, severe involvement may result in chills, pallor, weakness, fatigue, vasoocclusive crises, or congestive heart failure. Treatment with red blood cell transfusions may be indicated and for some patients is life-saving.

Because B19 can cross the placenta, fetal infection is possible in nonimmune females with acute infection. With time it has become clear that B19 may result in a variety of fetal effects, occasionally even death. This epidemiologic consideration is important in caring for pediatric patients with B19-associated disorders. Fetal effects of B19 infection may include anemia (ranging from mild and self-limited to severe), high-output congestive heart failure, hydrops fetalis (generalized edema with ascites, pleural effusions, and polyhydramnios), and intrauterine fetal demise. Neonatal encephalopathy, encephalitis, cerebral migratory abnormalities, and meningitis have rarely been reported. The majority of pregnant women with B19 infection are asymptomatic, which makes the true incidence of fetal involvement difficult to determine.<sup>72,77</sup> It is estimated that 30% to 66% of adult females are immune to B19 infection,<sup>77-80</sup> and therefore their fetuses

**Figure 16-17** Papular-purpuric gloves-and-socks syndrome. Petechial purpura of the palms in a patient with parvovirus B19 infection.

**Figure 16-18** Papular-purpuric gloves-and-socks syndrome. Erythema and petechiae of the plantar feet were accompanied by pruritus and sore throat in this young girl with parvovirus B19 infection.

are not at risk. In the majority of fetuses who acquire acute infection *in utero*, the infection is self-limited and the infants are delivered asymptomatic and at term.<sup>81</sup> The greatest risk appears to be when infection is acquired before 20 weeks' gestation, and the majority of fetal losses occur between 9 and 28 weeks' gestation, mostly between 20 and 24 weeks.<sup>77,82,83</sup> The overall risk of B19-related fetal loss in pregnancies complicated by B19 infection is estimated around 1% to 9%.<sup>77,80,84</sup> Surviving infants tend to be healthy with normal development and neurologic outcome.<sup>84,85</sup> B19-related teratogenicity has only rarely been reported.<sup>85,86</sup> The diagnosis of B19 infection during pregnancy can be confirmed by maternal B19 IgM and IgG antibodies or PCR assay (see below). These studies are usually corroborated with findings on prenatal ultrasonography, most often evidence of fetal anemia and hydrops.<sup>87</sup> PCR assays on fetal cord blood or amniotic fluid samples have also been utilized for diagnosis.<sup>88</sup> Management of severely afflicted fetuses with B19 infection includes fetal digitalization and *in utero* blood transfusions.

B19 may be associated with a variety of purpuric or petechial exanthems, including PPGSS (see below) and more generalized presentations. In one outbreak of petechial rashes, B19 was confirmed in 76% of 17 children, and the petechiae were widely distributed, often with accentuation in the axillary and inguinal regions as well as the distal extremities.<sup>89</sup> Some authors have suggested the terminology *parvovirus B19-associated purpuric-petechial eruption* for these polymorphous presentations that appear to correspond to the viremic phase of primary infection.<sup>90</sup>

## PAPULAR-PURPURIC GLOVES-AND-SOCKS SYNDROME

Papular-purpuric gloves-and-socks syndrome (PPGSS) is another viral exanthematous illness that in many (but not all) cases has been documented to be caused by B19. This rare disorder presents most often in young adults and less often in children and is usually diagnosed during the spring and summer months.<sup>91,92</sup> Patients with PPGSS present with the acute onset of rapidly progressive, symmetric swelling and erythema of the hands and feet, often with a petechial or purpuric component (Figs. 16-17 and 16-18). Bullous lesions are rarely present.<sup>93</sup> The eruption has a sharp demarcation at the wrists and ankles and is usually quite pruritic. A more diffuse, papular exanthem may occur elsewhere on the body. An associated enanthem consisting of hyperemia, petechiae, and erosions is often present and affects the soft and hard palate, pharynx, tongue, and inner lips.<sup>91,94</sup> The symptoms of PPGSS tend to be milder in children and adolescents when compared with adults.<sup>95</sup>

Associated symptoms include fever, arthralgias, malaise, and respiratory or gastrointestinal complaints. Hematologic complications including leukopenia and thrombocytopenia are rarely observed.<sup>91,94,96,97</sup> Mononeuritis multiplex has been described in asso-

ciation with perineuritis noted on skin biopsy.<sup>98</sup> PPGSS resolves spontaneously over 1 to 2 weeks, and recurrences are rare. Importantly, the antibody response to B19 seen in PPGSS may differ from that observed in patients with EI, such that patients with the exanthem of PPGSS may still be viremic and therefore infectious.<sup>91,94</sup> The B19 VP2 structural protein has been demonstrated in the endothelial lining of dermal blood vessels in skin biopsies from patients with PPGSS.<sup>99</sup>

The diagnosis of B19 infections is often made clinically in patients presenting with classic EI. In immunocompetent children who are otherwise well, laboratory confirmation of B19 infection is usually unnecessary. Instances in which such confirmation may be indicated, however, include atypical presentations, immunocompromised hosts, individuals with hematologic diseases, and those who have been exposed to gravid females. Serologic studies including enzyme immunoassays and radioimmunoassay are useful in detecting anti-B19 IgM and IgG antibodies, and other useful tests include direct hybridization with deoxyribonucleic acid (DNA) probes, *in situ* hybridization, and PCR studies.<sup>69,76,100</sup> In a pregnant female who has been exposed to B19, serologic testing for IgM and IgG antibodies should be performed, and if acute infection is documented, serial fetal ultrasonography is usually indicated. As mentioned, maternal and fetal serum PCR techniques may be useful, especially when serologic study results are unclear,<sup>101</sup> and B19 antigen detection in amniotic fluid samples has also been described.<sup>102</sup>

## Roseola Infantum

Roseola infantum (exanthem subitum, sixth disease) is a common childhood disease caused by human herpesvirus (HHV) type 6 or 7. HHV-6 and HHV-7 are ubiquitous members of the *Herpesviridae* family. These DNA viruses preferentially infect activated T cells, resulting in enhancement of natural killer cell activity and induction of numerous cytokines.<sup>103</sup> As with other herpesviruses, they become latent after primary infection and may reactivate during times of altered immunity.<sup>104</sup> Serologic studies have demonstrated that most children have been infected with HHV-6 before 3 years of age and with HHV-7 by 6 to 10 years of age.<sup>103-105</sup>

Transmission of HHV-6 and HHV-7 is believed to be primarily via saliva, and horizontal transmission between mother and child is well documented.<sup>104</sup> Persistent or intermittent excretion of HHV-6 in saliva and stool has been documented in parents of children who had documented primary infection.<sup>106</sup> Although most newborns have transplacentally acquired antibodies, by 6 months nearly all have become seronegative and are therefore susceptible to infection.<sup>103</sup> HHV-6 has been divided into two variants, HHV-6A and HHV-6B. Most childhood infections are ascribed to the HHV-6B variant, and HHV-6A may be more commonly implicated in immunocompromised hosts.<sup>107</sup> The

**Table 16-2** Some Clinical Associations with HHV-6 and HHV-7 Infection

Condition	HHV-6, HHV-7, or Both	Comment
Roseola infantum	Both	HHV-6 more common
Fever	Both	Infants mainly
Febrile seizures	Both	In young infants
Otitis media	6	
Meningitis	6	
Encephalitis	Both	
Encephalopathy	6	Basal ganglia/white matter abnormalities on brain MRI
Hepatitis	Both	
Lymphadenopathy	Both	
Lymphoproliferative disease	6	Proposed but unproven
Infections in patients who have had transplants	6	Viral reactivation
Hemophagocytic syndrome (macrophage activation syndrome)	6	Especially in patients who have had transplants
Drug hypersensitivity syndrome	Both, but mainly 6	Proposed as complex interplay between drug reaction and HHV infection
HIV-1 cofactor	Both	Proposed but unproven
Pityriasis rosea	7	Controversial
Mononucleosis	Both	In adults
Multiple sclerosis	6	In adults; controversial

MRI, magnetic resonance imaging.

diagnosis of these infections can be made via virus isolation in peripheral blood mononuclear cell (PBMC) cultures, serologic studies, qualitative PCR, reverse transcriptase-PCR (RT-PCR), and real-time quantitative PCR. PCR-based diagnosis has been applied to a variety of body fluids and tissues including plasma, whole blood, saliva, urine, cervical swabs, placenta and PBMCs. RT-PCR can detect messenger RNA (mRNA), which is present only during active replication and hence may be useful in distinguishing between primary infection and past or latent infection.<sup>108–110</sup>

A broad range of conditions has been potentially linked to infection with HHV-6 and HHV-7 (Table 16-2).<sup>103,105,107,111–115</sup> By far, however, the best-recognized association for both agents is that of roseola infantum. Roseola is a mild exanthematous illness that most often occurs in children under 3 years of age. The classic presentation is that of high fever (38 to 41°C [101 to 106°F]) that lasts for 3 to 5 days in an otherwise-well infant. With normalization of the temperature, the classic exanthem appears, initially on the trunk and eventually spreading to involve the extremities, neck, and face. The skin eruption is composed of fairly nondescript, erythematous, blanchable macules and papules (Fig. 16-19) that occasionally display a peripheral halo of vasoconstriction. The exanthem usually resolves over 1 to 3 days.

Associated signs and symptoms may include irritability, diarrhea, bulging fontanel, cough, cervical lymphadenopathy, and edematous eyelids.<sup>116</sup> Periorbital edema is quite common and when present in a febrile but otherwise well-appearing child may be a useful clue to the diagnosis during the preexanthematous stage. Nagayama spots are erythematous papules involving the mucosae of the soft palate and uvula and represent the enanthem that occurs in up to two-thirds of patients.<sup>107,116</sup> The differential diagnosis of the skin eruption in roseola infantum may include measles and rubella, although the temporal

**Figure 16-19** Roseola infantum. (A) Erythematous, blanchable macules and papules in an infant who had a high fever for 3 days preceding the skin eruption. (B) On closer inspection, some lesions reveal a subtle peripheral halo of vasoconstriction.

characteristics (rash after abrupt defervescence) are usually suggestive of roseola.

Primary HHV-6 infection may also be asymptomatic or may present in a manner distinct from classic roseola infantum. Nonspecific fever in infants with or without otitis media may often be the result of HHV-6 infection.<sup>117,118</sup> First febrile seizures in young children may also commonly be associated with primary HHV-6 infection.<sup>117,119</sup> Other potential central nervous system complications include encephalopathy and encephalitis, which tend to occur during the preexanthematous stage and may be associated with long-term neurologic morbidity.<sup>115,120</sup> HHV-6-associated encephalitis has occurred in both immunocompetent and immunocompromised individuals. The

prognosis is variable in these patients and ranges from complete recovery to severe neurologic sequelae or death.<sup>121,122</sup> Solid-organ and bone marrow transplant recipients are at increased risk of reactivation disease, which may be asymptomatic or present with rash, fever, encephalitis, pneumonitis, hepatitis, or bone marrow suppression.<sup>123,124</sup> In some patients, the clinical presentation of HHV-6 reactivation may mimic that of acute graft-versus-host disease.

Treatment for roseola infantum is unnecessary, and the illness usually spontaneously resolves without long-term sequelae. Although *in vitro* studies or clinical observations have suggested anti-HHV activity of ganciclovir, foscarnet, and cidofovir, these agents are rarely used clinically for patients with HHV-6 or HHV-7 infection. However, further research to identify effective treatment options is desirable given the wide array of complications that may be associated with severe infection or infection in the immunocompromised host.

## Other Viral Exanthems

### NONSPECIFIC VIRAL EXANTHEMS

Although several exanthematous eruptions may present with characteristic features such as lesion morphology or distribution, the majority are somewhat nonspecific and may be difficult to distinctly categorize. These eruptions may be hard to distinguish from drug reactions or in some younger patients, miliaria rubra (prickly heat). Unique defining characteristics such as an associated exanthem or symptom complex may be absent. Most nonspecific exanthems fall into the erythematous and/or papular categories, presenting with blanchable red macules and papules with a diffuse distribution (Fig. 16-20). Associated symptoms, which are generally nonspecific as well, may include fever, headache, myalgias, fatigue, and respiratory or gastrointestinal complaints.<sup>125</sup> Most nonspecific exanthems resolve without treatment over 1 week without long-term sequelae.

Common causes of nonspecific exanthems include nonpolio enteroviruses (see below) and respiratory viruses (i.e., adenovirus, rhinovirus, parainfluenza virus, respiratory syncytial virus, influenza virus). Other potential agents include Epstein–Barr virus (EBV), HHV-6 and HHV-7, and parvovirus B19, although these agents more often result in distinct exanthematous illnesses as discussed elsewhere in this chapter. In general, the majority of nonspecific exanthems occurring in the winter months are caused by the respiratory viruses and those

occurring during the summer months are most often caused by the enteroviruses.

Petechial exanthems, in particular, may pose a diagnostic dilemma to clinicians (given their potential association with life-threatening infections) and are associated with increased rates of hospitalization and diagnostic testing. Multiple viral organisms may be associated with a petechial exanthem, including parvovirus, respiratory syncytial virus, influenza and parainfluenza viruses, rhinovirus, EBV, cytomegalovirus (CMV), adenovirus, and enteroviruses. In a prospective study of children (0 to 18 years of age) who had petechiae and signs or symptoms of infection, real-time PCR was utilized to identify a variety of viruses in nasopharyngeal aspirates. Of 58 patients with a petechial rash, 67% were positive for a viral pathogen, and 41% were notable for viral coinfections (two or more pathogens).<sup>126</sup> The most common pathogens in this study were CMV and EBV (each 18% of the patients), followed by enteroviruses and rhinovirus (each 14% of the patients). Influenza A H1N1 and human bocavirus were also noted fairly often (9% each of the patients). Distinguishing clinically between viral and bacterial processes may be challenging. The ability to rapidly diagnose viral infection via quantitative PCR, however, may help minimize unnecessary antibiotic therapy, invasive diagnostics, and hospitalizations.<sup>126</sup>

### GIANOTTI–CROSTI SYNDROME

Gianotti–Crosti syndrome (GCS; papular acrodermatitis of childhood) was initially described in 1955 by Gianotti as an erythematous papular eruption symmetrically distributed on the face, buttocks, and extremities of children. A subsequent description by Crosti and Gianotti was made in 1956, and since then the disorder has been commonly known as Gianotti–Crosti syndrome. A viral etiology was suspected early on after the description of the disorder, and subsequently the notion of hepatitis B virus as a cause was hypothesized. It is currently well accepted that GCS is a distinct viral exanthem that may occur after infection with any of several viral agents, with hepatitis B being one possible (but uncommon) cause in certain parts of the world, especially Italy and Japan.<sup>127</sup>

GCS occurs predominantly in children between the ages of 1 and 6 years. Before the appearance of the exanthem, upper respiratory symptoms, fever, and lymphadenopathy may be present. The eruption is characterized by edematous, erythematous, monomorphic papules and occasionally papulovesicles distributed symmetrically over the face, buttocks (Fig. 16-21), and extensor surfaces of the upper (Fig. 16-22) and lower (Fig. 16-23) extremities. Occasionally the papules coalesce into larger, erythematous plaques (Fig. 16-24). Hemorrhagic changes or localized purpura (Fig. 16-25) may occasionally be present. The trunk is usually (but not always) spared in patients with GCS.<sup>128</sup> In most patients the skin eruption is asymptomatic, although mild pruritus may be present.

**Figure 16-20** Nonspecific viral exanthem. Nondescript erythematous macules and papules in an infant with a nonspecific symptom complex.

**Figure 16-21** Papular acrodermatitis of childhood. Erythematous, edematous papules symmetrically distributed on the bilateral buttocks.

**Figure 16-22** Papular acrodermatitis of childhood. Monomorphous, erythematous papules of the dorsal hands in a young girl who had similar lesions on the face and the extensor surfaces of her arms and legs.

**Figure 16-23** Papular acrodermatitis of childhood. Erythematous, edematous papules of the thighs and knees in a patient with Gianotti-Crosti syndrome.

A viral etiology has long been suspected as the cause of GCS. In 1970 two independent groups confirmed the association with hepatitis B infection.<sup>129,130</sup> In these patients, the exanthem was accompanied by acute anicteric hepatitis. In patients with hepatitis-associated GCS, hepatitis B surface antigen subtype ayw has been most classically implicated. Another term, *papulovesicular acrolocated syndrome* (PVAS), was traditionally used to describe a similar presentation with a more vesicular component. It was once believed that this presentation was distinct based on the presence of pruritus and the lack of both hepatitis and a hepatitis B association. In a review of 308 cases of Gianotti-Crosti syndrome in Italy, however, distinction between GCS and PVAS was not clinically possible, nor was there a significant difference in the presentation or course as related to the etiologic agent (i.e., hepatitis B versus other viruses).<sup>131</sup>

Subsequently multiple viral agents have been implicated in causing GCS. These include EBV, which is believed to be the most common etiology in the United States, as well as CMV, Coxsackie viruses, respiratory viruses (adenovirus, respiratory syncytial virus, parainfluenza virus), parvovirus B19, rotavirus, and HHV-6.<sup>127,131-138</sup> A possible association with immunizations has also been suggested. Vaccination reports have included MMR, *Haemophilus*, oral polio, diphtheria-pertussis-tetanus, Japanese B encephalitis, varicella, and hepatitis B vaccines.<sup>139-145</sup> Recurrence of the eruption and accentuation of lesions at the site of vaccination have been observed.<sup>146</sup> There is also a report of GCS occurring in association with primary HSV-1 gingivostomatitis in a 3-year-old boy.<sup>147</sup> GCS-like reactions have been observed

**Figure 16-24** Papular acrodermatitis of childhood. Erythematous papules coalesced into larger, edematous plaques in this patient.

**Figure 16-25** Papular acrodermatitis of childhood. Localized purpura of the ear lobe occurred in this patient with Gianotti-Crosti syndrome.

in some patients with molluscum contagiosum (see Chapter 15, Fig. 15-44, A)<sup>148</sup>; GCS seems to be a distinct exanthem occurring in response to a variety of viral agents and possibly vaccinations, with hepatitis B being an extremely rare cause in the United States.

Treatment for GCS is supportive. Although the eruption is self-limited, it may take 8 to 12 weeks to resolve completely. Postinflammatory hypopigmentation (Fig. 16-26) may occasionally persist for several months after resolution of the exanthem. Routine laboratory studies for hepatitis are generally not warranted. However, a thorough history (including potential risk factors for hepatitis) and physical examination (with attention to the presence or absence of hepatosplenomegaly and lymphadenopathy) should be performed. Hepatitis serologies and liver function studies should be performed only in patients in whom there is a clinical suspicion.

**Figure 16-26** Papular acrodermatitis of childhood, postinflammatory hypopigmentation. These postinflammatory changes are most common in patients with darker native complexions.

**Figure 16-28** Unilateral laterothoracic exanthem. Early involvement shows localization to the lateral trunk, axilla, and proximal inner arm in this patient.

**Figure 16-27** Unilateral laterothoracic exanthem. Erythematous macules and papules of the lateral trunk. The eruption eventually generalized.

**Figure 16-29** Unilateral laterothoracic exanthem. The thigh was the initial site of involvement in this patient whose lesions demonstrate an erythema infectiosum-like morphology. (Courtesy of Dr. Sarah Chamlin.)

### UNILATERAL LATEROTHORACIC EXANTHEM

Unilateral laterothoracic exanthem (ULE; asymmetric periflexural exanthem of childhood) was initially described by Bodemer and de Prost in 1992 as a distinct exanthem presenting initially in a unilateral, localized fashion.<sup>149</sup> It was probably described years earlier when Brunner et al. described a “new papular exanthem of childhood” in 1962,<sup>150</sup> and in 1986 when Taieb et al. reported five children with a “localized erythema” similar to that described in ULE.<sup>151</sup>

ULE is most common in patients between 1 and 5 years of age. It usually occurs during the winter or spring, although it has been described year round.<sup>150,152,153</sup> In most patients, onset of the skin eruption is unilateral and on the trunk (Fig. 16-27), often with extension toward the axilla (Fig. 16-28) and less often around the inguinal region or on an extremity (Fig. 16-29). The lesions spread in a centrifugal fashion and often become bilateral, although they maintain a predominance on the initial side of involvement. The skin lesions in ULE may show various morphologies, including macules, papules,

eczematous changes, and morbilliform, scarlatiniform, annular, or reticulate patterns. Some have described early lesions as consisting of a red papule surrounded by a pale halo.<sup>152</sup> Pruritus occurs in around 50% of patients. Vesicles and purpuric changes are rare. Desquamation is common during the healing stage, and postinflammatory pigment changes may also be present. Although skin biopsy is usually unnecessary, when performed it has revealed a lymphocytic infiltrate with notable clustering around the dermal eccrine ducts.<sup>152,154</sup> The most common initial misdiagnosis is that of contact dermatitis. The clinical differential diagnosis of ULE may also include nonspecific exanthem, pityriasis rosea, scarlet fever, miliaria, EI, tinea, and papular acrodermatitis of childhood.

Associated features may include a prodrome consisting of low-grade fevers and respiratory or gastrointestinal symptoms. Fatigue and conjunctivitis may also be present. Enlarged axillary and/or inguinal lymph nodes are occasionally noted, and hepatosplenomegaly is generally absent. An associated exanthem has not been described with ULE.

The etiology of ULE remains unclear, although most favor a viral etiology. Early reports suggested *Spiroplasma* infection,<sup>151</sup> although this has not been confirmed in subsequent studies. In a prospective case-controlled study using throat, stool, blood, and skin samples, several microbiologic investigations were performed for viral and bacterial infection. No differences between cases and controls were noted, and no consistent etiologic agent was identified.<sup>155</sup> Although parainfluenza virus and adenovirus infection were diagnosed in six patients in one series, confirmation of a causal role is lacking.<sup>153</sup> ULE was observed in a 1-year-old girl who also had positive EBV PCR in peripheral blood, suggesting a possible association.<sup>156</sup> The appearance of ULE after the onset of molluscum contagiosum has also been reported, similar to GCS (see above).<sup>157</sup> ULE appears also to be a distinct presentation pattern in response to a variety of potential infectious agents.

The lesions of ULE resolve spontaneously, but similar to those of papular acrodermatitis of childhood, they may be delayed. Most often ULE resolves over 3 to 4 weeks, although in some patients it may take up to 8 weeks. Treatment is supportive.

## ENTEROVIRAL EXANTHEMS

Enteroviruses, a subgroup of the picornaviruses, may cause a variety of clinical syndromes with associated exanthems. Human enteroviruses are small, single-stranded RNA viruses that include echovirus (31 serotypes), Coxsackievirus A (23 types), Coxsackievirus B (six types), enteroviruses 68 through 71 (four types), and polioviruses (three types).<sup>158</sup> The majority of enterovirus infections seen in practice are benign and manifested by fever alone or distinct syndromes, including hand-foot-and-mouth disease (HFMD), herpangina, hemorrhagic conjunctivitis, and pleurodynia.<sup>159</sup> However, severe or life-threatening infections may also result from enteroviral infection, including meningitis, encephalitis, myocarditis, neonatal sepsis, and polio. Infections in neonates are often disseminated and may be difficult to differentiate from bacterial processes.<sup>160</sup> Nonpolio enteroviruses are the leading cause of viral meningitis.<sup>159,161</sup> Spread of enteroviruses occurs person-to-person via the fecal-oral route and occasionally common source exposure (i.e., swimming pool water).<sup>162</sup> Enteroviral infections tend to predominate during the summer and fall, although sporadic cases may be seen throughout the year.

Nonspecific exanthems resulting from nonpolio enteroviruses are common and may present as macular and papular nonpruritic eruptions with or without petechiae. When a petechial component is present, the clinical presentation may be confused with that of more serious infections such as meningococcemia. This diagnostic confusion may be exacerbated by the concomitant presence of aseptic meningitis, which may accompany enterovirus, Coxsackievirus, or echovirus infections.<sup>39</sup> Other exanthem patterns may include urticarial, scarlatiniform, zosteriform, and vesicular forms.<sup>158</sup> Table 16-3 lists some exanthem/enanthem associations with the nonpolio enteroviruses.<sup>163-173</sup> Several are discussed in the following paragraphs in more detail.

HFMD is the best-recognized enteroviral exanthem. It is a disorder of young children, most commonly affecting those between 1 and 4 years of age. HFMD has been linked to several nonpolio enteroviruses, including Coxsackieviruses A5, A6, A7, A9, A10, A16 (most common), B1, B2, B3, and B5; echovirus 4<sup>174</sup>; and enterovirus 71.<sup>125</sup> Patients have fever, malaise, and the characteristic exanthem, which consists of gray-white, vesicular lesions on the palms (Fig. 16-30) and soles (Fig. 16-31) and less often involving the dorsal or lateral surfaces of the hands and feet. A less specific macular and papular erythematous eruption may be present on the buttocks, thighs, and external genitalia. Occasionally a more diffuse vesicular eruption with lesions in areas other than the palms and soles may be present (Fig. 16-32). The exanthem of HFMD consists of vesicles and erosions of the buccal surfaces, palate, tongue (Fig. 16-33), uvula, gingivae, and anterior tonsillar pillars. These lesions are painful and lead to anorexia and

**Table 16-3** Some Reported Exanthem/Enanthem Associations with Enteroviruses

Exanthem	Comment
Hand-foot-and-mouth disease	Most common; Coxsackievirus A or B, enterovirus 71; atypical form with high numbers of vesicles on extremities, palms, soles, face and buttocks may occur, especially in association with epidemics of Coxsackievirus A6 infection
Herpangina	Oral lesions and fever; Coxsackievirus A or B
Eczema coxsackium	Accentuation of erosions and vesicles in areas of skin previously or currently affected with AD
Hemorrhagic conjunctivitis	Eyelid edema, lacrimation, pain; Coxsackievirus A24 and enterovirus 70
Nonspecific exanthem	Any enterovirus
Gianotti-Crosti syndrome	Coxsackievirus A or B
Henoch-Schönlein purpura	Coxsackievirus B1
Still-like disease	Coxsackievirus B4
Zoster-like eruption	Echovirus 6
El-like eruption	Echovirus 12
Congenital skin lesions	Coxsackievirus B3
Eruptive pseudoangiomatosis	Echovirus
AGEP	Coxsackievirus B4
Nail matrix arrest	Patients with preceding hand-foot-and-mouth disease

Data from references 163, 164, 165, 166, 167, 168, 169, 170, 171, 172, 173. AD, Atopic dermatitis; AGEP, acute generalized exanthematous pustulosis; El, erythema infectiosum.

**Figure 16-30** Hand-foot-and-mouth disease. Deep-seated vesicles with erythema involving the palmar surface of the fingers.

occasionally dehydration. Cervical and submandibular lymphadenopathy may occasionally be present in patients with HFMD.

Although the course of HFMD is most often benign and treatment is supportive, epidemics of enterovirus 71 infection in Asia highlight the potential seriousness of the infection. In these epidemics, severe disease was seen most often in children under 5 years of age, with the majority of deaths occurring secondary to pulmonary edema or pulmonary hemorrhage.<sup>175</sup> Other complications included encephalitis,

**Figure 16-31** Hand-foot-and-mouth disease. Erythematous deep-seated and superficial vesicles involved the plantar surface in this infant with erosions of the palate and uvula.

**Figure 16-32** Hand-foot-and-mouth disease. Red to purple vesicles involved the knees and elbows in this patient with classic lesions involving the mouth, palms, and soles.

**Figure 16-33** Hand-foot-and-mouth disease. A painful erosion of the lateral aspect of the tongue.

aseptic meningitis, acute flaccid paralysis, myocarditis, and cardiopulmonary collapse.<sup>175–177</sup> The neurotropism of enteroviruses is demonstrated by the common finding of brain (especially brain stem) involvement on autopsy specimens from children who died of severe HFMD.<sup>178</sup>

**Figure 16-34** Atypical enterovirus exanthem. This 3-year-old girl had fever and the acute onset of a vesicular eruption on her upper (**A**) and lower (**B**) extremities and her face with a perioral accentuation. Her manifestation coincided with a local Coxsackievirus A6 epidemic.

Atypical forms of HFMD may occur, highlighted over recent years in the setting of epidemics of Coxsackievirus A6 infection.<sup>179–181</sup> In these patients, extensive numbers of vesicles and erosions may occur on the extremities (Fig. 16-34), perioral face, groin, and buttocks, in addition to the more classic locations. In addition, in patients with atopic dermatitis, accentuation of the blistering process may be noted in areas previously or concurrently affected with eczematous lesions. This observation has been termed *eczema coxsackium*,<sup>179</sup> and these patients may be mistakenly diagnosed as having *eczema herpeticum* (see Chapter 3). A similar accentuation of the viral exanthem may be seen in other areas of skin inflammation or injury, including sunburn, irritant dermatitis, tinea infection, or lacerations. Post-HFMD nail matrix arrest with onychomadesis (nail shedding), initially reported in five children in 2000,<sup>171</sup> is now a well-recognized postinfectious association. It may present as Beau lines (transverse depressions in the nail plate) or complete separation of the nail plate from the nail matrix (Fig. 16-35). Although this observation has been seen after infection with a variety of enteroviruses, Coxsackieviruses A6, A10, B1, and B2 have been the most commonly confirmed.<sup>182–186</sup> The changes tend to occur around 30 to 40 days after the onset of HFMD and are followed by spontaneous regrowth of normal nail plates.

Herpangina is a characteristic enanthem that may be caused by a variety of nonpolio enteroviruses, especially Coxsackieviruses A and

**Figure 16-35** Nail matrix arrest after hand-foot-and-mouth disease. Transverse ridging and eventual nail shedding occurred in this 5-year-old male 2 months after having the enteroviral infection. The nails spontaneously grew back normally within several months.

**Figure 16-36** Eruptive pseudoangiomatosis. This teenaged girl sought treatment in the summer with the acute onset of small, hemangioma-like papules. Note the surrounding halo of vasoconstriction surrounding each lesion. (Courtesy of Dr. Andrew Sagan.)

B. It presents with fever, sore throat, and malaise, usually in children between 3 and 10 years of age. Inspection of the oral mucosa reveals gray-white vesicles and erythematous erosions involving the palate, uvula, and tonsillar pillars. Although it may occasionally be confused with acute herpetic gingivostomatitis, labial and skin involvement is much more common with HSV infection. Treatment for HFMD or herpangina consists of pain control and ensurance of adequate fluid intake in order to prevent dehydration. The lesions spontaneously resolve over 1 week. Hand-washing by preschool-aged children and their caregivers was demonstrated to have a significant protective effect against community-acquired HFMD and herpangina during an enterovirus 71 outbreak in China.<sup>187</sup>

Echovirus exanths have been variably described with a number of presentations and morphologies. Some of these include macular, vesicular, urticarial, and petechial eruptions, erythema multiforme, HFMD, and roseola-like exanths.<sup>39</sup> Echovirus 6 has been associated with a dermatomal, vesicular eruption mimicking herpes zoster.<sup>163</sup> Echovirus type 9 infection may result in an illness with aseptic meningitis and a petechial eruption that may mimic meningoococcemia.<sup>188</sup> Echovirus 16 was classically associated with a roseola-like exanthem referred to as *Boston exanthem*, which was one of the initial exanths to be described and virologically confirmed. Approximately one-third of individuals with echovirus infection may develop a rubelliform eruption consisting of discrete pink-red macules that spread from the face and neck to the upper trunk and extremities. Some patients also have yellow or gray-white lesions on the oral mucous membranes that may resemble Koplik spots. Other symptoms that may be associated with echovirus infection include fever, gastrointestinal complaints, upper respiratory symptoms, and conjunctivitis.

Eruptive pseudoangiomatosis is an exanthem consisting of the acute onset of hemangioma-like lesions and possibly related to echovirus infection.<sup>189</sup> Cherry et al., in 1969, originally described four children with acute echovirus infection (two with echovirus 25 and two with echovirus 32) who developed such lesions with resolution occurring over 2 to 6 days.<sup>164</sup> Other affected children were subsequently described, all of whom presented with the acute onset and spontaneous resolution of angioma-like papules during the course of a viral illness.<sup>165,190</sup> The disorder has also been observed in adults.<sup>191,192</sup> The angiomatous papules in eruptive pseudoangiomatosis are often surrounded by a rim of blanching (Fig. 16-36), and histopathologic evaluation, when performed, has revealed dilated dermal blood vessels and plump endothelial cells without any increase in the number of blood vessels.<sup>165,193</sup> Associated symptoms have included fever, malaise, headache, diarrhea, and respiratory complaints. Although echoviruses have not been confirmed as the etiology by other investigators, a viral cause continues to seem most likely. Recurrence of eruptive pseudoangiomatosis has occasionally been observed.<sup>194</sup>

### Box 16-3 Some Disease Associations with Epstein–Barr Virus

- Asymptomatic infection
- Infectious mononucleosis
- Lymphoproliferative disorders:
  - X-linked lymphoproliferative syndrome
  - EBV-associated hemophagocytic syndrome
  - Lymphoproliferative disorders in immunocompromised patients
- Gianotti–Crosti syndrome
- Chronic EBV infection
- Acute genital ulceration
- Oral hairy leukoplakia
- Neoplastic disorders:
  - Burkitt lymphoma
  - Nasopharyngeal carcinoma
  - B- or T-cell lymphoma (including AIDS-associated B-cell lymphomas)
  - Extranodal NK/T-cell lymphoma, nasal type
  - Hodgkin disease
  - Hepatocellular carcinoma

AIDS, Acquired immunodeficiency syndrome; EBV, Epstein–Barr virus; NK, natural killer.

## INFECTIOUS MONONUCLEOSIS

IM is a common infection occurring during adolescence and is usually associated with EBV infection. Although most cases of IM are related to EBV infection, not all primary EBV infections manifest as IM.<sup>195</sup> The spectrum of disorders linked to EBV infection is shown in Box 16-3. Other etiologic agents of IM-like illness include CMV, hepatitis A, adenovirus, GABHS, *A. haemolyticum*, HHV-6, rubella virus, HIV, and *Toxoplasma gondii*.<sup>196,197</sup> Malignancy and drug reactions may also result in IM-like illnesses.<sup>195</sup>

Confirmation of EBV as the major cause of IM occurred in the late 1960s.<sup>195,197</sup> EBV is a member of the *Herpesviridae* family and as such is a large, DNA-containing virus with the ability to become latent after primary infection and with the potential for subsequent reactivation. The virus has tropism for both lymphocytes (especially B cells) and epithelial cells, with infection beginning in the oropharyngeal epithelial cells, which may shed the virus for up to 18 months after primary acquisition.<sup>197,198</sup> The primary transmission route is via saliva. Natural EBV infection occurs only in humans and results in lifelong infection.<sup>199</sup> It is estimated that more than 95% of adults are infected with EBV worldwide.

Primary EBV infection in infancy is mostly asymptomatic or presents with very mild, nonspecific symptoms such as upper respiratory tract symptoms, pharyngitis, lymphadenopathy, and fever.

**Figure 16-37** Infectious mononucleosis. A diffuse, erythematous macular and papular eruption occurred in this adolescent male after receiving amoxicillin therapy.

Epidemiologic studies suggest that most children have acquired EBV by 5 years of age in underdeveloped countries or lower socioeconomic classes, whereas primary infection occurs later in life (i.e., between 10 and 30 years) in developed countries and higher socioeconomic classes.<sup>195,200</sup> Older children and adolescents are more likely to develop clinical symptoms of IM after an incubation period of 2 to 7 weeks.

IM is generally a benign, self-limited illness characterized by fever, exudative tonsillopharyngitis, and lymphadenopathy. Malaise, fatigue, and headache are also common. The temperature may reach 40°C (104°F) and is often prolonged, lasting for 1 to 2 weeks. Physical examination may reveal splenomegaly, hepatomegaly, periorbital edema, palatal petechiae, jaundice, and a skin eruption. The lymphadenopathy is typically nontender and involves both the anterior and posterior cervical chains. Diffuse adenopathy is occasionally present. Historically, IM was divided into three syndromes: anginose, characterized by the classic triad of fever, pharyngitis, and lymphadenopathy; typhoidal, characterized by prolonged high fever; and glandular, characterized by mild pharyngitis, low-grade fever, and marked lymphadenopathy.

The skin eruption of IM is nonspecific, occurs in around 5% of patients, and may present as a macular, petechial, scarlatiniform, urticarial, or erythema multiforme-like rash.<sup>197,200</sup> After the administration of ampicillin or amoxicillin, however, 90% to 95% of patients develop an erythematous macular and papular eruption (Fig. 16-37) that may be related to ampicillin-antibody immune complexes resulting from B-cell activation.<sup>201</sup> This reaction occurs about 5 to 9 days after starting the antibiotic and does not appear to represent a true drug allergy.

Useful laboratory evaluations in patients with IM include hematologic and hepatic panels and serologic analysis. Complete blood cell counts often reveal an absolute lymphocytosis, often with more than 10% atypical lymphocytes (representing activated T cells). Other aberrations may include anemia, thrombocytopenia, and neutropenia, the latter developing 1 to 2 weeks into the illness. Autoimmune hemolytic anemia is uncommon, occurring in around 3% of cases.<sup>201</sup> Mild hepatitis may be manifested by elevations in the hepatic transaminases, alkaline phosphatase, and L-lactate dehydrogenase (LDH). Coagulopathy is usually absent. The most useful confirmatory examination is the

EBNA, Epstein–Barr virus nuclear antigen; Ig, immunoglobulin; IM, infectious mononucleosis.

serologic assay for heterophile antibodies. These IgM antibodies can be readily measured with a variety of rapid test kits (i.e., monospot) and have high specificity. Although up to 15% of patients with IM may initially be negative for heterophile antibodies, many become positive on repeat testing performed during the second or third week of the illness.

Virus-specific serologies can help confirm a definitive diagnosis of EBV infection and should be used to diagnose IM in children under 4 years of age (who are often heterophile antibody negative), patients with atypical presentations, or those with severe or prolonged illness.<sup>197</sup> EBV serology interpretations are shown in Table 16-4. Detection methods for EBV-related proteins or DNA are also available. Real-time PCR and measurements of EBV viral load seem particularly useful in diagnosing acute IM when the serologic studies are inconclusive.<sup>202</sup>

Complications of IM include splenic rupture, upper airway obstruction, hematologic issues (hemolytic anemia, thrombocytopenia, aplastic anemia, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, and disseminate intravascular coagulation), chronic fatigue, and neurologic findings. Subcapsular splenic hemorrhage with rupture is fortunately quite rare (<0.5% of cases in adults). It presents as an abrupt onset of left upper-quadrant abdominal pain and may be treated by splenectomy or nonoperative management. Upper airway obstruction may result from tonsillar hypertrophy and is treated as an inpatient with close observation, maintenance of the airway, hydration, and occasionally systemic corticosteroids.<sup>201</sup> Neurologic complications include cranial nerve palsies, Guillain–Barré syndrome, meningoencephalitis, aseptic meningitis, optic neuritis, and seizures. Other less common complications include pneumonia (which is often related to coinfection with a bacterial or another viral agent), electrocardiographic abnormalities, rhabdomyolysis, and chronic liver disease.<sup>197,201</sup> EBV is the most common infectious trigger of hemophagocytic lymphohistiocytosis (see Chapter 10).

Chronic fatigue syndrome (CFS) may follow IM in both adolescents and adults, with 13% of adolescents (mainly females) meeting criteria 6 months after IM in one study.<sup>203</sup> CFS is defined as at least 6 months of severe fatigue and disabling musculoskeletal and cognitive symptoms without any other explanation. In the aforementioned cohort, the figures for CFS in this group decreased to 7% at 12 months and 4% at 24 months after IM. It appears that female gender and greater fatigue severity are predictors for the development of CFS in adolescents with IM.<sup>204</sup>

The management of IM is primarily supportive. Adequate rest, fluids, and analgesics (acetaminophen, nonsteroidal anti-inflammatory agents) are commonly recommended. Patients with splenomegaly are counseled to avoid strenuous exercise and contact sports to prevent the complication of splenic rupture. These activities should

be avoided for the duration of splenomegaly, usually 1 month after onset of symptoms.<sup>195</sup> Most splenic ruptures occur within 3 weeks of the diagnosis, but it has been reported as late as 7 weeks after the diagnosis.<sup>205</sup> Amoxicillin and ampicillin should be avoided in patients with suspected IM. Corticosteroids are generally recommended only for patients with complications such as marked tonsillar hypertrophy with the potential for airway obstruction, massive splenomegaly, myocarditis, hemolytic anemia, or hemophagocytic syndrome.<sup>206</sup> Acyclovir, which may show *in vitro* activity against EBV, is of no proven value in the treatment of EBV-associated IM or lymphoproliferative syndromes, although antiviral agents may benefit immunocompetent patients when used in adjunct with corticosteroids.<sup>195,202,206</sup>

Acute genital ulceration (AGU; *ulecus vulvae acutum*; Lipschütz ulcer) is another potential presentation of primary EBV infection, presenting most commonly in teenaged girls. The initial report of this observation is credited to Lipschütz, who in 1913 proposed a classification of AGU into three categories, the third type being the sudden onset of genital ulcers in non-sexually active girls and young women.<sup>207</sup> This presentation may be associated with several possible infectious agents, but one of the most common appears to be EBV. Other reported agents may include CMV, *Mycoplasma pneumonia*, and influenza A virus.

AGU associated with EBV infection presents with painful genital ulcers, often bilateral (and occasionally in a "kissing pattern") and involving the labia minora or majora (or both). Edema is often present and may at times be severe. Tissue necrosis may occur, rarely necessitating surgical debridement. Other clinical features may include pharyngitis, lymphadenopathy, fever, and fatigue, but these classic symptoms of IM may not develop until later in the course (and in some patients may not develop at all).<sup>208</sup> The primary differential diagnosis is infection with HSV, and viral culture or PCR studies are often necessary, as are serologic studies for EBV. Seroconversion for EBV may be observed weeks after the initial presentation, with initially negative testing. EBV PCR testing on blood or genital tissue (when biopsy is performed) may be positive, although *in situ* hybridization and EBV RNA and protein staining in tissue samples suggests that AGU is most likely related to inflammatory events rather than direct viral cytopathic effects.<sup>207,209</sup> AGU caused by EBV infection is usually treated supportively, and the lesions tend to heal over 3 to 6 weeks; systemic corticosteroids have been recommended by some authors. This infectious cause of AGU is likely underrecognized and should be strongly considered in young females who have acute painful ulcers and who deny genital or oral sexual activity.<sup>210</sup>

## Exanthems Associated with *Mycoplasma pneumoniae* Infection

*Mycoplasmas* are a distinct class of bacteria that lack rigid cell walls and are thus insensitive to antibiotics that inhibit cell-wall synthesis such as penicillins. The best-recognized agent in this class is *M. pneumoniae*, a prominent etiology of atypical pneumonia in school-age children, adolescents, and adults. This infection generally presents with the insidious onset of fever, malaise, headache, and cough, and may be associated with skin findings in up to one-third of patients.<sup>211</sup> A variety of cutaneous eruptions have been potentially linked to *M. pneumoniae* infection. Some of these include nonspecific erythematous macular and papular eruptions,<sup>212–214</sup> erythema nodosum,<sup>211</sup> urticaria,<sup>211</sup> erythema multiforme minor,<sup>215</sup> GCS,<sup>216</sup> leukocytoclastic vasculitis,<sup>217</sup> bullous PPGSS,<sup>218</sup> Stevens–Johnson syndrome,<sup>219,220</sup> and subcorneal pustular dermatosis.<sup>221,222</sup> Stevens–Johnson syndrome is the most significant cutaneous association with *M. pneumoniae* infection and is discussed in detail in Chapter 20.

## Rickettsial Diseases

Although the use of molecular technology has resulted in some reclassifications of agents included in the order Rickettsiales, these organisms are all included in this section. These genus groups include *Bartonella*, *Coxiella*, *Ehrlichia*, *Anaplasma*, and *Rickettsia*. Table 16–5 is a summary of several rickettsial organisms and their disease

**Table 16-5** Some Rickettsial Organisms and Their Disease Associations

Organism	Disease Association(s)	Vector
<b>BARTONELLA</b>		
<i>Bartonella henselae</i>	Bacillary angiomatosis, CSD, endocarditis, bacillary peliosis	?Cat flea
<i>Bartonella quintana</i>	Trench fever, bacillary angiomatosis, endocarditis, bacillary peliosis	Human body louse
<b>COXIELLA</b>		
<i>Coxiella burnetii</i>	Q fever, endocarditis	Tick
<b>EHRLICHIA</b>		
<i>Ehrlichia chaffeensis</i>	Human monocytic ehrlichiosis	Lone Star tick
<i>Anaplasma phagocytophilum</i>	Human granulocytic ehrlichiosis (anaplasmosis)	Deer tick, dog tick
<b>RICKETTSIA</b>		
<i>Rickettsia akari</i>	Rickettsialpox	House-mouse mite
<i>Rickettsia conorii</i>	Mediterranean spotted fever	Dog tick
<i>Rickettsia prowazekii</i>	Epidemic typhus	Human body louse
<i>Rickettsia rickettsii</i>	Rocky Mountain spotted fever	Wood tick, dog tick
<i>Rickettsia typhi</i>	Endemic typhus	Rat flea
<i>Rickettsia tsutsugamushi</i>	Scrub typhus	Trombiculid mite

CSD, Cat-scratch disease.

associations. Bacillary angiomatosis caused by *Bartonella henselae* and *Bartonella quintana* is discussed in Chapter 12. Cat-scratch disease, caused by *B. henselae* is discussed in Chapter 14. Some other rickettsial disorders are discussed here.

Rickettsial infections are arthropod-borne diseases caused by microorganisms that occupy an intermediate position between bacteria and viruses. Spread by blood-sucking insects such as the body louse, fleas, and ticks, the various rickettsial diseases that occur in the United States include endemic or murine typhus, rickettsialpox, RMSF, and Q fever. Human granulocytic ehrlichiosis (HGE) (now also known as *anaplasmosis*) and human monocytic ehrlichiosis (HME) cases have also been reported with an expanding geographic distribution.

## ENDEMIC TYPHUS

Endemic (murine) typhus is caused by *Rickettsia typhi* and is transmitted by the rat flea *Xenopsylla cheopis*. It occurs worldwide, especially in warm climates with heavy populations of rats or opossums.<sup>223</sup> Although endemic typhus occurs most often in developing nations, it continues to occur in the United States, especially in Gulf Coastal areas and Texas.<sup>224</sup> Adults are most often affected, but children have constituted up to 75% of infections in some outbreaks.<sup>223</sup> Clinical manifestations most commonly include fever and headache, with rash occurring in around two-thirds of patients. The eruption is variably characterized as macular, papular, and occasionally petechial. Other features may include nausea, vomiting, malaise, myalgias, diarrhea, arthralgia, lymphadenopathy, conjunctivitis, and pneumonitis. Effective treatments include doxycycline and chloramphenicol. Endemic typhus should be considered in the child with prolonged fever and a rash, especially those residing in southern California, southern Texas, and Hawaii.<sup>225</sup>

## RICKETTSIALPOX

Rickettsialpox, caused by *Rickettsia akari*, is transmitted to humans by the house-mouse mite *Liponyssoides sanguineus*. Although rickettsialpox is rarely reported or diagnosed, it remains endemic in certain regions of the United States, particularly New York City.<sup>226</sup> The disorder begins with the bite of an infected mite, which results in a black eschar and subsequently other symptoms. The classic triad of rickettsialpox consists of fever, eschar, and rash. The skin eruption presents as numerous, monomorphic red papules with a small, central vesicular component. Although it may occasionally be confused with varicella, the rash of rickettsialpox is characterized by fewer lesions, less pruritus, monomorphic nature, and presence of an eschar at the site of the original bite of the mite.<sup>226</sup> Other features include myalgias, gastrointestinal symptoms, arthralgias, and lymphadenopathy. Although rickettsialpox is self-limited over 7 to 10 days, treatments of choice include doxycycline or chloramphenicol.

## ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF) is caused by *Rickettsia rickettsii* and is the most common rickettsial illness in the United States. In one 4-year period during the mid-1990s, the average annual RMSF incidence was 2.2 cases per million persons, with the highest incidence confirmed among children 5 to 9 years of age (3.7 per million).<sup>227</sup> Of 4800 cases reported to the CDC between 1990 and 1998, 20% of cases and 15% of reported deaths were in children under 10 years of age.<sup>228</sup> During 2000 through 2007, the annual reported incidence of RMSF increased to 7 cases per million persons, the highest rate ever recorded, and children ages 5 to 9 years appeared to have the highest risk of a fatal outcome.<sup>229</sup> Among children living in the southeastern and south central United States, 12% had positive *R. rickettsii* antibody titers in one serologic survey, and hence exposure to the agent may be more common than indicated by reports of disease.<sup>230</sup> Because of the rapid progression of disease and the high mortality rate that may be seen without appropriate therapy, prompt diagnosis and initiation of specific treatment is vital in children with RMSF. Despite the name of this disease, it has been reported throughout the continental United States except for in Maine and Vermont.<sup>228,231</sup> The highest incidence is in Oklahoma, Tennessee, Arkansas, and the South Atlantic region; the most important factor in transmission of the disease is the prevalence of infected ticks.<sup>232,233</sup>

RMSF is transmitted by the bite of the wood tick (*Dermacentor andersoni*) in the Western United States and Canada and the dog tick (*Dermacentor variabilis*) in the Eastern United States. Most cases occur during the spring and summer months. Even in areas considered to be highly endemic for the disease (i.e., Virginia, North Carolina, Oklahoma), only a small fraction of ticks are infected with *R. rickettsii*.<sup>234</sup> Up to 40% of individuals diagnosed with RMSF do not recall a history of tick bite.<sup>234</sup> Importantly, ticks may attach to any body site (some of which are difficult to observe), often have a painless bite, and commonly go unnoticed.<sup>232</sup>

Patients with RMSF usually report symptoms within 14 days of the tick bite. The initial prodromal symptoms include headache, gastrointestinal symptoms, malaise, and myalgias. These are followed by fever and rash. The classic triad of RMSF consists of fever, headache, and rash, but many patients with the disease do not show symptoms in this classic fashion. Headache is a very prominent feature, may be severe, and is usually accompanied by severe myalgias. Patients with gastrointestinal complaints may have nausea, vomiting, and generalized or focal abdominal pain, occasionally mimicking an acute abdomen.<sup>234</sup> Neurologic findings may include meningismus or impaired level of consciousness (which occur in approximately one-third of cases),<sup>235</sup> seizures, and psychiatric complaints. Photophobia may also be present.

An exanthem occurs in up to 90% of patients with RMSF and usually appears around day 3 to 5 of the illness. It begins as discrete erythematous blanching macules and papules, which begin in a peripheral fashion and spread centrally (centripetally). Common locations for early lesions include the ankles, wrists, palms, and soles. With time, the skin lesions evolve into petechial macules and papules

**Figure 16-38** Rocky Mountain spotted fever. Erythematous macules and petechiae involving the hand and forearm.

(Fig. 16-38). Occasionally they become hemorrhagic, and focal areas of necrosis may occur. Larger areas of purpura may be present, and in some patients the skin eruption mimics that of meningococcemia. Skin necrosis and gangrene may occasionally result. Some patients have a delayed appearance of the rash, and in up to 10% the rash is completely absent ("spotless" RMSF).<sup>234</sup> These patients seem to have the same course as patients with a rash, and the index of suspicion must be higher in them, incorporating clinical and epidemiologic clues when present. Other mucocutaneous features may include hyperpigmentation, jaundice, and mucosal erosions.

Laboratory findings in RMSF may include a left shift with a normal to low white blood cell count, thrombocytopenia, liver function abnormalities, and decreased serum sodium. A lymphocytic cerebrospinal fluid pleocytosis is often noted. The differential diagnosis of RMSF includes other rickettsial diseases, meningococcal disease, Kawasaki disease, drug reactions, measles, and other viral exanthems. The diagnosis is usually made on a clinical basis, and if the disease is even remotely suspected, prompt institution of a tetracycline-class antibiotic should occur. Biopsy of skin lesions reveals endothelial-cell damage with a perivascular and interstitial mononuclear-cell infiltrate and small-vessel vasculitis, as well as extravasation of red blood cells and fibrin thrombi within vessels.<sup>236,237</sup> The indirect fluorescent antibody (IFA) test is the most widely used diagnostic examination and detects anti-*R. rickettsii* IgM and IgG antibodies, which are usually present 10 to 14 days after acute infection. Enzyme-linked immunosorbent assay (ELISA) testing has also been utilized.<sup>238</sup> PCR-based diagnosis is typically available only in specialized laboratories. Skin biopsy with immunohistochemical staining is highly specific but may not be available in all locales; when necessary, skin specimens can be submitted to the CDC via state health departments.<sup>239</sup>

The treatment of choice for RMSF is doxycycline, which is preferable to other tetracycline agents because of its reliable absorption, twice-daily dosing schedule, and broader spectrum of coverage for other tick-borne diseases.<sup>232,234</sup> If RMSF is strongly suspected, treatment should be promptly initiated and not delayed while waiting for laboratory confirmation.<sup>239</sup> Chloramphenicol is also effective but is generally used only for patients in whom a contraindication to doxycycline is present (i.e., pregnancy). In an analysis of risk factors for fatal RMSF, evidence for the superiority of tetracyclines was demonstrated even when compared with chloramphenicol therapy.<sup>240</sup> It should be noted that the risk of dental staining, which may be associated with doxycycline therapy in children under 8 years of age, is generally far outweighed by the risk of RMSF going untreated. Doxycycline therapy is recommended by the AAP and by the CDC as the treatment of choice in both RMSF and ehrlichiosis (see below).<sup>241</sup> Dental staining appears to be dose- and duration-related and is unlikely to occur in children treated with short courses of tetracyclines.<sup>233,242</sup> Therapy should be continued until the patient demonstrates clinical improvement and is afebrile for at least 3 days. Most patients are treated for 7 to 10 days.

Useful measures in preventing RMSF include wearing long clothing when outdoors (especially when in high-risk areas for tick bites), use of insect repellents effective against ticks (see Chapter 18), and frequent inspection for ticks with tweezers removal when necessary. It seems that transmission of the organism probably cannot occur until after 24 hours of tick attachment.<sup>243</sup>

## Q FEVER

Q fever, caused by the rickettsia *Coxiella burnetii*, is a worldwide zoonosis affecting domestic animals, birds, and arthropods.<sup>244</sup> It is transmitted to humans through contact with infected domestic animals including cattle, sheep, goats, or the products of these animals.<sup>236</sup> The primary route of human infection appears to be via inhalation of contaminated aerosols, and because the organism has a low respiratory infective dose, there is concern over its potential use as an agent of biologic warfare.<sup>244</sup> Tick bites, ingestion of unpasteurized milk or dairy products, and human-to-human spread are unusual sources of transmission of *C. burnetii* to humans.

The presentation of Q fever in humans is variable, and because the symptoms are so variable, it is likely underreported and underdiagnosed.<sup>245</sup> It may present as a nonspecific flu-like illness, atypical pneumonia, or hepatitis. Other clinical manifestations may include fever, myocarditis, pericarditis, osteomyelitis, and central nervous system infection.<sup>246</sup> Malaise is common and may persist for months after the acute symptoms have disappeared. Rash is reported in up to 20% of patients overall but has a higher prevalence in children (up to 50%) and does not appear to have distinguishing features. Erythematous macules, petechiae, purpura, urticaria, vesicles, livedo reticularis, and erythema nodosum have been reported.<sup>236</sup> Subcutaneous nodules representing necrotizing granulomatous inflammation have also been observed.<sup>247</sup> The diagnosis of Q fever is confirmed by serologic studies or PCR, and treatment in children consists of doxycycline for 14 days, or if the disease is mild and uncomplicated, for 5 days followed by additional treatment with trimethoprim/sulfamethoxazole if fever persists.<sup>245</sup> In some patients, Q fever is a self-limited disease that is diagnosed retrospectively.<sup>244</sup> A history of recent contact with farm animals and pets in the presence of consistent clinical findings should prompt investigation for *C. burnetii*.<sup>246</sup>

## EHRLICHIOSIS

*Ehrlichia* are obligate intracellular bacteria that belong to the family *Rickettsiaceae*. The two forms of disease of most concern in the United States are human monocytic (monocytotropic) ehrlichiosis (HME) and human granulocytic (granulocytotropic) ehrlichiosis (HGE), both of which are transmitted by tick bites and have similar clinical manifestations.

HME is caused by *Ehrlichia chaffeensis*, and occurs primarily in the southeastern and south central United States. States with the highest reported incidences are Mississippi, Oklahoma, Tennessee, Arkansas, and Maryland.<sup>248</sup> The most common vector is the Lone Star tick (*Amblyomma americanum*), and the distribution of disease closely parallels the endemic regions for this arthropod.<sup>249</sup> Most cases of HME occur during late spring and summer.

HGE, also known as human granulocytic anaplasmosis (HGA), is caused by *Anaplasma phagocytophilum*, which was previously known as "the agent of human granulocytic ehrlichiosis."<sup>250</sup> This infection is caused by bites from infected deer ticks or dog ticks and is seen with a broader geographic distribution in the United States. The highest annual incidence rates have been reported in Connecticut, Wisconsin, and New York.<sup>248</sup> Most cases of HGE occur between the months of April and September.

There may be considerable overlap of the clinical manifestations in patients with HME and HGE, although HME tends to be a more severe disease. Nonspecific symptoms of both disorders include fever, fatigue, headache, malaise, chills, myalgia, nausea, and rash (which is more common in pediatric patients). Hematologic aberrations may include

progressive leukopenia, thrombocytopenia, and anemia, and hemophagocytic lymphohistiocytosis has been seen in the setting of *E. chaffeensis* infection.<sup>251</sup> Some patients have elevation of liver transaminases, alkaline phosphatase, and lactate dehydrogenase, and hyponatremia may also be present. Hepatosplenomegaly and systolic murmur are common examination findings in patients with HME.<sup>249</sup> Shock necessitating pressor support and mechanical ventilation has been reported in patients with HME.<sup>252</sup> Neurologic features may include meningitis or meningoencephalitis (especially in HME) and peripheral nerve manifestations such as brachial plexopathy, cranial nerve palsies, facial nerve palsy, and demyelinating neuropathy (primarily in HGE).

The incidence of rash in patients with HME or HGE is not well established but seems to occur less often than that seen in patients with RMSF. It has been described as macular, papular, or petechial. Other less commonly reported patterns include vesicular, nodular, purpuric, vasculitic, erythrodermic, and ulcerated types.<sup>236</sup> The distribution is variable, although in the case of HME, it tends to spare the face, palms, and soles. The onset of the cutaneous eruption is most often within the first 3 to 10 days of the illness. The skin lesions seen in patients with HGE may predominate in the vicinity of the tick bite. The differential diagnosis of ehrlichiosis is broad, including septic shock, meningococcemia, thrombotic thrombocytopenic purpura, toxic shock syndrome, RMSF, Lyme disease, murine typhus, tularemia, babesiosis, and other tick-borne fevers.

Diagnostic options for ehrlichiosis include examination of peripheral blood smears, immunohistology, PCR assay, isolation of the organism, and serologic studies.<sup>248,253</sup> The most clinically relevant laboratory study is that of paired serologies (often via indirect immunofluorescence assay), which often need to be performed by a reference laboratory. Western blotting has also been utilized.<sup>254</sup> The treatment of choice for ehrlichiosis is doxycycline, and chloramphenicol is also a useful agent.<sup>236,249,255</sup> As with RMSF, treatment should be promptly initiated if there is a clinical suspicion for the diagnosis. Rifampin has been successfully used in children with HGE and may be another option for patients with non-life-threatening disease.<sup>111</sup> Efforts to reduce contact with ticks are also useful in lowering the risk of ehrlichiosis.

Fungi are a group of simple plants that lack flowers, leaves, and chlorophyll and get their nourishment from dead or living organic matter, thus depending on plants, animals, and humans for their existence. Fungal infections that affect humans may be superficial, deep, or systemic and can occasionally be fatal. Although they do not rank as pathogens with the bacteria or viruses, a number of species once thought to be ubiquitous and harmless have been implicated in various diseases, and with the increasing use of broad-spectrum antibiotics, corticosteroids, and potent cytotoxic agents and the increasing incidence of acquired immunodeficiency, deep mycoses have become increasingly significant.

The pathogenic fungal diseases are divided into superficial and deep infections. The superficial infections are those limited to the epidermis, hair, nails, and mucous membranes. Deep fungal infections are those in which the organisms affect other organs of the body or invade the skin through direct extension or hematogenous spread.

## Superficial Fungal Infections

There are three common types of superficial fungal infection: dermatophytosis, tinea versicolor, and candidiasis (moniliasis). Those caused by dermatophytes are termed *tinea*, *dermatophytosis*, or because of the annular appearance of the lesions, *ringworm*. In addition, *tinea nigra*, a superficial infection of the stratum corneum caused by a yeast-like fungus and often misdiagnosed as a melanocytic lesion, and *piedra*, an asymptomatic infection of the hair shaft, may be noted in both children and adults.

The dermatophytes are a group of related fungi that live in soil (geophilic), on animals (zoophilic), or on humans (anthropophilic). They digest keratin and invade the skin, hair, and nails, producing a diverse array of clinical lesions. Depending on the involved site, the infection may be termed *tinea capitis*, *tinea faciei*, *tinea barbae*, *tinea corporis*, *tinea manuum*, *tinea pedis*, *tinea cruris*, or *tinea unguium* (*onychomycosis*, *tinea* of the nails). The diagnosis and management of fungal diseases of childhood have become easier in the past decade owing to the development of more effective diagnostic techniques and therapeutic agents.

## DIAGNOSIS OF FUNGAL INFECTIONS

Tests for fungal infection are rewarding procedures readily available to all physicians, not merely those trained in dermatology. Diagnosis of ringworm of the scalp may be aided by the presence of fluorescence under a Wood light examination, although the changing epidemiology of this infection in the United States has made this examination clinically irrelevant in most cases. Other diagnostic studies that may be useful include direct microscopic examination of skin scrapings or infected hairs and fungal culture. These tests can be performed simply, inexpensively, and rapidly in the office. Laboratory confirmation of fungal infection is useful in confirming the diagnosis, in detecting the asymptomatic carrier state, and in the case of *tinea capitis*, in demonstrating a mycologic cure when clinical symptoms have resolved. Dermatophyte identification may also provide useful epidemiologic information (i.e., human-to-human vs. animal-to-human transmission) and may help guide the clinician's choice of antifungal therapy. Definitive proof of fungal infection should be considered when prolonged systemic therapy is being considered, in patients with some features but who lack lymphadenopathy (the most predictive clinical finding), and in patients who fail empiric therapy.<sup>1</sup>

### Wood Light Examination

The discovery in 1925 that hair infected by certain dermatophytes would fluoresce when exposed to ultraviolet light filtered by a Wood filter led to a helpful but occasionally improperly used diagnostic tool. When a Wood light examination is performed, it must be remembered that infected hairs, not the skin, fluoresce when exposed to light rays emitted by this lamp. Although the nature and the source of the fluorescent substance in infected hairs are not fully understood, this phenomenon is believed to be the result of a substance, perhaps pteridine, emitted when the fungus invades the hair.

Optimally, a powerful Wood lamp should be used in a completely darkened room. The usefulness of Wood lamp examination depends on the pattern of arthroconidial formation and hair invasion. Organisms that result in ectothrix infection (i.e., *Microsporum audouinii* and *Microsporum canis*) result in brilliant green fluorescence with this examination. However, those organisms associated with endothrix infection (i.e., *Trichophyton tonsurans* and *Trichophyton violaceum*), where organisms are present within the hair shaft, show no fluorescence. *Trichophyton schoenleinii*, the cause of favus (see below), produces a pale green fluorescence on Wood lamp examination. Sources of error in Wood light examinations include an insufficiently darkened room; the blue or purple fluorescence produced by lint, scales, serum exudates, or ointments containing petrolatum; and failure to remember that it is the infected hair and not the skin that fluoresces.

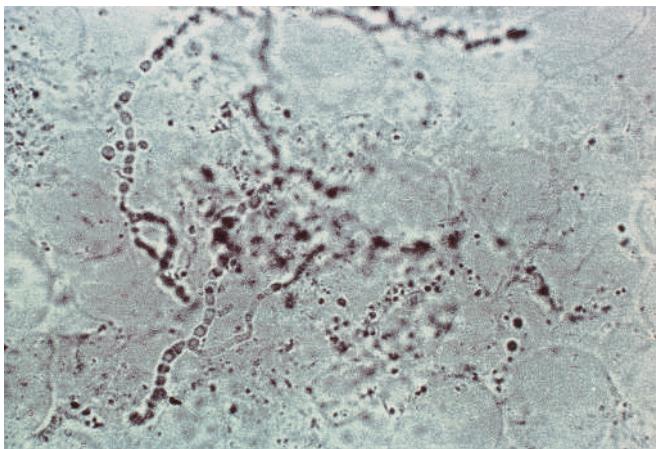

### Potassium Hydroxide Wet-Mount Preparations

Microscopic examination of skin scrapings is an important but commonly overlooked aid in the diagnosis of suspected fungal infection of the skin or hair. This examination will yield rapid results but requires considerable experience, because false-positive interpretations are common. Material for mycologic study should be taken by gently scraping outward from the active border of a suspected lesion with a number 15 scalpel blade or the edge of a glass slide. Moistening the skin with alcohol before performing the scraping may be useful in adhering the skin debris to the blade before it is smeared on a slide. Cut hairs, nail scrapings, subungual debris, and material from the edge of an affected nail may also be used for wet-mount examination. The material is placed on a glass microscope slide with care and spread out flat and evenly in a single layer. A coverslip is applied, and a few drops of 10% to 20% potassium hydroxide (KOH) are added at the side of the coverslip until the entire space between coverslip and slide is filled. Gentle heating of the preparation (with care to prevent boiling of the KOH, because this will cause crystallization) should be performed until the horny cells and debris are rendered translucent. If the KOH solution contains dimethylsulfoxide (DMSO), the slide should not be heated, because heating a DMSO-KOH preparation will dissolve fungi as well as epidermal cells.<sup>2</sup>

After collection and preparation of the specimen, gentle pressure is applied to the coverslip. This will improve the preparation by forcing out trapped air and thinning the specimen, thus allowing better visualization of fungi. The light of the microscope condenser should be dimmed to enhance contrast between branched hyphae and epidermal elements, and the specimen should be viewed under low power. A positive KOH examination reveals branching fungal hyphae with septations (Fig. 17-1).

### Fungal Culture

Although direct microscopic examination of skin scrapings will often confirm the suspicion of *tinea*, definitive identification rests on

**Figure 17-1** KOH examination in tinea. Note the septated fungal elements (hyphae). (Courtesy of Alfred W. Kopf, MD.)

isolation of the fungus by the gold standard, fungal culture. There are several types of fungal culture media, but the most popular are Sabouraud dextrose agar or mycobiotic agar (Mycosel) containing cycloheximide and chloramphenicol, which suppress growth of common saprophytic and bacterial contaminants respectively.<sup>3</sup> Dermatophyte test medium (DTM) agar is another commonly used media that also contains antibiotics (cycloheximide, gentamicin, and chlortetracycline), which inhibit saprophytic fungi and bacteria. DTM also contains a color indicator that changes from yellow to orange to red in the presence of dermatophytes. This medium is particularly useful for physicians who lack detailed knowledge of fungus-colony morphology and simply require confirmation of dermatophyte infection. However, one disadvantage of DTM is that the addition of the color indicator precludes laboratory identification of the exact dermatophyte, because it may obscure some colonial features used to distinguish these organisms.

Specimens for fungal culture may be obtained via a variety of collection procedures. Traditional methods include plucking broken hairs or scraping scale, but these procedures may be frightening or painful for younger children. Other modalities include use of a sterile toothbrush, wet gauze, cytobrushes, and adhesive tape. Use of a cytobrush has demonstrated very high sensitivity when compared with the traditional method of scraping the scalp.<sup>4</sup> The simplicity and reliability of the cotton swab technique has also been confirmed.<sup>5</sup> In this method, a sterile cotton-tipped applicator moistened with tap water (or Culturette swab in transport medium) is rubbed vigorously and rotated over the affected area of the scalp and then inoculated onto the appropriate fungal medium. This technique isatraumatic, readily available, and both sensitive and specific, even with delays between collection and plating of the sample.<sup>5</sup>

Trichoscopy (which refers to dermoscopy of the hair) has been recently reported as a useful diagnostic modality in the diagnosis of various hair disorders including tinea capitis.<sup>6</sup> A dermatoscope is a device composed of a magnifier attached to a nonpolarized light source utilized primarily by dermatologists. As such, this methodology is likely less applicable to the primary care provider. When utilized in tinea capitis, trichoscopy reveals comma-shaped and corkscrew hairs, black dots, and broken (not tapered) hairs.<sup>6,7</sup>

## THE DERMATOPHYTOSES

### Tinea Capitis

Tinea capitis, the most common dermatophytosis of childhood, is a fungal infection of the skin and hair of the scalp characterized by scaling and patchy alopecia. It is generally a disease of prepubertal children, especially those between the ages of 3 and 7 years, although infants and adults are occasionally affected. Neonatal tinea capitis has been reported.<sup>8,9</sup> In a prospective, cross-sectional surveillance study

**Table 17-1** Clinical Manifestations of Tinea Capitis in Children

Clinical Feature	Comment
<b>SCALP</b>	
Alopecia	One or multiple patches; may simulate alopecia areata
Scaling	May be minimally inflammatory; may mimic seborrheic dermatitis
Erythema	Localized or widespread
Pustules	Differential diagnosis includes sterile folliculitis or bacterial folliculitis
"Black dots"	Alopecia with hair shafts broken off at surface of skin; may simulate trichotillomania
Kerion	Boggy, tender plaque with pustules and purulent discharge; represents a vigorous host immune response
Scarring	Rarely seen when untreated; usually follows kerion
Favus	Yellow, cup-shaped crusts around the hair
<b>OTHER</b>	
Lymphadenopathy	Common; cervical or occipital
Id reaction	Widespread, papular or papulovesicular eruption; extremity-predominant; usually seen after initiation of therapy; must be recognized as distinct from true drug reaction

of children in kindergarten through fifth grade in a large U.S. metropolitan area, 6.6% of children overall had positive cultures for *T. tonsurans*, and the infection rates at participating schools ranged from 0% to 19.4%, with African-American children demonstrating the highest rates of infection (12.9%).<sup>10</sup>

A variety of dermatophytes may cause tinea capitis, especially *T. tonsurans* (the most common etiology in the United States, where it causes >90% of infections), *T. violaceum*, *M. canis*, and *M. audouinii*. Across Europe, *M. canis* remains the most common organism, although shifts toward *T. tonsurans* are being observed, especially in the United Kingdom.<sup>11</sup> These organisms may be anthropophilic (spread from humans, i.e., *T. tonsurans* and *T. violaceum*); zoophilic (spread from animals, i.e., *M. canis* and *M. audouinii*); or geophilic (spread from soil). Dermatophytes have a short incubation period (generally 1 to 3 weeks) and infect boys more commonly than girls. Predisposing factors for tinea capitis include large family size, crowded living conditions, and low socioeconomic class.<sup>3</sup> In addition to transmission from other humans or animals, dermatophyte spread via fomites (hairbrushes, combs, hats, and contaminated grooming instruments) is well documented. The reason for increased resistance to tinea capitis infection after puberty is unknown, but may be related to a higher content of fungistatic fatty acids in the sebum of postpubertal individuals. Hair-care practices (styling, frequency of washing, use of oils or grease), traditionally believed to play a significant role in the acquisition of tinea capitis, appear to not play a major role.<sup>12</sup>

Asymptomatic scalp carriage of dermatophytes varies and tends to correlate with the amount of tinea capitis in a community.<sup>13</sup> Such carriers constitute a major reservoir for transmission of the organisms causing the disease. Asymptomatic carriage is most common with the anthropophilic organisms *T. tonsurans* and *T. violaceum*, and most carriers are African-American, Afro-Caribbean, or black children in Africa.<sup>3</sup> Household contacts may be a significant source of asymptomatic carriers, and cosleeping and comb sharing seem to be important factors in the spread of disease in this setting.<sup>14</sup> Varied treatment options have been suggested for the carrier state, although there is a paucity of well-designed clinical studies.

The clinical manifestations of tinea capitis are varied and are summarized in Table 17-1. It may present in a "seborrheic dermatitis" pattern, with diffuse scaling and minimal inflammation (Fig. 17-2).

**Figure 17-2** Tinea capitis. Diffuse scaling with minimal erythema and patchy alopecia.

**Figure 17-3** Tinea capitis. Multiple patches of alopecia with erythema and scaling. Note the presence of pustules.

One or multiple patches of alopecia may be present (Fig. 17-3), and at times tinea capitis may present in a fashion similar to alopecia areata. “Black dot” tinea presents with alopecic areas with small black dots within them, representing the ends of broken off hair shafts (Fig. 17-4). This form is most commonly seen with endothrix infections such as *T. tonsurans*. It should be noted that the black-dot sign is probably overemphasized and although present may often be relatively inconspicuous.

Scalp pustules may be present (Fig. 17-5) and need to be distinguished from bacterial or sterile folliculitis. Kerion (Fig. 17-6) is a markedly inflammatory presentation of tinea capitis and reveals a boggy plaque with alopecia, pustules, and often purulent drainage from the surface. These lesions represent a vigorous host immune response to the dermatophyte and are caused most often by *M. canis* and *T. tonsurans* (and in rural areas by *Trichophyton verrucosum*). Although kerions may heal spontaneously, aggressive therapy is desirable, because the severe inflammatory response may result in permanent scarring alopecia (Fig. 17-7). Kerion has also been observed in neonates.<sup>15</sup>

Lymphadenopathy, especially cervical or suboccipital, is very common in patients showing symptoms of tinea capitis. In one study, presence of lymphadenopathy was highly suggestive of a positive fungal culture in children who were suspected of having tinea capitis, especially those with the concomitant presence of alopecia or scaling.<sup>16</sup>

Favus, a severe chronic form of tinea capitis rarely seen in the United States, is caused by the fungus *T. schoenleinii*. This disorder is characterized by scaly erythematous patches with yellow crusts or “scutula,” representing hairs matted together with hyphae and keratin

**Figure 17-4** “Black dot” tinea capitis. This well-demarcated patch of alopecia is composed of numerous broken-off hair shafts (black dots).

**Figure 17-5** Tinea capitis. This young girl had multiple pustules throughout her scalp with minimal inflammation, scaling, or alopecia. Culture revealed *Trichophyton tonsurans*.

**Figure 17-6** Kerion. This fluctuant, erythematous, boggy, and crusted plaque was exquisitely tender to palpation. *Trichophyton tonsurans* was isolated in fungal culture.

debris (Fig. 17-8). Such infections often result in scarring and permanent alopecia.<sup>17</sup>

A widespread papular hypersensitivity or dermatophytid (id) reaction may occur in patients with tinea capitis. This usually presents as tiny lichenoid papules on the scalp, trunk, and extremities (Fig. 17-9)

**Figure 17-7** Scarring alopecia after kerion. This patch of alopecia persisted after therapy for a severe kerion.

**Figure 17-8** Favus. This severe form of tinea capitis is caused most often by *Trichophyton schoenleinii*. (Courtesy of Israel Dvoretzky, MD and Benjamin K. Fisher, MD.)

that may be pruritic. This reaction is commonly seen after initiation of antifungal therapy and needs to be differentiated from a drug reaction so as to avoid the unnecessary discontinuation of therapy for the tinea. Although this distinction may not always be straightforward, drug reactions tend to be morbilliform, more widespread, and more erythematous. Id reactions represent an immune response to the dermatophyte and are best treated symptomatically with topical corticosteroid preparations and oral antihistamines as needed.

The differential diagnosis of tinea capitis includes seborrheic dermatitis, psoriasis, alopecia areata, trichotillomania, folliculitis, impetigo, lupus erythematosus, and a variety of less common scalp dermatoses. Confirmation of the diagnosis is desirable, and the gold standard is fungal culture, as discussed earlier. Wood light examination may be useful if the infection cause is an ectothrix organism but this is less common in the United States. Demonstration of the fungus by KOH wet-mount preparations of broken hairs or black dots col-

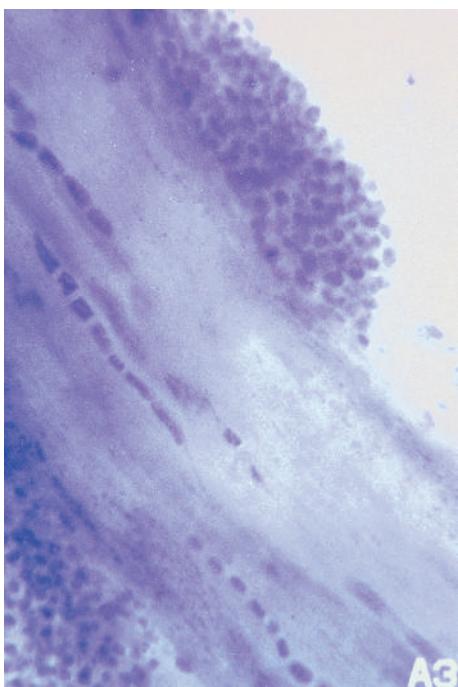

**Figure 17-9** Dermatophytid (id) reaction. These flesh-colored, pruritic papules developed on the extensor extremities (**A**) and face (**B**) after initiating oral therapy for tinea capitis.

lected with a forceps or of skin scrapings from scaly areas may be useful. Microscopic examination of an infected hair (Fig. 17-10) will reveal tiny arthrospores surrounding the hair shaft in *Microsporum* infection (ectothrix infection) and chains of arthrospores within the hair shaft (endothrix infection) in *T. tonsurans* and *T. violaceum* infections.

The color change in a DTM-plated fungal culture may begin within 24 to 48 hours for fast-growing dermatophytes and appears as a pinkish or red zone around the developing colony. The color will intensify as growth proceeds, with full color development for most cultures in 3 to 7 days (Fig. 17-11). When DTM medium is used, however, the culture should not be evaluated for color after 10 days, because contaminant fungal growth may cause color change by that time, thus leading to false-positive results. It must be remembered that fungi grow best at room temperature and require oxygen. Accordingly, the culture media should be left at room temperature, and the tops of the culture tubes or bottles should be left slightly unscrewed (or the tubes maybe covered only with a cotton plug) to allow aeration of the preparation.

Tinea capitis requires systemic therapy, because the drug needs to penetrate the hair follicle. For decades, the treatment of choice for tinea capitis has been griseofulvin, and this drug remained the only agent approved by the US Food and Drug Administration (FDA) for the treatment of this disorder in children until recently. Terbinafine oral granules are now approved by the FDA for treatment of tinea capitis in children 4 years of age and older. Several other agents, including the azole antifungals (fluconazole, itraconazole, and ketoconazole) have been increasingly evaluated as alternative approaches to therapy. Hence, although griseofulvin remains the gold standard, newer treatment options continue to be explored and may, in the near future lead to a modification of the traditional approach to therapy. In some instances, these newer agents may be preferable given similar efficacy to griseofulvin and shorter treatment durations.<sup>18</sup>

Griseofulvin is a well-tolerated and safe drug that has been extensively used worldwide for this indication. Although in the past doses

**Figure 17-10** KOH examination of hair. Note multiple spores surrounding the hair shaft (ectothrix) in this patient with *Microsporum* infection. (Courtesy of Alfred W. Kopf, MD.)

**Figure 17-11** Fungal cultures. Cultures plated on Sabouraud agar (top row, two on left) and dermatophyte test medium (DTM; top row, two on right) reveal fungal growth and color change (yellow to red on DTM), confirming the presence of a dermatophyte.

of 10 mg/kg per day were utilized, most experts currently recommend 20 to 25 mg/kg per day of microsize griseofulvin for 6 to 8 weeks (10 to 15 mg/kg per day if the ultramicrosize form is used). Absorption of griseofulvin is enhanced by a fatty meal, which should be recommended to the patient and parents. Treatment failures are reported and may represent increasing resistance of dermatophytes, although noncompliance with therapy or repeat exposure to infected contacts are probably more common reasons for treatment failure.

Side effects of griseofulvin are rare and include headache, gastrointestinal disturbance, photosensitivity, and rare morbilliform drug reactions. Hematologic and hepatic toxicity is very uncommon, and routine laboratory monitoring is generally not recommended. Although potential cross allergy with penicillins or cephalosporins is often mentioned, in reality this risk is quite low. Concomitant therapy with an antifungal shampoo such as ketoconazole or selenium sulfide

twice to thrice weekly is desirable, because these agents may aid in removing scales and eradicating viable spores, which may help decrease the potential spread of infection.<sup>19,20</sup> This recommendation should be made regardless of the choice of the systemic agent.

Contraindications to griseofulvin therapy include pregnancy, hepatic failure, and porphyria (especially acute intermittent, variegate, and porphyria cutanea tarda). The drug has rarely been implicated in causing exacerbations of lupus erythematosus or lupus-like syndromes.<sup>21</sup> Drug interactions include warfarin-type anticoagulants, barbiturates, and oral contraceptives, and in addition, a disulfiram-like reaction may occur with alcohol ingestion.

Terbinafine is an allylamine antifungal agent that has been demonstrated very effective as therapy for tinea capitis. It is currently approved for onychomycosis and as noted above, was more recently approved for treatment of tinea capitis in children 4 years of age and older (in the oral granules formulation). Comparative studies between terbinafine and griseofulvin have demonstrated that treatment with the former for 4 weeks is at least as effective as griseofulvin for 8 weeks.<sup>22,23</sup> In a comparison of terbinafine oral granules with griseofulvin oral suspension, the former resulted in greater rates of clinical cure and mycologic cure for patients infected with *T. tonsurans* (but not *M. canis*).<sup>24</sup> Metaanalyses of trials comparing griseofulvin to terbinafine have confirmed that the former is superior for infections caused by *M. canis*, whereas terbinafine may be superior for infections caused by *T. tonsurans*.<sup>25,26</sup> Studies have evaluated a variety of terbinafine treatment regimens and durations, including continuous therapy for 1 to 10 weeks (package recommendation for terbinafine granules: 6 weeks) and pulsed dosing, somewhat similar to that described for itraconazole (see below). Suggested dosing regimens for terbinafine include 3 to 6 mg/kg per day or a schedule based on patient weight. According to this schedule, the granules (which come in packets of either 125 mg or 187.5 mg) are dosed as follows: weight less than 25 kg: 125 mg/day; 25 to 35 kg: 187.5 mg/day; greater than 35 kg: 250 mg/day.<sup>27</sup> When the granules are used, they should be sprinkled onto nonacidic food such as mashed potatoes or pudding and swallowed without chewing.<sup>28</sup> Some authors have suggested that the weight-scheduled dosing may underdose individuals at the high-end of the weight range. In a duration-finding study of terbinafine in the treatment of tinea capitis, a 2- or 4-week regimen was found to be clinically superior to a 1-week regimen.<sup>29</sup> If it is used, higher doses of terbinafine or a longer course of therapy may be necessary for *M. canis* infections.<sup>30,31</sup>

Oral terbinafine has an excellent safety profile overall and is the most commonly used systemic antifungal agent in Europe.<sup>32</sup> Side effects related to its use are rare and include gastrointestinal symptoms, dizziness, headache, taste or smell disturbances, depression, and uncommonly, drug reactions (see Chapters 20 and 22). Elevated hepatic transaminases and cytopenias are occasionally seen, and some drugs including cimetidine, terfenadine, and cyclosporine may interact. Laboratory monitoring (complete blood cell count and liver enzymes) at baseline and during therapy is advisable.

Ketoconazole, a broad-spectrum azole antifungal compound, has good activity against dermatophytes, especially *Trichophyton* species. However, given the potential risk of hepatotoxicity and the lack of a liquid formulation, this drug is not a favorable alternative to griseofulvin. Other azole antifungal agents such as fluconazole and itraconazole seem to offer more promise as alternative agents in the treatment of tinea capitis.

Fluconazole, which is currently approved for systemic mycoses, has been demonstrated effective in tinea capitis and as with the other newer agents, may require a shorter treatment duration. It has an excellent safety profile, is usually well tolerated, and is available in a liquid suspension for children (10 and 40 mg/mL). Fluconazole has shown efficacy against both *Microsporum* and *Trichophyton* species. Most studies have evaluated dosing of 3 to 6 mg/kg per day for 2 to 4 weeks.<sup>33-35</sup> Once weekly pulse dosing for 8 to 12 weeks has also been demonstrated effective.<sup>36</sup> Potential adverse effects of fluconazole include gastrointestinal symptoms, headache, drug interactions, and drug reaction. Hematologic and hepatic toxicity may occasionally occur.

Itraconazole is another azole antifungal agent that has been studied for use in tinea capitis, where it has been demonstrated effective in

most (but not all) studies. It is currently approved for onychomycosis and some systemic mycoses, and in studies has shown efficacy against both *Microsporum* and *Trichophyton* species. Itraconazole is effective in a 100-mg capsule and a 10 mg/mL oral solution. The dosing recommended for this agent is 3 to 5 mg/kg per day, with the lower end of the dosing schedule utilized when the oral solution is used. There are numerous studies evaluating itraconazole as a therapy of tinea capitis, and it has been demonstrated effective both in continuous dosing for 2 to 12 weeks and in a variety of pulsed dosing regimens. One such pulsed regimen consists of a daily dose for 1 week followed by repeat pulsing for 1 week given 2 weeks later, and a third pulse given 3 weeks after the second pulse.<sup>37</sup> In this regimen, the decision to administer the second or third pulse was determined by the response of the patient at that point in the therapy. Side effects of itraconazole therapy include headache, gastrointestinal complaints, and occasional hepatic dysfunction. The oral solution seems to be associated with an increased incidence of gastrointestinal side effects. Multiple drug interactions are possible, and hence all concomitantly ingested medications should be carefully referenced before considering itraconazole therapy.

An important consideration in the child with tinea capitis is school attendance and the issue of contagiousness. It is not practical to keep children with tinea capitis out of the classroom, because spore shedding may continue for months, even after adequate therapy.<sup>38</sup> Appropriate therapy should be instituted, and children receiving treatment should be allowed to attend school.<sup>39</sup> Measures should be taken, where feasible, to avoid transmission between susceptible hosts, including no sharing of combs, brushes, hats, or hooded jackets. In patients in whom appropriate therapy has not led to improvement in symptoms, siblings and close contacts should be examined and fungal cultures performed. Haircuts, shaving of the head, or wearing a cap during treatment are unnecessary.<sup>39</sup>

The treatment of kerion (also known as *kerion celsi*) deserves special mention. These markedly inflammatory reactions not uncommonly result in permanent scarring alopecia, and therefore rapid institution of aggressive therapy is indicated. In addition to antifungal therapy, systemic antibiotics should be considered, especially in the presence of significant crusting, because secondary bacterial infection may concomitantly occur. Skin swab for bacterial culture and sensitivity may be useful in this setting to guide the choice of antimicrobial. Oral corticosteroids are recommended by many in the treatment of kerions in a dose of 0.5 to 1 mg/kg per day for 2 to 4 weeks, although good controlled studies are lacking. Anecdotally this approach seems to be associated with more rapid resolution of the inflammation and reduction of pain. However, some authors report excellent outcomes in patients with kerion that was treated with antifungal therapy alone.<sup>40</sup>

### Tinea Faciei

Dermatophyte infection of the face is referred to as *tinea faciei*. Although it often presents in a similar fashion to *tinea corporis* (see below) with annular, scaly plaques (Fig. 17-12), *tinea faciei* may sometimes be quite subtle clinically, especially if topical corticosteroids have been used. In some instances, when the classic annular configuration is absent or the changes are markedly inflammatory, it is referred to as *tinea incognito* (Figs. 17-13 and 17-14), which may also occur in nonfacial areas (Fig. 17-15). *Tinea incognito* typically occurs in patients who have received preceding therapy with topical corticosteroids or calcineurin inhibitors.<sup>41</sup> Although localized mild *tinea faciei* may respond to topical antifungal therapy, systemic treatment (as described for *tinea capitis*) is often required to completely clear these lesions and minimize the rate of recurrence.

### Tinea Barbae

*Tinea barbae* is an uncommon fungal infection of the bearded area and surrounding skin of adolescent and adult males. Because the most common etiologic agents are zoophilic species of *Trichophyton mentagrophytes* and *T. verrucosum* (occasionally *T. violaceum* and *Trichophyton rubrum*), it occurs primarily among individuals from rural areas in close contact with cattle or other domestic animals. Autoinoculation of *T. rubrum* from infected nails (onychomycosis) has been reported in association with *tinea barbae*.<sup>42</sup>

The infection is usually confined to one side of the face and may consist of a solitary lesion or multiple areas of involvement. The

**Figure 17-12** *Tinea faciei*. Annular, erythematous scaly plaques of the face.

**Figure 17-13** *Tinea faciei/incognito*. This markedly inflamed ear had been treated with a variety of topical preparations (including topical corticosteroids, after which the annular border developed) before the diagnosis of *tinea*.

majority of infections are characterized by highly inflammatory purulent papules, pustules, exudate, crusting, and boggy nodules. The hairs within the infected areas are loose or absent, and pus may be expressed through the follicular openings. Spontaneous resolution may occur, or the lesions may persist for months with resultant alopecia and scar formation. Occasionally a less inflammatory superficial variety may occur, characterized by mild pustular folliculitis, erythematous patches with broken-off hairs, and a vesiculopustular border with central clearing similar to that seen in *tinea corporis*.

*Tinea barbae* must be differentiated from bacterial folliculitis of the bearded area (sycosis barbae), contact dermatitis, herpes zoster, or severe herpes simplex. Sycosis barbae is distinguished by the presence of papular and pustular lesions pierced in the center by a hair that is loose and easily extracted. Herpes simplex or herpes zoster usually presents with clusters of vesicles or erosions on an erythematous

**Figure 17-14** Tinea faciei/incipit. This 2-year-old girl was treated with topical antibiotics and steroids before referral. Culture grew *Trichophyton tonsurans*, and the infection cleared with combined oral and topical antifungal therapy.

**Figure 17-16** Tinea corporis. An expanding, erythematous, annular plaque.

**Figure 17-15** Tinea incognito. This impressive dermatitis involving the diaper region ultimately cleared after systemic antifungal therapy. Fungal culture revealed *Trichophyton mentagrophytes*.

**Figure 17-17** Tinea corporis. Multiple annular, erythematous, scaly plaques, with hyperpigmentation of the upper back and shoulders of a teenaged boy.

base, and the diagnosis is confirmed by Tzanck preparation, direct fluorescent antibody examination, or viral culture. Tinea barbae can be confirmed by microscopic examination of a KOH wet-mount of skin scrapings for fungal elements and/or fungal culture.

Treatment of tinea barbae consists of warm compresses (which help to remove crusts) and topical or oral antibiotics for the common secondary bacterial infection. The mainstay of therapy is an oral antifungal agent. With appropriate therapy, resolution occurs over 4 to 6 weeks.

### Tinea Corporis

Superficial tinea infections of the skin are termed *tinea corporis*. Sites of predilection include the nonhairy areas of the face (particularly in children; see *Tinea Faciei*), the trunk, and extremities, with exclusion of ringworm of the scalp (*tinea capitis*), bearded areas (*tinea barbae*), groin (*tinea cruris*), hands (*tinea manuum*), feet (*tinea pedis*), and nails (*onychomycosis*). Contact with other individuals, such as is seen in high school and college wrestlers ("*tinea corporis gladiatorium*"), and domestic animals, particularly young kittens and puppies, is a common cause of the affliction in children. The causative organism in young children is often *M. canis* and occasionally *M. audouinii* or *T. mentagrophytes*. In older children and adults, *T. rubrum*, *T. verrucosum*, *T. mentagrophytes*, or *T. tonsurans* are more likely to be responsible. In children with infection caused by *T. rubrum* or *Epidermophyton floccosum*, parents with tinea infection (especially *tinea pedis* or *onychomycosis*) are commonly the source of infection.

*Tinea corporis* tends to be asymmetrically distributed and is characterized by one or more annular, sharply circumscribed scaly plaques with a clear center and a scaly, vesicular, papular, or pustular border (hence the term *ringworm*) (Figs. 17-16 and 17-17). When multiple lesions are present they may become coalescent, resulting in bizarre polycyclic configurations (Fig. 17-18). Although *tinea corporis* may occur in people of all ages, it is most commonly seen in children, in individuals in warm humid climates, and in patients with systemic diseases such as diabetes mellitus, leukemia, or immunodeficiency. Although extensive *tinea* infection is considered a sign of possible immunodeficiency, it may also occur in otherwise-healthy, immunocompetent children (Fig. 17-19).

*Tinea corporis* is commonly manifested as classic ringworm with annular, oval, or circinate lesions. The pattern may, however, be variable, and it may mimic a variety of other dermatoses, including the herald patch of pityriasis rosea, nummular eczema, psoriasis, contact dermatitis, seborrheic dermatitis, *tinea versicolor*, vitiligo, erythema migrans (Lyme disease), granuloma annulare, fixed drug eruption, and lupus erythematosus. The use of topical corticosteroids may mask the diagnosis by altering the presenting features while the infection persists. Presentations that may occur in this setting include *tinea incognito* (as described) and Majocchi granuloma. This perifollicular granulomatous disorder, which also occurs on the legs of women with *tinea* who shave, is a distinctive variant of ringworm and essentially represents a granulomatous folliculitis and perifolliculitis caused by *T. rubrum* or *T. mentagrophytes*. It presents with erythematous plaques

**Figure 17-18** Tinea corporis. Multiple annular erythematous plaques with confluence and a polycyclic configuration occurred in this immunocompromised patient.

**Figure 17-20** Majocchi granuloma. This annular plaque developed follicular papules after treatment with topical corticosteroids.

**Figure 17-19** Tinea corporis. Extensive involvement was noted in this otherwise healthy, immunocompetent 3-year-old girl. Culture revealed *Trichophyton mentagrophytes*.

**Figure 17-21** Majocchi granuloma. An annular plaque studded with multiple small pustules. This lesion developed after treatment with topical corticosteroids.

or patches that reveal scattered papules, papulonodules, or pustules studding the surface (Figs. 17-20 and 17-21). If observed early in the course of the process, a hair may be noted in the center of the papular or pustular lesions.

Tinea corporis can often be diagnosed based upon the clinical presentation. Diagnostic examinations include KOH wet-mount examination of skin scrapings and fungal culture, as described earlier for tinea capitis. Wood lamp examination is usually not useful for diagnosing tinea corporis.

Confusion often exists among nondermatologists regarding the classification and management of cutaneous fungal infections. By definition, this term incorporates disorders caused by either dermatophyte or *Candida* infection. It must be recognized, however, that dermatophytes and *Candida* are not synonymous, and that although nystatin is an effective agent against candidal infection, it is inappropriate and ineffective in the treatment of tinea (dermatophyte) infections. Conversely, some antifungal preparations that are active against dermatophytes, such as tolnaftate and terbinafine, seem to be minimally effective agents for treating candidal infections.

Topical antifungal therapy is generally effective for superficial or localized tinea corporis. These agents are usually applied twice daily, are well tolerated, and have very few side effects aside from occasional instances of irritant or allergic contact dermatitis. Table 17-2 lists some commonly used topical antifungal agents for dermatophyte infections.<sup>43</sup> Although clinical improvement and relief of pruritus may be seen within the first week of therapy, treatment should be continued for at least 2 to 3 weeks to ensure complete resolution.

If a patient shows no clinical improvement after several weeks of therapy, the diagnosis should be reconsidered or if confirmed and the patient has recalcitrant disease, a course of systemic therapy may be required. In certain situations, systemic antifungal therapy (similar to that described for tinea capitis) may be necessary from the start. These may include disseminated or severe disease, infection in an immunocompromised host, and Majocchi granuloma, in which case the depth of infection within the hair follicle requires the degree of penetration permitted only by a systemic agent.

Combination antifungal/corticosteroid preparations (i.e., 1% clotrimazole/0.05% betamethasone dipropionate) are widely used by nondermatologists in the treatment of superficial fungal infections, but care should be exercised with these products because their use may result in persistent or worsening infection.<sup>44,45</sup> In addition, some of these products contain a fairly potent corticosteroid, and hence their indiscriminate use can result in topical corticosteroid toxicities, including skin atrophy, telangiectasia, striae (Fig. 17-22), or systemic absorption. In some instances, such as severe tinea manuum or tinea pedis, such a combination product may be useful but should be applied for no longer than 2 to 4 weeks. This combination product should never be used in the diaper area, on the face, in fold areas, or under occlusion, and it is not recommended for children younger than 12 years of age.

Tinea corporis gladiatorum, which can impact an individual wrestler's ability to compete, as well as have an effect on entire wrestling squads, may require systemic therapy, especially when extensive. Many have advocated different approaches for prevention, although

**Figure 17-22** Steroid-induced striae. These lesions developed in the axilla of this patient after long-term therapy with betamethasone dipropionate in combination with clotrimazole. (Courtesy of Leonard Milstone, MD.)

well-designed clinical trials have been minimal. In one study, 100 mg of oral fluconazole given once weekly resulted in a significantly decreased incidence of infection when compared with placebo.<sup>46</sup> In a prospective longitudinal study, 100 mg of fluconazole given once daily for 3 days before onset of the competitive wrestling season and again 6 weeks into the season led to a dramatic decrease in the incidence rate of tinea gladiatorum.<sup>47</sup>

### Tinea Imbricata

Tinea imbricata (Tokelau), which is caused by *Trichophyton concentricum*, is a superficial dermatophyte infection seen primarily in tropical regions of the Far East, South Pacific, South and Central America, and parts of Africa. It is characterized by concentric rings of scaling that form extensive patches with polycyclic borders. With time, the lesions spread peripherally and form large plaques that may cover almost the entire skin surface, although the scalp, axillae, palms, and soles are usually spared. When fully developed, the concentric rings are seen as parallel lines of scales overlapping each other, resembling tiles or shingles (*imbrex* means “having overlapping edges,” like a shingle) on

a roof. Diagnosis is based on the characteristic clinical presentation, microscopic demonstration of interlacing septate hyphae, and identification of the organism by fungal culture. Although treatment with a systemic antifungal agent will usually clear the eruption within 2 to 4 weeks, there is a tendency for recurrence when treatment is discontinued. Susceptible individuals tend to carry the disease for their lifetime, given the difficulty in achieving a total cure.<sup>48</sup>

### Tinea Cruris

Tinea cruris (“jock itch”) is an extremely common superficial fungal infection of the groin and upper thighs. It is seen primarily in male adolescents and adults and occurs less commonly in females. Tinea cruris is most symptomatic in hot, humid weather and is most commonly noted in obese individuals or those subject to vigorous physical activity and chafing. Tight-fitting clothing such as athletic supporters, jockey shorts, wet bathing suits, and panty hose may contribute to this condition as well. The three most common dermatophytes to result in tinea cruris are *E. floccosum*, *T. rubrum*, and *T. mentagrophytes*. Tinea pedis is a common coexisting condition, possibly related to autoinoculation of the dermatophyte with clothing that comes into contact with the feet.

Tinea cruris presents as sharply marginated, erythematous plaques with an elevated border of scaling, pustules, or vesicles. It is usually but not always bilaterally symmetric and involves the intertriginous folds near the scrotum, the upper inner thighs (Fig. 17-23), and occasionally the perianal regions, buttocks, and abdomen. The scrotum and labia majora are usually spared, and if they are involved or satellite papulopustules are present, the diagnosis of candidiasis (Fig. 17-24) should be considered. The lesions of tinea cruris may vary in color from red to brown, and central clearing may be present. In chronic infection the redness and scaling may be slight, the active margin may be subtle or ill-defined, and lichenification may be present.

Tinea cruris must be differentiated from intertrigo, seborrheic dermatitis, psoriasis, irritant contact dermatitis, allergic contact dermatitis (generally resulting from therapy), or erythrasma (a superficial dermatosis caused by the diphtheroid *Corynebacterium minutissimum*). A characteristic coral-red fluorescence under Wood light examination is helpful in distinguishing erythrasma (see Chapter 14). The diagnosis of tinea cruris can be confirmed by a KOH wet-mount microscopic examination of cutaneous scrapings or by fungal culture.

Topical therapy (as discussed for tinea corporis) usually suffices for tinea cruris and is applied for 3 to 4 weeks. Other useful measures include reducing excessive chafing and irritation by the use of loose-fitting cotton underclothing, drying thoroughly after bathing or perspiration, and weight loss. The use of an absorbent antifungal powder (i.e., Micatin, Tinactin, or Zeasorb-AF) is sometimes helpful, and oral antifungal therapy is occasionally indicated for severe or recalcitrant disease. Tinea pedis, if present, should also be adequately treated as a preventative measure.

**Figure 17-24** Genital candidiasis. Erythema and scaling of the scrotum with involvement of the adjacent thigh regions. Note the associated satellite papules.

**Figure 17-25** Intertriginous tinea pedis. Scaling, erythema, and maceration of the plantar foot and toe-web spaces.

### Tinea Pedis

Tinea pedis, or “athlete’s foot,” is relatively uncommon in young children but quite common in adolescents and adults, in whom it represents the most prevalent type of ringworm infection. Although children are not completely immune, most instances of athlete’s foot in prepubertal individuals actually represent misdiagnosed cases of foot dermatitis, dyshidrotic eczema, contact dermatitis, or other dermatoses.<sup>49,50</sup> The differential diagnosis of tinea pedis also includes psoriasis, juvenile plantar dermatosis, erythrasma, and secondary syphilis. Associated conditions or complications include onychomycosis (see **Tinea Unguium [Onychomycosis]**), secondary bacterial superinfection, id reaction, and cellulitis.

The etiologic agents most often responsible for tinea pedis are *T. rubrum* and *T. mentagrophytes* and less often *E. floccosum* or (especially in children) *T. tonsurans*. The disorder may present clinically in a variety of different ways. The interdigital type, which is the most common presentation, reveals inflammation, scaling, and maceration in the toe-web spaces (Figs. 17-25 and 17-26), especially the lateral ones. The inflammatory or vesicular type shows inflammation with vesicles (Fig. 17-27) or larger bullae and usually results from *T. mentagrophytes* infection. This type occurs most often in summer, and an immune response to fungal elements may be reflected by a vesicular id eruption on the hands, extremities, and trunk. Moccasin-type tinea pedis presents with erythema, scaling, fissuring, and hyperkeratosis

**Figure 17-26** Tinea pedis. This 6-year-old girl showed erythema and desquamation of the plantar foot and toes (A) and toe-web erythema and maceration (B).

**Figure 17-27** Vesicular tinea pedis. Erythema and scaling are accompanied by intensely pruritic, deep-seated vesicles on the plantar surface.

on the plantar surfaces (Fig. 17-28), often extending to the lateral foot margins. Contrary to the eruption seen in foot eczema, the dorsal aspects of the toes and feet are usually spared, although they may occasionally be involved (Fig. 17-29). This form may be resistant to topical therapy, thus requiring an oral antifungal medication.

The diagnosis of tinea pedis is based upon the clinical picture, with confirmation by KOH examination and fungal culture. Treatment may be challenging, and efforts to protect the feet from commonplace sites of exposure to the organisms (i.e., public showers, gyms, locker rooms,

**Figure 17-28** Moccasin-type tinea pedis. Erythema and scaling with involvement of the lateral foot borders. Note the associated onychomycosis.

**Figure 17-29** Tinea pedis. Involvement of the dorsal surface of the foot is occasionally noted. Note the toe-web involvement.

pool decking) and to keep the feet dry are both important. Such efforts might include thorough drying of the feet after bathing, avoidance of occlusive footwear or nonbreathable socks, and the use of sandals or other footwear in high-risk areas. Absorbent antifungal powders or sprays may be used once or twice daily in individuals prone to these infections, especially after physical exertion and bathing. Those prone to hyperhidrosis can use 6.25% to 20% aluminum chloride (i.e., Certain Dri, Drysol, or Xerac AC) in an effort to decrease recurrent infection.

The usual treatment of choice for tinea pedis is a topical antifungal preparation applied twice daily. Acute vesicular lesions are best treated with wet compresses applied for 10 to 15 minutes two to four times daily in addition to the antifungal therapy. In patients with severely inflammatory disease or those with underlying chronic medical conditions such as diabetes or immunosuppression, oral antifungal therapy should be considered. The choices for oral therapy are similar to those discussed for tinea capitis, and a review of the literature reveals that terbinafine may be one of the more effective agents for this indication.<sup>51</sup>

In instances in which the diagnosis is indeterminate, a topical antifungal agent and a corticosteroid formulation may both be used for a short period (2 to 4 weeks), at which time a fungal culture performed at the initiation of therapy can generally confirm or refute the diagnosis of tinea. If the diagnosis of tinea pedis is confirmed, the topical corticosteroid can be discontinued. Moccasin-type tinea pedis may require the addition of a keratolytic agent (i.e., lactic acid or urea) in addition to the antifungal in order to treat the hyperkeratosis and accentuate penetration of the antimicrobial. Id reactions, when present, are best treated with topical corticosteroids and oral antihistamines (if needed) and generally improve with eradication of the primary infection.

### Tinea Manuum

Ringworm infection of the palmar hand (tinea manuum) is uncommon in childhood and when present is generally seen in postpubertal individuals. When ringworm occurs on the dorsum of the hand, it is referred to as *tinea corporis* rather than *tinea manuum*. Tinea manuum is usually unilateral and is caused by the same fungi responsible for tinea pedis: *T. rubrum*, *T. mentagrophytes*, and *E. floccosum*. It may be seen in association with tinea pedis, and when occurring on only one hand, presents in a fashion that has been termed *two-foot, one-hand syndrome*.

Clinical manifestations include a diffuse hyperkeratosis of the fingers and palm and a less common patchy inflammatory or vesicular reaction. Involvement of the fingernails (onychomycosis, see below) commonly occurs and may be a clue to the diagnosis. When onychomycosis is present, it usually involves some but not all of the nails on the affected hand. Total nail involvement, if present, should suggest the possible diagnoses of psoriasis or lichen planus. The differential diagnosis of tinea manuum includes psoriasis, allergic or irritant contact dermatitis, dyshidrosis, and an id reaction. Unilateral involvement may be another clue to the diagnosis, which can be confirmed by KOH microscopic examination or fungal culture.

The management of tinea manuum is essentially the same as that recommended for tinea pedis, and when the latter infection is simultaneously present, it should be appropriately treated as well.

### Tinea Unguium (Onychomycosis)

*Onychomycosis* is a general term that refers to a fungal infection of the fingernails or toenails. *Tinea unguium* is a term that specifically implies dermatophyte infection of the nails. However, the two terminologies are often used interchangeably in clinical practice, and for the purposes of the discussion, *onychomycosis* will refer to dermatophyte nail infections caused usually by *T. rubrum*, *T. mentagrophytes*, *T. tonsurans*, and *E. floccosum*. Periungual infection caused by *Candida albicans* is discussed in the section on candidiasis. Onychomycosis is more common in adults, although it does occur in children, often in association with tinea pedis or tinea manuum but also as a primary infection. The overall prevalence of onychomycosis in children has been estimated to be between 0 and 2.6%.<sup>52,53</sup> The lower incidence in children has been attributed to faster nail growth, smaller surface area for invasion, less nail trauma, lower incidence of tinea pedis, and less time spent in environments prone to infected fomites such as locker rooms.<sup>54</sup> The majority of prepubertal children with onychomycosis have a first-degree relative with onychomycosis and/or tinea pedis. Pediatric onychomycosis affects the toenails in two-thirds of patients and the fingernails in one-third.<sup>55</sup>

Onychomycosis is classified into several different patterns, including distal subungual, proximal subungual, and white superficial. The distal subungual type is the most common and is characterized by invasion of the underlying nailbed and inferior portion of the nail plate, which leads to onycholysis (detachment of the nail plate from the nailbed) and thickening of the subungual region, which takes on a discolored yellow-brown appearance<sup>56</sup> (Figs. 17-30 and 17-31). Proximal subungual onychomycosis is relatively uncommon and occurs when the invasion of the nail unit starts at the proximal nail-fold (the area near the cuticle). Clinically, destruction of the proximal nail plate is seen along with similar changes to the distal subungual type (Fig. 17-32). This form of onychomycosis is most common in individuals infected with human immunodeficiency virus (HIV), and it is considered by some to be an early marker for this infection. White

**Figure 17-30** Onychomycosis, distal subungual type. Yellow-white discoloration and thickening with the distal nail surfaces most involved.

**Figure 17-32** Onychomycosis, proximal subungual type. White discoloration of the nail plate with the process originating at the proximal nailfold regions.

**Figure 17-31** Onychomycosis, distal subungual type. (A) Diffuse involvement of the right foot with partial involvement of the left foot was present in this 14-year-old girl with Down syndrome. (B) Note the marked subungual debris and nail-plate destruction. Culture revealed *Trichophyton tonsurans*, a less common cause of onychomycosis.

superficial onychomycosis occurs with superficial infection of the nail plate and presents as well-delineated white plaques on the dorsal nail plate.

The diagnosis of onychomycosis is confirmed by direct microscopy of KOH wet-mount preparations and fungal culture. Material for

examination should be taken from the subungual debris, underside of the nail plate, nail clippings, or nailbed when necessary. Confirmation of the diagnosis is important, because many cases of nail dystrophy are not fungal in origin and are instead the result of another diagnosis such as psoriasis, postdermatitis onychodystrophy, chronic paronychia, trauma, drug-induced onycholysis, pachyonychia congenita, lichen planus, or a variety of other conditions (see Chapter 7). It must be remembered that onychomycosis is seldom symmetrical and that it is common to find involvement of only one, two, or three nails of only one hand or foot. In patients who have involvement of all nails, an alternative diagnosis should be highly suspected. In children diagnosed with onychomycosis, a search for other concomitant mycoses (especially tinea pedis and tinea capitis) should be completed.<sup>57</sup> Importantly, other close contacts with onychomycosis or tinea pedis should also be treated in an effort to end the cycle of transmission.

In general, topical agents tend to be relatively ineffective for the treatment of onychomycosis, in large part because of poor penetration through the nail plate. Topical antifungal therapy, however, is an important consideration as adjunctive therapy when tinea pedis is concomitantly present, in which case it may lower the relapse rate for onychomycosis. In addition, ciclopirox 8% nail lacquer solution has shown promise as an effective topical agent for onychomycosis, occasionally as monotherapy or more commonly, as an adjunctive treatment.<sup>58,59</sup> In a randomized prospective study of 40 children with onychomycosis treated with ciclopirox lacquer monotherapy over 32 weeks, mycologic cure was achieved in 77%.<sup>60</sup> Definitive therapy for onychomycosis in many patients, however, is best achieved with the use of oral antifungal agents. When considering therapy for this condition in children, many factors need to be incorporated into the equation, including the results of diagnostic studies, severity of the infection, age of the patient, and the risk-to-benefit ratios of the treatments being considered. Parents of younger children should be given the appropriate information regarding therapy and be allowed to make an informed decision. In many instances a trial of topical therapy with further consideration of systemic therapy if needed down the road may be a desirable option for parents. A systematic review of published studies on systemic therapy for pediatric onychomycosis revealed cure rates of 70% to 80%, similar to that seen in adults, and very good safety profiles.<sup>61</sup>

Griseofulvin has traditionally been the treatment of choice for systemic therapy of onychomycosis. However, this agent requires long-term administration and is associated with low cure rates and high relapse rates. Newer antifungal agents including fluconazole, itraconazole, and terbinafine appear promising as therapies for this condition, and the latter two medications are FDA-approved for this indication in adults. All of these agents have high affinity for keratin, another advantage over griseofulvin, and all remain concentrated in the nails for months after discontinuation of therapy.<sup>56</sup> In addition, they seem to result in much lower relapse rates.

**Figure 17-33** Tinea versicolor. Hypopigmented, minimally scaly macules and patches of seborrheic areas of the trunk.

**Figure 17-34** Tinea versicolor. Occasional involvement of the face and/or neck is noted, especially in darkly pigmented individuals.

The newer antifungal agents have been dosed in a variety of fashions in studies of onychomycosis. Fluconazole has usually been given as a weekly dose but may require 12 to 26 weeks of treatment.<sup>62</sup> Itraconazole and terbinafine appear to be effective with a more convenient dosing regimen. Itraconazole pulse therapy (given daily for 1 week/month for 3 to 4 months) is a preferred strategy in adults with onychomycosis. This approach has been studied in pediatric patients and appears to be effective and relatively safe,<sup>54,63</sup> although adequately randomized trials are lacking. Terbinafine has demonstrated significant effectiveness in the treatment of onychomycosis. This agent is usually given as a daily dose for 3 to 4 months, and several studies have suggested superior efficacy and cost effectiveness over the other antifungal drugs.<sup>64–66</sup>

### TINEA VERSICOLOR

Tinea versicolor ( pityriasis versicolor ) is an extremely common superficial fungal disorder of the skin characterized by multiple scaling, oval macules, patches, and thin plaques distributed over the upper portions of the trunk, proximal arms, and occasionally the neck or face. It is caused by the yeast forms of the dimorphic fungus *Malassezia furfur*, which are referred to as *Pityrosporum orbiculare* and *Pityrosporum ovale*. This organism is part of the normal cutaneous flora. The disorder occurs worldwide, and the majority of cases present in adolescents, possibly in relation to the lipophilic nature of the organism and the sebum-rich environment of the affected regions. Tinea versicolor only occasionally occurs in prepubertal children. Although *Malassezia* is part of the normal flora, in immunocompromised hosts this yeast may be associated with opportunistic infections, including catheter-related fungemia, peritonitis, septic arthritis, pulmonary infection, and sinusitis.<sup>67</sup>

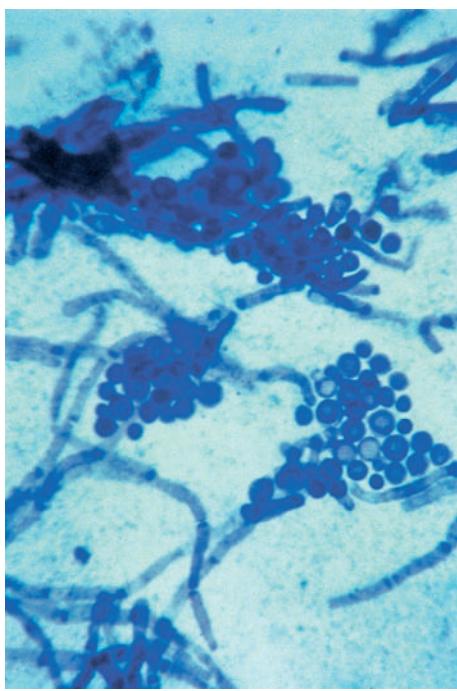

The diagnosis is usually made clinically based on the characteristic presentation. Lesions may be most appreciated during summer months when sun exposure leads to increasing discrepancies in skin pigmentation between affected and unaffected areas. Examination reveals thin, scaly papules and plaques distributed on the chest, back (Fig. 17-33), and less commonly on the face and neck (Fig. 17-34). They may be hypopigmented or hyperpigmented (Fig. 17-35) depending on the patient's complexion and history of sun exposure,

**Figure 17-35** Tinea versicolor. This immunosuppressed teenager with inflammatory bowel disease had hyperpigmented (rather than hypopigmented) scaly papules and plaques.

and sometimes mild erythema is present. Scalloping of the borders is common, and lesions may be so numerous that they coalesce into larger patches. Lower extremities and genitals are rare sites of involvement. Interestingly, azelaic acid is a dicarboxylic acid produced by *M. furfur* that inhibits the dopa-tyrosinase reaction, which may result in the hypopigmentation seen in this disorder. This acid is marketed as an acne therapy product for acne-induced hyperpigmentation (see Chapter 8).

The differential diagnosis of tinea versicolor includes vitiligo, pityriasis alba, postinflammatory hypopigmentation or hyperpigmentation, pityriasis rosea, tinea, psoriasis, and confluent and reticular papillomatosis of Gougerot and Carteaud (see Chapter 23). Distinguishing clinical features are usually sufficient to differentiate these various conditions. Vitiligo presents with depigmentation rather than hypopigmentation, with well-demarcated patches most often localized around orifices and bony prominences. Pityriasis alba presents with

**Figure 17-36** KOH preparation of tinea versicolor. Short, blunt-ended hyphae and clusters of spores are present in the classic “spaghetti-and-meatballs” pattern in scrapings from a patient with tinea versicolor.

hypopigmented patches, but these lesions are usually limited to the face, occur in atopic individuals, and are only rarely as extensive as one would expect for tinea versicolor. The diagnosis can be confirmed by a KOH wet-mount of cutaneous scrapings, which reveals the highly characteristic short fungal hyphae and spores in grape-like clusters (the “spaghetti-and-meatballs” pattern) (Fig. 17-36) on microscopic examination. Fungal culture is generally not useful, because the organism is difficult to grow on culture media and *M. furfur* is part of the normal skin flora.

The treatment options for tinea versicolor are many, although better randomized, placebo-controlled prospective clinical trials investigating their efficacy and safety are needed.<sup>68</sup> Tinea versicolor may respond to a variety of topical preparations. However, because the course of the disorder is usually chronic, recurrences are common, and the pigmentary changes may take months to years to revert, adequate patient education and setting appropriate expectations are vital. Selenium sulfide 2.5% shampoo is a convenient, inexpensive, safe, and relatively effective mode of therapy, especially for younger patients. It is applied in a thin layer for 10 minutes before rinsing for 1 to 2 weeks. Less frequent intermittent applications (i.e., every other week or monthly) are then useful for maintenance. Ketoconazole 2% shampoo has also been recommended and was shown effective when applied as a single application or daily for 3 days.<sup>69</sup> More recently, terbinafine 1% spray has become available and is applied once to twice daily for 1 to 2 weeks. Topical antifungal creams are also effective, but their use is often impractical given the wide surface area of skin usually involved.

Oral therapy is desirable in patients with severe disease or recurrent disease or in those in whom topical therapies have failed. A variety of oral antifungal agents including ketoconazole, fluconazole, itraconazole, and terbinafine have been proposed for this condition. Multiple dosing regimens have been advocated, including continuous, intermittent, and single-dose approaches. A favorite systemic regimen for tinea versicolor is single-dose (400 mg) ketoconazole followed by physical activity to promote secretion of the drug onto the skin via sweating. The patient then delays showering or rinsing for 10 to 12 hours and repeats the therapy in 1 week. Recently, however, the FDA has recommended against ketoconazole as a first-line antifungal therapy, given concerns over potentially severe liver toxicity.

Itraconazole single-dose therapy (400 mg) was compared with a 7-day continuous therapy (200 mg daily dose), and both regimens were found to be equally effective.<sup>70,71</sup> In another randomized prospective study, single- and multiple-dose regimens of ketoconazole and fluconazole were compared, and single-dose (400 mg) oral fluconazole provided the best clinical and mycological cure rates with no relapse during 12 months of follow-up study.<sup>72</sup> In a study of extensive tinea versicolor, single-dose ketoconazole (400 mg) was compared with two doses of fluconazole (300 mg) with a 2-week interval between doses. Similar clinical response was noted in both groups (81.5% improvement for fluconazole, 87.9% for ketoconazole) with no significant adverse events in either group.<sup>73</sup>

There is no current consensus or gold standard of care for systemic therapy of tinea versicolor. If an imidazole antifungal agent is used, however, the potential for drug interactions (especially with itraconazole and ketoconazole), liver toxicity (itraconazole and ketoconazole), congestive heart failure (itraconazole), and other side effects must always be considered and discussed with the patient and/or parent.

### TINEA NIGRA

Tinea nigra is a superficial fungal infection of the stratum corneum caused by the black yeast-like mold *Phaeoannellomyces* or *Hortaea werneckii* (formerly called *Cladosporium* or *Exophiala werneckii*). Because it is not caused by a dermatophyte fungus, *tinea* (as with tinea versicolor) is a misnomer. This infection occurs most often in warm humid areas of Central or South America, Africa, Asia, and occasionally the coastal southern United States. It presents as an asymptomatic, light to dark brown or black, sharply marginated macule or patch, usually involving the palm and less likely the dorsal surface of the hand or plantar foot. Visible scaling is rare. The most important aspect of tinea nigra is the potential misdiagnosis as malignant melanoma. Other misdiagnoses may include postinflammatory hyperpigmentation, fixed drug eruption, or chemical stain.<sup>74</sup> Direct microscopic examination of a KOH wet-mount preparation of skin scrapings reveals gray-brown to green hyphae and budding yeast cells, and fungal culture is confirmatory. Tinea nigra is treated with a topical antifungal preparation such as miconazole, clotrimazole, or terbinafine cream. The application of keratolytic agents such as salicylic acid or Whitfield ointment (6% benzoic acid and 3% salicylic acid) or 10% thiabendazole solution is another therapeutic option.

### PIEDRA

Piedra is an asymptomatic fungal infection of the hair shaft caused by *Piedraia hortae* (black piedra) or various *Trichosporon* species (formerly known as *Trichosporon beigelii*; white piedra). The species that most commonly cause white piedra are *Trichosporon inkin*, *Trichosporon cutaneum* and *Trichosporon ovoides*.<sup>75,76</sup>

Black piedra is seen most commonly in tropical areas of South America, the Far East, and the Pacific Islands. It is characterized by small, hard, and adherent brown-black nodules on the hair shafts of the scalp, which on hair microscopy are composed of honeycomb-like masses of fungal ascospores. These nodules contain phosphorus, sulfur, and calcium, which are all part of the extracellular material involved in the organization of the fungus.<sup>77</sup> Fungal culture usually confirms the diagnosis. Traditional therapy consists of hair removal by clipping or shaving, and oral terbinafine may be useful.<sup>78</sup>

White piedra is seen in temperate climates of South America, Europe, Asia, Australia, and the southern United States. It may affect the scalp as well as eyelash, eyebrow, beard, axillary, or pubic hair. Traditional burkha-clad Muslim women may be predisposed to this condition.<sup>79</sup> White piedra may be underreported in the United States, with recent reports in children from the northeastern states, several of whom were immigrants. This observation suggests that cases in the United States may be primarily imported and hence influenced by immigration trends.<sup>80</sup> It is characterized by asymptomatic, soft, white-tan elongated nodules on the hair shaft that may be mistaken for the nits of head louse infestation or hair casts. Additionally, the differential diagnosis may include monilethrix and trichorrhexis nodosa. Microscopic examination of a hair mount reveals yeast-like

cells completely encircling the hair shaft and occasional hyphae perpendicular to the hair shaft. The organism can be recovered from a fungal culture. Again, clipping or shaving the hair is usually curative. Oral itraconazole and fluconazole have been demonstrated effective in open-label studies, but recurrence may be noted.<sup>79,80</sup> Concomitant use of an azole (i.e., ketoconazole) shampoo has been advocated as adjunctive therapy, and topical antifungal creams have also been used.

Although the etiologic agent of white piedra usually results in this benign hair condition, disseminated infection may occur in immunocompromised hosts, especially those with neutropenia and HIV infection.<sup>81,82</sup> Low-birthweight neonates are another population at risk for fungal septicemia with this organism.<sup>83</sup> Cutaneous lesions may occur with disseminated disease and consist of purpuric papules, nodules, and necrosis. Therapy of *Trichosporon* sepsis/multiorgan dissemination is difficult, because many isolates are resistant to amphotericin B, and the mortality rate is high.

## Candidiasis

Candidiasis (moniliasis) is an acute or chronic infection of the skin, mucous membranes, and occasionally internal organs caused by yeast-like fungi of the *Candida* genus. Although several candidal species may be associated with human infection, *C. albicans* is by far the most common cause. *C. albicans* is not a normal cutaneous saprophyte but usually exists in the microflora of the oral cavity, gastrointestinal tract, and vagina. It becomes a cutaneous pathogen when there is an alteration in host defenses, either localized or generalized, that allows the organism to become invasive.

Factors that predispose to candidiasis include endocrinologic disorders (i.e., diabetes mellitus, hypoparathyroidism, and Addison disease), genetic disorders (i.e., Down syndrome, acrodermatitis enteropathica, and chronic mucocutaneous candidiasis [CMC]), malignancy (especially leukemia or lymphoma), and certain systemic medications (i.e., antibiotics, corticosteroids, and immunosuppressive agents).

Newborns and infants are physiologically susceptible to candidal infection, which may be commonly manifested as oral candidiasis (thrush), diaper candidiasis, or intertrigo. Other presentations of candidal infection in childhood include vulvovaginitis, angular cheilitis (perlèche), and nail involvement (paronychia). Neonatal, congenital, systemic, and CMC are additional patterns of infection with *Candida*. Candidiasis in the infant is often traceable to an infected mother who may be a vaginal or intestinal carrier of the organism. These infants may harbor *C. albicans* in the mouth or intestinal canal, and the infected saliva or stools constitute a focus for cutaneous infection. The presence of *Candida* species in the mouths of children has been proposed as a possible factor contributing to dental caries.<sup>84</sup> There follows a review of several types of mucocutaneous candidiasis in children, including a discussion of congenital and neonatal candidiasis and risk factors for severe disease. (Diaper candidiasis is discussed in detail in Chapter 2.)

### ORAL CANDIDIASIS (THRUSH)

Oral candidiasis (thrush) is a painless or painful *Candida* infection of the tongue, soft and hard palates, and buccal and gingival mucosae. It is characterized by white to gray, friable, pseudomembranous patches or plaques overlying a reddened mucosa (Fig. 17-37) (see Chapter 2, Fig. 2-26) and is most commonly seen in infants. Thrush may be acquired at the time of delivery during passage through an infected birth canal, during nursing from the skin of the mother's breast or hands, or from imperfect sterilization of feeding bottles.<sup>85</sup> Oral candidiasis also occurs at a greater rate in children with cystic fibrosis, diabetes, or immunodeficiency and in those who have undergone organ transplantation.<sup>86,87</sup> In some of these instances, the predisposition toward this infection may be related to therapies for the condition (i.e., inhaled or oral corticosteroids in patients with asthma). It has also been shown to be positively correlated with dental caries in children.<sup>88</sup>

The diagnosis of oral candidiasis is often clinical, and it can be confirmed by gentle attempts to remove the curd-like plaques that, in distinction to milk or formula residue, adhere to the underlying oral

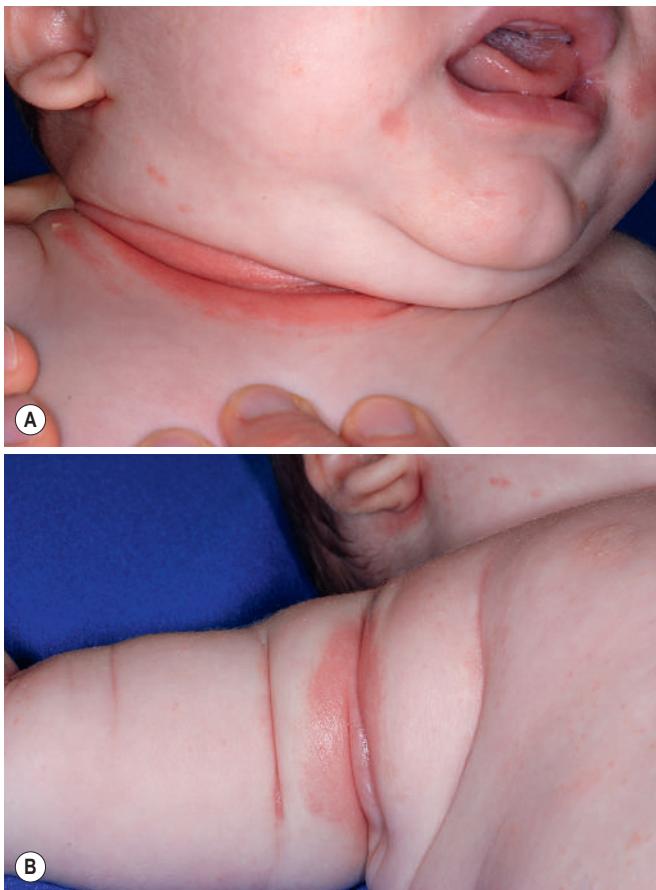

**Figure 17-37** Oral candidiasis. White, friable plaques on the dorsal tongue of an otherwise healthy infant girl.

mucosa. Removal is accomplished by gently rubbing the area with a cotton applicator or tongue blade, which results in an underlying inflammatory mucosal erosion. The organism may be identified by microscopic evaluation of a KOH wet-mount preparation of these materials or by fungal culture. Although most infants with oral thrush do not experience impairment of appetite or feeding, severe disease may be associated with such complications as well as significant pain. Immunocompromised infants often have a severe expression of oral candidiasis.

The usual approach to therapy, and one that is usually effective, is the administration of nystatin oral suspension, one dropperful in each cheek given four times daily. Massage of the suspension on the mucosa by the parent is useful after administration, and the medication is used for 7 to 14 days. Nystatin is unabsorbed from the gastrointestinal tract, as are some other topical therapies that have been used, including gentian violet, amphotericin B, miconazole, and clotrimazole. Options for older children include nystatin and clotrimazole tablets or troches. Although it has been suggested that clotrimazole or nystatin troches or suppositories may be inserted into the tip of a slit pacifier or nipple for the treatment of infants with oral candidiasis, these approaches have not been evaluated in controlled studies and the possibility of aspiration must be considered.<sup>85,89</sup> When treating infants with persistent or recurrent oral candidiasis, asymptomatic maternal vaginal candidiasis and candidal contamination of nipples or pacifiers should be considered as possible reservoirs for reinfection.<sup>90</sup> Oral antifungal agents, most notably fluconazole, have been demonstrated quite effective in the treatment of oral candidiasis in immunocompromised children.<sup>91,92</sup> In general, absorbable antifungal therapy should be used primarily if there is risk of dissemination or widespread disease is present.<sup>93</sup>

### INTERTRIGO

The moist warm conditions found in intertriginous areas favor the development of candidal infection. Intertrigo (see Chapter 3) refers to a condition marked by intense erythema in skin folds, including the axillary regions, the anterior neck fold (Fig. 17-38), posterior auricular regions, and inguinal creases. Although it does not always represent a fungal process, *C. albicans* infection is common, and secondary bacterial (i.e., *Staphylococcus aureus*) infection may occasionally be present. *Streptococcal intertrigo* refers to intertrigo in association with group A β-hemolytic streptococcus (GABHS; *Streptococcus pyogenes*) infection.<sup>94</sup> It presents with intertriginous inflammation that is well demarcated, weeping, and superficially eroded (Fig. 17-39). It is often associated with a foul odor and lacks the satellite papules and papulopustules that are characteristic of candidal intertrigo. Surface swabs

**Figure 17-38** Intertrigo. **(A)** Erythema and maceration of the anterior neck fold. Note the peripheral satellite papules and involvement of the auricular crease. **(B)** This infant also had involvement of the axillae. Skin swabs were positive for *Candida albicans*.

**Figure 17-39** Streptococcal intertrigo. This infant had well-demarcated erythema with erosive changes, weeping, and a foul odor. *Streptococcus pyogenes* was isolated on bacterial culture. Note the absence of satellite papules or pustules that are characteristic of candidal intertrigo.

are helpful for confirming the diagnosis via streptococcal rapid antigen test and/or bacterial culture.<sup>95</sup>

Treatment of intertrigo with a topical antifungal agent (i.e., clotrimazole, econazole, or ketoconazole cream) applied two to three times daily is usually sufficient. More severe cases may require the addition of a low-strength topical corticosteroid or when bacterial infection is

**Figure 17-40** Perlèche (angular cheilitis). Erythema, fissuring, and exudate of the mouth angle.

suspected, an appropriate oral antibiotic with activity against both *S. aureus* and GABHS.

### CANDIDAL VULVOVAGINITIS

*C. albicans* is a common inhabitant of the vaginal tract, and its incidence increases in diabetes and pregnancy and in females taking antibiotics or oral anovulatory preparations. When vulvovaginitis occurs, the labia become edematous and red, white patches appear on an erythematous mucosal surface, and leukorrhea develops. The resultant symptoms include painful itching, burning, and dysuria. The infection may spread to the perineum, perianal region, gluteal folds, and upper inner aspects of the thighs as well. Although vulvovaginitis is more common in adults, it occurs in premenarchal as well as adolescent females, and in the latter, it may be a marker for type 2 diabetes.<sup>96</sup> It accounted for nearly 62% of all gynecological problems seen during childhood and adolescence in one large study.<sup>97</sup> In premenarchal girls, psoriasis or atopic dermatitis may present with similar features and may be more common than candidiasis.<sup>98</sup> The differential considerations of candidal vulvovaginitis include bacterial infection, foreign body, contact dermatitis, poor hygiene, lichen sclerosus et atrophicus (typically quite distinguishable clinically) and sexual abuse.<sup>98,99</sup> The most common bacterial causes appear to be groups A and B β-hemolytic streptococci, *S. aureus*, *Proteus mirabilis*, *Escherichia coli*, and enterococci.<sup>97,100–102</sup>

The diagnosis of candidal vulvovaginitis is established by the clinical signs and symptoms and by demonstration of the fungus by KOH wet-mount examination and/or fungal culture. Treatment options include antifungal vaginal tablets, cream, or suppositories (i.e., clotrimazole, miconazole, nystatin, terconazole) used daily for 3 to 7 days (up to 14 days for nystatin). A single-dose regimen using a 500-mg vaginal tablet of clotrimazole was also found to be clinically efficacious.<sup>103</sup> A single-dose regimen of fluconazole (150 mg) is quite effective in adolescents and adults.

### PERLÈCHE

Perlèche (angular cheilitis) is a common disorder characterized by fissuring and inflammation of the corners of the mouth (Fig. 17-40) with associated maceration and exudate. This condition appears to be related to moisture collecting at the mouth angles and does not usually have any association with nutritional or vitamin deficiency. Whereas in adults it is often related to ill-fitting dentures, perlèche in children may be seen in conjunction with dental malocclusion, the presence of orthodontic appliances, and lip licking. Therapy is best accomplished by correction of the underlying predisposing factor; that is, the condition often improves after the completion of orthodontia or after modification of lip-licking behavior. Treatment consists of the application of a low-strength (i.e., class 6 or 7) topical corticosteroid ointment 2 to 3 times daily. A topical antifungal preparation (i.e., econazole or

**Figure 17-41** Chronic paronychia. Nail-plate ridging, periungual erythema, and cuticle loss are seen in this patient with chronic *Candida* infection.

clotrimazole) should be added for more severe presentations, because *C. albicans* is often present, and if secondary bacterial infection is present, topical or oral antibiotic therapy is indicated.

### CHRONIC PARONYCHIA

Chronic paronychia (see Chapter 7) is usually associated with *C. albicans* infection and presents with transverse ridging of the nail plate, loss of the cuticle, and mild proximal/lateral periungual erythema (Fig. 17-41). It is distinguished from acute paronychia not only by the natural history (acute paronychia is more sudden in onset) but by lack of the marked edema, pain, and pustule formation, which are classically seen in the acute (bacterial) type. Chronic paronychia in children may be related to repeated finger or thumb sucking. Therapy with a topical antifungal cream applied twice daily is usually effective, although the nail plate may take several months to grow out normally. Oral fluconazole may also be effective for severe or resistant involvement. Attempts to decrease moisture of the affected digits will accentuate the response to therapy and help to minimize recurrences.

### EROSIO INTERDIGITALIS BLASTOMYCETICA

Erosio interdigitalis blastomycetica (derived from Latin, meaning “an erosion between digits caused by a budding fungus”) is a red, itchy, and occasionally slightly painful eruption of the web spaces between the fingers or toes. It is most common in individuals whose hands or feet are exposed to moisture often and most commonly involves the lateral two web spaces (i.e., between the third and fourth and between the fourth and fifth digits). Erosio interdigitalis blastomycetica presents with erythema, maceration, and peeling of the affected region (Fig. 17-42) with a scaly and occasionally vesicular border. More severe presentations with marked inflammation and frank ulceration have been reported in adults and termed *interdigital ulcer*.<sup>104</sup> Erosio interdigitalis blastomycetica seems to be caused by infection with *C. albicans*, and occasionally there may be an associated Gram-negative infection (see Chapter 14). Treatment consists of keeping the hands and feet as dry as possible and the use of a topical antifungal and (when needed) antibacterial preparation.

### BLACK HAIRY TONGUE

*Black hairy tongue* is a term used to describe a disorder primarily affecting adults and occasionally adolescents that is characterized by hypertrophic, elongated filiform papillae that form a dense black to blue-black surface on the midportion of the dorsal tongue. It occurs less often in young children but has been observed in an infant as young as 2 months of age.<sup>105,106</sup> The etiology is unknown, but it is frequently attributed to *C. albicans* or bacterial infection and is often associated with the prolonged use of antibiotics, including erythromycin and

**Figure 17-42** Erosio interdigitalis blastomycetica. Erythema, maceration, and peeling of the fourth toe-web space. This eruption cleared rapidly with topical azole antifungal therapy.

linezolid. Treatment consists primarily of improved oral hygiene, and gentle brushing of the dorsal tongue with a soft toothbrush and a small amount of toothpaste two to three times daily is usually effective.

### NEONATAL AND SYSTEMIC CANDIDIASIS

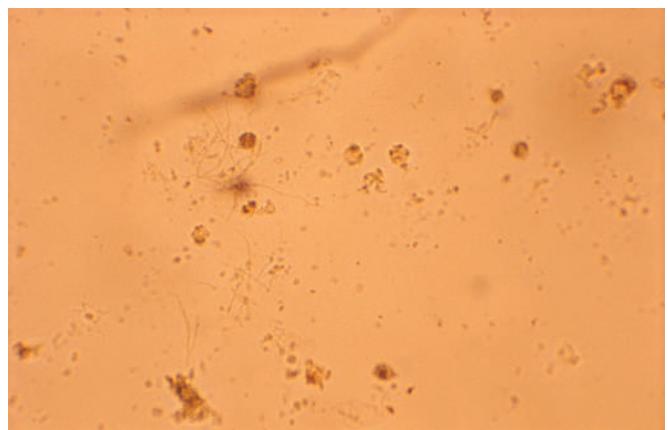

Two types of candidiasis in the newborn period have been reported: a congenital form in which the skin lesions are present at birth or within the first 6 days of life and a neonatal form commonly seen after the first week of life. Neonatal candidiasis develops as a result of infection acquired by passage through an infected maternal birth canal. This perinatal or postnatal acquisition of *Candida* encompasses several clinical presentations including localized disease (i.e., oral thrush and diaper dermatitis), systemic infection related to invasive procedures and infected indwelling devices, and invasive fungal dermatitis seen in extremely low-birthweight neonates. Although *C. albicans* is the primary pathogen, *Candida parapsilosis* is becoming a more significant pathogen in the neonatal setting (and in some reports has become the most commonly isolated species), and *Candida glabrata* has been reported after *in vitro* fertilization and embryo transfer.<sup>107–112</sup>

Congenital candidiasis is acquired *in utero* and may be associated with premature labor, especially in instances where a foreign body (i.e., intrauterine device [IUD] or cervical sutures) is present. It may also be associated with *Candida* chorioamnionitis.<sup>113</sup> A history of maternal candidal vulvovaginitis is common in infants with congenital candidiasis, although the former is present in a high percentage (up to 25%) of pregnant women and in most instances is not associated with this neonatal infection.<sup>114</sup> Congenital candidiasis tends to run a more benign course in full-term infants without risk factors but may result in serious systemic infection in premature neonates, especially those of extremely low birthweight. Other risk factors for invasive candidal infection include extensive instrumentation in the delivery room and invasive procedures utilized during the neonatal period. In patients with risk factors for dissemination, systemic antifungal therapy should be initiated.

Congenital cutaneous candidiasis (CCC) presents with multiple, widespread erythematous macules, papules, and pustules (Fig. 17-43) and occasionally bullae. In full-term infants, this form of candidiasis is often limited to the skin and resolves over 1 to 2 weeks.<sup>108</sup> The most common locations of involvement are the back, extensor surfaces of the extremities, and skin folds, with relative sparing of the diaper area.<sup>115</sup> Pustules on the palms and soles (Fig. 17-44) are a common and useful diagnostic finding. Oral thrush is uncommon in this setting, but nail changes (yellow discoloration, thickening, paronychia) (Fig. 17-45) are occasionally present. Such nail changes may be the sole manifestation of congenital candidiasis, and onychomadesis (separation of the nail plate from the nailbed) with nail shedding may occur.<sup>116</sup> The clinical findings in CCC may resemble erythema toxicum

**Figure 17-43** Congenital cutaneous candidiasis. Widespread erythematous papules and pustules in a 10-day-old male. This otherwise healthy child had involvement limited to the skin and no risk factors for dissemination. His mother reported a history of vulvovaginal candidiasis during the last trimester of pregnancy.

**Figure 17-46** KOH examination of candidiasis. Spores and pseudohyphae as noted on microscopic examination of skin scrapings from a patient with candidiasis.

**Figure 17-44** Congenital cutaneous candidiasis. Erythematous papules, papulovesicles, and pustules were present at birth in this full-term infant male. No extracutaneous involvement was noted.

**Figure 17-45** Congenital candidiasis. Yellow discoloration with ridging and nail-plate separation in a newborn male with no other manifestations of *Candida* infection.

neonatorum, bacterial folliculitis or pustulosis, bullous impetigo, and congenital herpes, varicella, enterovirus, or syphilis. The definitive diagnosis of CCC is made by the microscopic finding of spores and pseudohyphae on skin scrapings (Fig. 17-46) or culture of the organism. Another useful diagnostic modality is examination of the placenta, which may reveal typical changes of candidiasis (including funisitis, abscesses, or chorioamnionitis).<sup>115,117</sup> In patients with CCC limited to the skin and without risk factors for disseminated disease, topical antifungal therapy often suffices.

Systemic candidiasis occurs primarily in very low-birthweight (<1500 g) infants and is typically seen between the second and sixth weeks of life. The immature immune defenses of this population contribute to this propensity toward systemic disease.<sup>115</sup> Predisposing factors, in addition to prematurity, include presence of a central catheter or endotracheal tube, receipt of intravenous lipid emulsion, administration of broad-spectrum antibiotics, and use of intrapartum antibiotics.<sup>118</sup> Systemic candidiasis is uncommon in infants of birth weight greater than 1500 g, but when it occurs the greatest risk factors appear to be exposure to broad-spectrum antibiotics and thrombocytopenia (<50,000/mm<sup>3</sup>).<sup>119</sup>

Common features of systemic candidiasis include apnea, hyperglycemia, temperature instability, lethargy, hypotension, and increasing respiratory requirements.<sup>111</sup> The skin surface may or may not be involved. These patients may have candidal septicemia, meningitis, urinary tract infection, or disseminated disease. Since the kidneys act as a filter for *Candida*, spores may be present on microscopic examination of urine samples.<sup>117</sup> Renal pelvis fungus balls may be seen in up to 42% of these infants, and endocarditis, septic arthritis, endophthalmitis, and osteomyelitis may also occur. The diagnosis is confirmed by isolation of *Candida* from blood, urine, cerebrospinal fluid, or other normally sterile sites. Systemic candidiasis requires parenteral antifungal therapy and may result in permanent neurodevelopmental deficits in long-term survivors. The mortality rate in extremely low-birthweight (<1000 g) infants is 20% to 34% and even higher when *Candida* is isolated from more than one sterile body fluid.<sup>118,120</sup>

*Invasive fungal dermatitis* refers to a clinical entity seen in extremely low-birthweight infants and consists of a distinct cutaneous presentation of *Candida* infection in combination with a high risk for internal dissemination.<sup>114</sup> The affected infants develop lesions after several days of life. Skin involvement is characterized by erosive and ulcerative lesions (Fig. 17-47) with extensive crusting. Vesicles, bullae, and “burn-like” erythema may also be present, and desquamation and widespread denudation are common. A high index of suspicion should be maintained in extremely low-birthweight infants with any of these findings, because disseminated infection is common, including fungemia, meningitis, urinary tract infection, and other organ involvement. Potential risk factors for this form of candidiasis include vaginal birth, postnatal steroids, and prolonged hyperglycemia.<sup>114</sup> The immature skin barrier function seen in extremely premature infants is believed

**Figure 17-47** Invasive fungal dermatitis. Erythema with maceration, crusting, and peeling in an extremely low-birthweight newborn with candidiasis. (Courtesy of Moise Levy, MD.)

to be pathogenic, with skin serving as the portal of entry for this infection.<sup>114,121</sup>

### CHRONIC MUCOCUTANEOUS CANDIDIASIS

Chronic mucocutaneous candidiasis (CMC) is characterized by recurrent infections of the skin, nails, and oral, esophageal, or genital mucosae with *Candida* species, usually *C. albicans*. This disorder appears to be a common phenotype for a variety of defects in the immune response, most notably in the cellular branch of the immune system and mainly the specific responses to antigens of *Candida* species.<sup>122</sup> CMC may be seen in the setting of primary immunodeficiencies including severe combined immunodeficiency, dedicator of cytokinesis 8 (DOCK8) deficiency, signal transducer and activator of transcription (STAT) 3 deficiency causing autosomal dominant hyperimmunoglobulin (Ig) E syndrome, and autosomal recessive autoimmune polyendocrinopathy candidiasis with ectodermal dystrophy (APECED) associated with mutation in AIRE. More recently, CMC has been associated with various inborn errors of interleukin (IL)-17-mediated immunity, shown in some autosomal dominant kindreds to be associated with gain-of-function STAT1 mutations.<sup>123–125</sup> In patients with the STAT1 mutation, reduced production of interferon- $\gamma$  and IL-22 have also been demonstrated.<sup>125</sup> Pure CMC (without another syndrome association) has been reported in some families with mutations in the genes for the IL-17 receptor (*IL17RA*) and IL-17 ligand (*IL17F*).<sup>126</sup>

The clinical features of CMC are marked by the mucocutaneous findings. Oral candidiasis (thrush), esophageal candidiasis, candidal diaper dermatitis, candidal intertrigo, and paronychia that are persistent and recalcitrant to therapy are all common. Angular cheilitis (perlèche) is also seen. Generalized, scaly, erythematous, and crusted papules and plaques may be present, especially on the scalp, where they may lead to scarring alopecia. Nail involvement is notable for nail-plate thickening and discoloration, and chronic paronychia may be present. Systemic candidiasis does not usually occur in patients with CMC. Dental-enamel dysplasia occurs in some patients with APECED syndrome (see below), and at times may be so severe that it leads to early loss of dentition. Other infections may occur with increased incidence in these patients as well, most commonly tinea, pyogenic skin infection, sinusitis, pneumonitis, and urinary tract infection. Severe complications that may occur in patients with CMC include squamous cell carcinoma, functional debilitation of the hands, esophageal strictures, and cerebral aneurysms.<sup>127</sup>

The most common endocrinopathies noted in association with CMC are hypoparathyroidism, hypoadrenalinism (Addison disease), and gonadal failure. These endocrine abnormalities commonly do not appear until adolescence or adulthood, and therefore serial evaluations for endocrine function are indicated in patients with CMC, especially those with one endocrinopathy or with family members affected

with APECED.<sup>128</sup> APECED, which is also known as *autoimmune polyendocrinopathy syndrome type I (APS1)*, is an autosomal recessive disorder caused by mutations in the autoimmune regulator (AIRE) gene.<sup>129,130</sup> The classic triad of this disorder is CMC, hypoparathyroidism, and adrenocortical failure, and the diagnosis of APECED requires the presence of at least two of these components.<sup>131</sup> Besides the candidal infections and endocrine abnormalities, patients have ectodermal dystrophy manifested most commonly as alopecia areata, as well as nail dystrophy and dental-enamel defects. Other observed defects may include vitiligo, chronic active hepatitis, growth-hormone deficiency, thyroid disease, diabetes mellitus, pernicious anemia, keratopathy, ovarian failure, testicular failure, celiac disease, and iridocyclitis.<sup>127,129,132</sup> The autoimmune diathesis also is responsible for the candidal infections. Patients have been shown to have neutralizing autoantibodies directed against interferons, IL-17, and IL-22, cytokines that are important in immune responses to the candidal organism.<sup>126,133,134</sup>

Treatment of CMC includes addressing the immunodeficiency status (and augmenting or correcting it when feasible) and administration of topical and/or oral antifungal medications. Topical antifungal creams are useful for treatment of localized cutaneous lesions. Oral or vaginal candidiasis may benefit from oral troches or suspensions and vaginal creams or suppositories, respectively. The mainstays of therapy for CMC, however, are the oral antifungal agents, including ketoconazole, fluconazole, and itraconazole. When these agents are used as ongoing therapy for this indication, the possible side effects, potential for drug interactions, and risk-to-benefit ratio must all be taken into consideration. Biologic therapies directed at the observed cytokine aberrations in these disorders are being studied.

## Deep Fungal Disorders

In contrast to the superficial dermatophytes, which are confined to dead keratinous tissue, certain mycotic infections have the capacity for deep invasion of the skin or subcutaneous tissues as well as the potential for systemic infection, especially of the lungs and reticuloendothelial system. There follows a review of several deep fungal infections, which have been divided into the subcutaneous, systemic, and opportunistic mycoses.

### SUBCUTANEOUS MYCOSES

The subcutaneous mycoses are a group of disorders caused mainly by fungi that exist as soil saprophytes and are normally of low virulence but may result in infection involving the skin and subcutaneous tissues. Although these infections are found most often in adults with occupational exposure to soil and plants, all age groups are potentially susceptible. Rhinosporidiosis, which has been classified variably as a fungus or a protozoan parasite, has been included in this category and usually affects the nasal, nasopharyngeal, and ocular mucosae.

### Sporotrichosis

Sporotrichosis is a granulomatous fungal infection of the skin and subcutaneous tissues caused by *Sporothrix schenckii*, a dimorphic fungus of worldwide distribution commonly isolated from soil and plants. It occurs in patients of all ages but is observed most commonly in adult males who, because of their occupation or leisure-time activities, are likely to be exposed to contaminated soil or vegetation (farmers, florists, gardeners, forestry workers, miners, and individuals who work with contaminated packing material). Childhood infection, although significantly less common, does occur and may go undiagnosed without a high index of suspicion.<sup>135</sup> Although human transmission can occur after close contact with suppurative wounds of sporotrichosis, the majority of clustered cases are most likely related to simultaneous inoculation from the same source.<sup>136,137</sup> Although disease is usually limited to the skin and subcutaneous tissues, disseminated sporotrichosis with fungemia may occur, especially in the setting of HIV infection.<sup>138</sup>

The clinical presentation of sporotrichosis is variable, and several factors such as inoculum load, host immune status, virulence of the involved strain, and depth of the inciting trauma may influence the

**Figure 17-48** Sporotrichosis. Erythematous papules and nodules on the plantar surface with early lymphangitic (sporotrichoid) spread.

clinical presentation.<sup>139</sup> The lymphocutaneous form is most common in adults, and presents with a painless, erythematous papule or nodule that begins on exposed areas of skin, most commonly the upper extremity. The initial lesion often follows a penetrating injury such as that inflicted by a splinter, thorn, grain, rock, piece of glass, or cat scratch (cats are perhaps the only animals capable of transmitting this disorder<sup>140</sup>) contaminated with the organism. The lesions are often solitary and enlarge over several weeks. Secondary discrete lesions may develop and often progress toward more proximal sites, a pattern that has been referred to as "sporotrichoid"<sup>141</sup> (Fig. 17-48). Regional lymphadenopathy and lymphadenitis are common. The skin lesions may ulcerate centrally and heal with scarring, although spontaneous clearing is unusual. In a series of 25 children with sporotrichosis, 60% had lesions on an extremity (followed by the face as the next most common site), and the majority had the lymphocutaneous form of the infection.<sup>142</sup> Epidemic sporotrichosis related to transmission from infected cats was reported in 1998 through 2004 in Brazil and affected humans, cats, and dogs.<sup>143</sup>

The fixed cutaneous form of sporotrichosis is characterized by localized skin lesions without lymphatic involvement. The skin findings range from scaly papules to verrucous, ulcerated plaques or nodules with or without satellite lesions. This form seems more common in children, and there may be a delay in diagnosis given the lack of a typical sporotrichoid distribution pattern.<sup>135</sup> It has been hypothesized that children manifesting fixed cutaneous forms may possess host factors that limit the infection to the inoculation site, even if the strain is capable of producing the more classic lymphocutaneous form commonly seen in adults.<sup>144</sup> This form of sporotrichosis was reported in a 3-week-old neonate in whom the source of infection was unknown.<sup>145</sup>

Disseminated cutaneous sporotrichosis is rare and usually occurs in individuals with immunologic defects or chronic disease. In these patients the cutaneous lesions may be widespread and develop after hematogenous spread of the infection from a primary focus in the skin or an occult pulmonary focus. Multiple additional organs may be involved, including the bones, joints, and central nervous system (CNS). This form of sporotrichosis may mimic tuberculosis (especially with upper-lung radiographic lesions) and is associated with significant morbidity and mortality. Multifocal cutaneous ulcers have also been reported in sporotrichosis in association with misuse of topical corticosteroids and self-inoculation.<sup>146</sup> Osteoarticular sporotrichosis has been used to describe involvement presenting as tenosynovitis, periostitis, or monoarticular arthritis, often in immunosuppressed individuals.<sup>147</sup>

The differential diagnosis of cutaneous sporotrichosis includes atypical mycobacterial infection; bacterial abscess or ecthyma; *Nocardia*; foreign-body granuloma; chromoblastomycosis; cutaneous manifestations of systemic mycoses; leishmaniasis; anthrax; and tularemia. The gold standard for diagnosis is fungal culture of a skin-biopsy specimen. Direct examination of smears or biopsy material may be nonspecific. Histopathologic examination of skin-biopsy specimens may

reveal the organisms when enhanced via the application of special stains such as Gomori methenamine silver (GMS) or periodic acid-Schiff (PAS) stains. Molecular detection methods and serologic studies have also been utilized.<sup>139</sup>

The traditional treatment of choice for cutaneous sporotrichosis in adults has been orally administered saturated solution of potassium iodide (SSKI), 3 to 6 g per day for adults and half the dose for children. SSKI therapy may be associated with increased lacrimation or salivation, metallic taste, gastrointestinal discomfort, diarrhea, and headache. Treatment is continued until 4 to 6 weeks after clinical resolution of lesions. This therapy is still the most commonly used treatment in resource-limited settings.<sup>148</sup>

The treatment of choice for sporotrichosis in developed countries is usually oral itraconazole for 3 to 6 months with a reported success rate of 90% to 100% for cutaneous or lymphocutaneous disease.<sup>149</sup> In children the recommended dose is 5 mg/kg daily, and in adults a range of 100 to 400 mg daily has been recommended. Fluconazole is another option, although it may be less effective. Terbinafine and local hyperthermia are other potential therapies for nondisseminated disease, and amphotericin B is indicated for patients with life-threatening, disseminated, or extensive infection.

### Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is an uncommon chronic fungal infection of the skin and subcutaneous tissue caused by a variety of dematiaceous fungi (filamentous fungi with melanin-type pigment in the fungal wall). At least five organisms are implicated in the disease, including species of *Phialophora*, *Fonsecaea*, or *Cladophialophora*, all of which are common inhabitants of decaying wood and soil. Several cases have been reported after penetrating wounds of the skin, especially from splinters and thorns.<sup>150</sup> The disease is rare during childhood and is seen most commonly in tropical and subtropical climates.<sup>151</sup> The highest number of cases are diagnosed in Madagascar.<sup>152</sup>

Chromoblastomycosis is characterized initially by the formation of small scaly papules that may expand into nodules. The lesions, which are most often confined to the lower leg or foot, coalesce into larger nodules and plaques and characteristically develop a very verrucous (warty) surface. There may be purulent drainage, and the lesions may be painless or tender. The surface may be studded with multiple "black dots." Longstanding lesions may result in edema of the extremity and scarring.

The differential diagnosis of chromoblastomycosis includes other deep fungal, mycobacterial, and bacterial infections, as well as cutaneous tuberculosis, leishmaniasis, leprosy, squamous cell carcinoma, and tertiary syphilis. The diagnosis is confirmed by microscopic recognition of the organism in KOH wet-mount preparations or tissue biopsy specimens and by fungal culture. When the disease is localized, the treatment of choice is surgical excision of the affected tissue. Several destructive modalities including cryotherapy, heat therapy, electrodesiccation, and radiation therapy have been used. In more advanced cases, surgical or destructive approaches are not feasible and medical therapy is necessary. Systemic agents utilized for chromoblastomycosis include itraconazole (which appears to be the most effective<sup>153</sup>), terbinafine, thiabendazole, ketoconazole, and 5-flucytosine.<sup>151</sup> Amphotericin B tends to be less effective. Amputation of the affected limb is usually a last resort.<sup>154</sup>

### Mycetoma

Mycetoma, also called *Madura foot*, is a chronic granulomatous infection of the subcutaneous tissues along with invasion of the fascia, muscles, and bone, and when an extremity is involved, enlargement of the affected area. Although the majority of lesions are seen on a lower extremity, they may also occur on the hand, shoulder, buttocks, knees, or other regions of the body. The organisms that cause mycetoma are usually introduced by skin trauma. Mycetoma is endemic in Latin America, the Indian subcontinent, Africa, and between the latitudes of 15° South and 30° North around the Tropic of Cancer (the so-called "mycetoma belt").<sup>155</sup> This belt includes Sudan, Somalia, Senegal, India, Yemen, Mexico, Venezuela, Colombia, and Argentina.<sup>156</sup>

Mycetoma may be caused by various species of true fungi (eumycotic mycetoma), including *Pseudallescheria boydii*, *Madurella*

*mycetomatis*, *Madurella grisea*, and *Phialophora verrucosa*. It may also be caused by anaerobic fungus-like bacteria, the actinomycetes (actinomycotic mycetoma or actinomycetoma), usually by species of *Nocardia*, *Actinomadura*, or *Streptomyces*, including *Actinomadura madurae*, *Actinomadura pelletieri*, *Nocardia brasiliensis*, and *Streptomyces somaliensis*. These organisms exist as saprophytes in soil or on vegetable matter. The most common agent worldwide is *N. brasiliensis*. Mycetoma is uncommon in childhood and relatively rare in the United States, occurring most commonly in young adults and workers in rural tropical and subtropical areas who walk barefoot and are thus more readily exposed to the organisms.

The infection begins as one or more small, firm papules that gradually evolve into subcutaneous nodules with sinus tracts, draining abscesses, edema, and enlargement of the affected extremity. Purulent drainage is common and “grains” of various colors may be visible in the exudate, the color depending on the infecting organism. Eventually, crusting and granulation tissue may develop, and the infection may extend to the deeper tissue levels and bone. A preliminary diagnosis can be made by microscopic examination of the granules to identify their actinomycete or fungal nature, but tissue culture is generally necessary for confirmation. Treatment of mycetoma depends on the causative agent. Therapeutic options for actinomycotic mycetoma include sulfonamides, streptomycin, tetracyclines, rifampicin, ciprofloxacin, amikacin, penicillin, imipenem, and dapsone. Treatment of eumycotic mycetoma is more difficult and usually a combined approach of medical and surgical therapy. Small lesions may be best treated with complete excision. Medical therapies include the azole antifungals (especially ketoconazole and itraconazole) and amphotericin B.<sup>157</sup> Unfortunately there is no single drug that gives consistently good results, and longstanding cases with extensive tissue destruction and fibrosis are often resistant to all forms of therapy.

### Rhinosporidiosis

Rhinosporidiosis is a rare disorder caused by the organism *Rhinosporidium seeberi*. It occurs throughout the world but is most common in the tropics, especially in India and Sri Lanka. It has been occasionally reported in the United States, especially the southern portion. Although rare in children, a cluster of pediatric cases was reported in rural northeast Georgia between 1981 and 1994.<sup>158</sup> Studies have suggested a possible link to swimming or bathing in freshwater ponds, lakes, or rivers.<sup>159</sup> Although *R. seeberi* was originally thought to be a protozoan parasite, it has most consistently been classified as a fungus given its microscopic appearance and identification with fungal stains. Recent information supports its classification as a novel group of aquatic protistan parasites.<sup>159</sup>

Rhinosporidiosis is characterized by papules, nodules, and pedunculated vascular polypoid growths on the mucous membranes of the nose, nasopharynx, soft palate, and conjunctivae. Other potential sites of involvement include the upper respiratory passages, lacrimal sacs, skin, larynx, genitalia, or rectum. Tracheal involvement has been rarely reported.<sup>160</sup> The surface often has a raspberry-like appearance and is studded with tiny white or yellow nodules. The lesions may become hyperplastic and may reach enormous size, and symptoms are often associated with physical obstruction. Diagnosis is confirmed by microscopic examination, and the organism is notoriously difficult to isolate in culture. Fine-needle aspiration cytology may reveal the sporangia and spores of *R. seeberi*.<sup>161</sup> Treatment generally consists of electrosurgical destruction or surgical removal of lesions when feasible. Antimicrobial agents, most notably dapsone, have been reportedly effective in some patients.

### SYSTEMIC MYCOSES

The systemic mycoses comprise a group of fungal disorders that arise from internal foci, usually the lungs or upper respiratory tract. When the skin lesions result from dissemination of the infection, the prognosis is generally poor. Primary inoculation disease of the skin occasionally occurs with these infections. Disorders in this group include blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and histoplasmosis. Actinomycosis and nocardiosis, although often included under the group of disorders because of true fungi, are actually

caused by fungus-like Gram-positive bacteria and are discussed in the section on bacterial infections (see Chapter 14).

### Blastomycosis

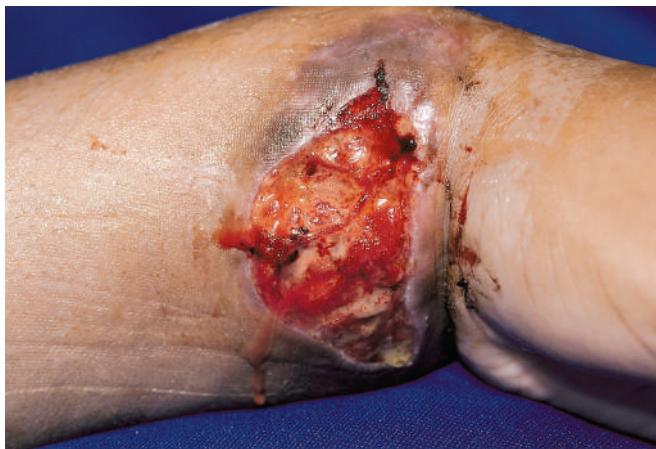

Blastomycosis (North American blastomycosis, Gilchrist disease, Chicago disease) is a systemic granulomatous infection caused by the dimorphic fungus, *Blastomyces dermatitidis*. It occurs most often in the southeastern and south central states that border the Mississippi and Ohio Rivers and the Great Lakes states. It is considered endemic in several focal areas of northern Wisconsin and Michigan. Blastomycosis occurs in three forms: pulmonary, disseminated (systemic), and primary cutaneous inoculation, which is quite rare. Primary inoculation blastomycosis has been reported primarily in laboratory technicians working with the organism and in pathologists who perform autopsies on animals or humans with the disease.<sup>162</sup> The organism has been cultured from soil, which is believed to be the reservoir for infection in humans.<sup>163</sup> Blastomycosis is rare in children, especially those under 1 year of age, and when it occurs, extrapulmonary disease (including CNS involvement) is fairly common.<sup>164,165</sup> South American blastomycosis is a chronic granulomatous disease caused by *Paracoccidioides brasiliensis* and is also known as paracoccidioidomycosis. It is discussed briefly later in this chapter.

Primary infection usually involves the lungs, and patients may exhibit nonspecific flu-like symptoms, cough, low-grade fever, night sweats, hemoptysis, or minimal symptomatology. Chest radiography is often nonspecific during acute infection. Many patients with acute pulmonary blastomycosis may go undiagnosed and thus untreated. The disorder may heal spontaneously, progress to chronic pulmonary disease with or without cavitation, or disseminate, primarily to skin, subcutaneous tissues, bones, and joints. Acute respiratory distress syndrome (ARDS) may occasionally occur.<sup>166</sup> Other potential sites of dissemination are the gastrointestinal tract, liver, spleen, genitourinary tract, and CNS.

Skin involvement in North American blastomycosis is most commonly associated with disseminated disease and only occasionally associated with primary inoculation. Primary cutaneous blastomycosis is extremely rare in children and often presents with a localized chancroid-like ulcer.<sup>167</sup> The primary types of skin changes noted in all forms of cutaneous blastomycosis are verrucous (warty) lesions and cutaneous ulcers.<sup>168</sup> Verrucous lesions present with heaped-up hyperkeratosis with a surrounding erythematous or violaceous color (Fig. 17-49). They may be confused with multiple other cutaneous

**Figure 17-49** Cutaneous blastomycosis. Verrucous, crusted, erythematous plaque on the chin in a 15-year-old male with respiratory symptoms and bone pain. (Reprinted with permission from Cummins RE, Romero RC, Mancini AJ. Disseminated North American blastomycosis in an adolescent male: a delay in diagnosis. *Pediatrics* 1998;102(4):977–9. © American Academy of Pediatrics. All rights reserved.)

**Figure 17-51** Cutaneous coccidioidomycosis. Multiple verrucous papules and plaques in a patient with cutaneous coccidioidomycosis disseminated from a primary pulmonary infection.

infections or squamous cell carcinoma. The ulcerative lesions begin as papules or pustules and progress to superficial ulcers with granulation tissue (Fig. 17-50). Cutaneous lesions disseminated from a primary pulmonary focus are usually symmetrical and generally appear on the exposed areas of the body (the face, wrists, hands, and feet). Skin lesions may also occur over areas of osteomyelitis and present as draining sinus tracts. In patients with primary cutaneous inoculation blastomycosis, the skin lesions occur with focal lymphadenopathy or lymphangitis but without evidence for systemic involvement.<sup>169</sup> Sources for primary inoculation disease include clinical exposures as noted above (i.e., laboratory or morgue, primarily in adults), animal bite or scratch, and other forms of skin trauma. The skin lesions of blastomycosis heal eventually (even without therapy), often resulting in permanent scarring.

North American blastomycosis is diagnosed by identification of the thick-walled, broad-based budding yeast cells in tissue samples or growth in fungal culture. Serologic studies are not useful, and enzyme immunoassays are sensitive but not available on a widespread basis. Cytologic examination of specimens (i.e., sputum) may be useful.<sup>170</sup> Urine-antigen detection may be useful in children for both diagnosis and for monitoring response to therapy.<sup>171</sup> Deoxyribonucleic acid (DNA) probe and polymerase chain reaction (PCR) assays have also been reported.<sup>172</sup> A high index of suspicion must be maintained in the patient with cutaneous ulcers or verrucous skin lesions, especially if other symptoms of systemic disease are present, most notably those referable to the lungs or bones, and if the patient resides in (or has traveled to) an endemic area. A delay in diagnosis is common, especially in children.<sup>165,173,174</sup>

Treatment depends upon the extent of disease and immune status of the patient. Whereas observation alone may be an option for mild pulmonary or primary inoculation skin disease, most patients require therapy, especially those with severe disease or immunocompromised or disseminated involvement. Local excision has been utilized for small lesions limited to skin. Systemic therapeutic options for blastomycosis include itraconazole, ketoconazole, fluconazole, and amphotericin B. Azole antifungal therapy should be continued for at least 6 months and for at least 1 year in patients with blastomycotic osteomyelitis.<sup>175,176</sup> Life-threatening, CNS, or disseminated disease, as well as infection in the immunocompromised host, should be treated initially with amphotericin B, and therapy can be switched over to itraconazole after clinical stabilization.<sup>175,176</sup> Liposomal amphotericin B appears to have superior CNS penetration.

### Coccidioidomycosis

Coccidioidomycosis is a deep fungal infection caused by *Coccidioides immitis*, a soil saprophyte endemic in the hot, arid desert areas of the

southwestern United States (especially the San Joaquin Valley in California), Mexico, and parts of South America. Inhalation of air-borne arthroconidia results in infection, which in many cases is asymptomatic. Rare fomite transmission has been reported.<sup>177</sup> Occasional epidemics of coccidioidomycosis have been seen, often after severe dust storms and even in 1994 after a California earthquake.<sup>178</sup> The incidence of coccidioidomycosis has been increasing in the United States, and in some highly endemic regions nearly 100% of the population has serologic evidence of past exposure.<sup>162</sup>

*C. immitis* infection is often asymptomatic or may present with influenza-like symptoms of fever, cough, chest pain, headache, sore throat, and fatigue.<sup>179</sup> Erythema nodosum or erythema multiforme may develop. Generalized arthralgias may accompany these acute symptoms, and this syndrome is referred to as *desert rheumatism* or *Valley fever*. Acute pulmonary infection, which accounts for 98% of cases, usually resolves without therapy over several weeks.<sup>180</sup> Around 5% of patients will have asymptomatic residual lesions in the lungs, usually nodules or thin-walled cavities.<sup>180</sup>

Extrapulmonary disease occurs in a minority of patients, and in this case the organism disseminates hematogenously to any of several organs including the meninges, bones, joints, skin, and soft tissues. Disseminated disease is most common in African-Americans, Filipinos, and Native Americans, as well as in patients with immunosuppression.<sup>179</sup> More recently, *Coccidioides* species have become significant opportunistic pathogens in patients infected with HIV and in recipients of organ transplants.<sup>181</sup>

Skin involvement in coccidioidomycosis may be seen in the setting of acute disease or disseminated disease and, rarely, as a primary inoculation infection. During the acute phase of infection, a generalized erythematous macular exanthem may appear within the first 1 to 2 days of illness. As mentioned earlier, erythema multiforme or erythema nodosum lesions may also present during this phase of the illness, as may Sweet syndrome (see Chapter 20) or an entity referred to as *interstitial granulomatous dermatitis*. The latter refers to a granulomatous dermatitis that may occur in the setting of a variety of infectious, inflammatory, or autoimmune disorders.<sup>181</sup> In addition to these “parainfectious” cutaneous stigmata, infectious skin lesions may present (primarily with disseminated disease) as single or multiple verrucous, granulomatous papules and plaques (Fig. 17-51), subcutaneous abscess, acneiform papules, and pustules. Although lesions may occur anywhere on the skin surface, they are most common on the head (particularly the nasolabial fold), neck, and chest.<sup>182</sup> Cutaneous findings in coccidioidomycosis are not specific and as with many deep fungal disorders, may suggest a variety of potential diagnoses in the differential. Primary cutaneous inoculation is relatively rare and occurs through injury by contaminated splinters or thorns or by accidental inoculation in laboratory or autopsy rooms. This form of coccidioidomycosis is usually characterized by a painless

ulcerated plaque with lymphangitis and lymphadenopathy (similar to that seen in sporotrichosis or blastomycosis). Although healing usually takes place within a few months, there are rare reports of patients with primary cutaneous inoculation developing systemic dissemination.<sup>183</sup>

The diagnosis of coccidioidomycosis can be confirmed by demonstration of the characteristic large, thick-walled mature spherules with endospores in tissue-biopsy specimens. Fungal culture of materials such as pus, sputum, or aspirates will often grow *C. immitis*, but because the organism is highly infectious, special precautions are necessary to prevent laboratory accidents caused by air-borne spread of arthrospores. Serologic and skin testing are also useful in making the diagnosis of coccidioidomycosis. The coccidioidin skin test usually becomes positive soon after the development of symptoms in patients with primary infection, although anergy may be present in progressive disease.<sup>180</sup> IgM and IgG (complement fixation) antibodies may be present, the latter appearing between 4 and 12 weeks after infection and disappearing several months later if disease resolution occurs. Changes in the antibody titer may be useful for monitoring disease activity and response to therapy. A high titer of complement fixation antibody denotes severe extensive disease and a poorer prognosis; complement fixation antibodies in cerebrospinal fluid indicate the presence of CNS infection. *In situ* hybridization and PCR techniques may also be useful in confirming the diagnosis.<sup>181</sup>

The majority of infections with coccidioidomycosis are self-limiting, go undetected, and do not require specific therapy. Disseminated disease, however, may follow a fulminant course or persist for several years. The choice of the therapeutic agent and decisions regarding length of therapy depend on the immune status of the host, the seriousness of the infection, and the organs involved. Therapeutic options include amphotericin B, ketoconazole, itraconazole, and fluconazole. Amphotericin B is the recommended initial therapy for severe or progressive infection, and fluconazole is recommended for CNS infections.<sup>184</sup> Patients with CNS infection with *C. immitis* may require amphotericin B infusions into the cerebrospinal fluid. Pulmonary resection has a role in managing severe hemoptysis, sequestrations, or lung cavitations.

### Paracoccidioidomycosis

South American blastomycosis (paracoccidioidomycosis) occurs almost exclusively in South and Central America and is caused by infection with the dimorphic fungus, *P. brasiliensis*. The disorder is endemic in Brazil (where the majority of cases occur), Venezuela, Colombia, Ecuador, Argentina, and Peru. It may occur many years after relocation out of an endemic region.<sup>185</sup> Paracoccidioidomycosis has become an opportunistic infection in individuals with HIV infection. It is most common in adults and uncommon in childhood, when it is referred to as the *acute juvenile form*. It is thought that the organism lives as a saprophyte on vegetation or in soil and that the infection is acquired by direct implantation into the skin or mucous membranes, possibly through the practice of cleaning the teeth with small pieces of infected vegetation or in pulmonary lesions by direct inhalation of the organism.

Paracoccidioidomycosis may present with a wide spectrum of involvement, ranging from asymptomatic pulmonary infection to symptomatic infection involving one or several organs that may progress in a fulminant fashion. The most common organs of involvement are the lungs, skin, mucosae, lymph nodes, and bone. Mucocutaneous involvement presents with infiltrative, ulcerative lesions on the lips and in the mouth, pharynx, or nasal cavity. The ulcerative and verrucous plaques may extend and ultimately progress to destroy the nose, lips, and facies. Pain and dental loss may occur. Hematogenous or lymphatic spread results in subcutaneous abscesses, and the lymph nodes draining the affected areas are palpable, painful, and adherent to the overlying skin, occasionally progressing to form chronic sinuses and suppurative plaques. Primary cutaneous infection is rarely reported.<sup>186</sup> The juvenile form tends to be more aggressive and involve primarily the reticuloendothelial system.<sup>185</sup>

Paracoccidioidomycosis is diagnosed by recognition of the typical yeast forms in tissue specimens, fungal culture, serologic studies (mainly in immunocompetent hosts), or newer molecular methodologies such as PCR, which may be useful in observing response to

therapy.<sup>185</sup> Treatment usually consists of azole antifungals or amphotericin B.

### Histoplasmosis

Histoplasmosis is another deep fungal infection caused by a thermally dimorphic fungus, in this case, *Histoplasma capsulatum*. This organism (*H. capsulatum* var. *capsulatum*) is endemic in the Americas, especially in Ohio and the Mississippi river valleys and Latin America, and is more concentrated in places where the soil is enriched by bird excreta or bat guano.<sup>187</sup> The other variety, *H. capsulatum* var. *duboisii*, is endemic in some areas of Africa. Infection is usually acquired by inhalation of fungal microconidia and may result in various manifestations from asymptomatic infection to disseminated, progressive disease. Transmission from fomites, direct inoculation, organ transplantation, and sexual contact have also been reported.<sup>188</sup> Histoplasmosis affects infants and children as well as adults.

The manifestations of histoplasmosis are quite varied. The classically recognized forms of histoplasmosis are acute pulmonary, chronic cavitary, and disseminated. Primary infection is asymptomatic or produces very mild symptoms in up to 95% of patients. Many patients manifest pulmonary symptoms including cough and chest pain along with fever and malaise. A chronic pulmonary form may resemble tuberculosis both clinically and radiographically. Involvement of the reticuloendothelial system may occur, and accounts for most of the signs of progressive disseminated histoplasmosis (PDH). PDH tends to occur in patients with compromised cell-mediated immunity. Bone marrow involvement with pancytopenia is common, as are hepatosplenomegaly and lymphadenopathy.<sup>189</sup> Gastrointestinal bleeding, meningitis, adrenal gland involvement, and endocarditis may also occur with disseminated histoplasmosis. Disseminated disease occurs in fewer than 1% of those infected. Cardiac tamponade may develop in up to 25% of patients with pulmonary histoplasmosis.<sup>188</sup>

Skin involvement is uncommon in histoplasmosis but may be seen in the disseminated form and rarely in a primary inoculation form. The morphologic characteristics include papules, plaques, pustules, purpura, nodules, ulcers, abscesses, molluscum-like lesions, severe dermatitis, exfoliative erythroderma, and verrucous lesions. Erythema multiforme and erythema nodosum may both occur, usually in the setting of acute pulmonary infection. The characteristic ulcerative, mucocutaneous lesions of the nose, mouth, pharynx, larynx, genitals, and perianal region are seen in chronic disseminated disease and in patients with immunodeficiency. Lesions in these regions may present as superficial or deep ulcerations with heaped up borders, nodular masses, or verrucous plaques.<sup>190</sup> Oral manifestations are seen in 25% to 75% of patients with disseminated disease.<sup>191,192</sup>

Children with histoplasmosis tend to have more disseminated disease. In fact, 20% of apparently immunocompetent patients with disseminated infection are children.<sup>187</sup> A disseminated form of histoplasmosis in infants may be associated with transient hyperglobulinemia and T-cell deficiency and when occurring after exposure to a large inoculum of the pathogen, has a high mortality rate.<sup>193</sup> In children with histoplasmosis, the incidence of extensive ulcers along the gastrointestinal mucosa that give rise to diarrhea and other gastrointestinal disturbances suggests that organisms may be ingested rather than inhaled in these individuals.

The gold standards for diagnosing histoplasmosis are identification of the small intracellular yeast-like organisms in tissue specimens, sputum, or peripheral blood, and fungal culture. Tissue biopsies from skin or mucosal lesions reveal necrotizing granulomas along with the yeast forms. The usefulness of the histoplasmin skin test is quite low, given its nonspecificity especially in endemic areas.<sup>189</sup> *Histoplasma* serologies (including complement fixation and immunodiffusion precipitin bands) are available but hampered by high rates of false-positive and false-negative responses. Detection of *Histoplasma* antigen in urine may be useful but also has the disadvantage of many potential causes for false-positive results, especially other endemic mycoses.<sup>190</sup> An enzyme-linked immunosorbent assay (ELISA) against *H. capsulatum* circulating antigens has good sensitivity and excellent specificity,<sup>194</sup> although it may not be readily available. PCR assays are also being developed, although none is currently commercially available.

In mild cases of histoplasmosis, treatment may not be necessary, and the disorder runs a benign, self-limited course. For severe or widespread disease, systemic antifungal therapy with amphotericin B is usually indicated. For more localized or less severe disease (i.e., chronic pulmonary histoplasmosis), oral azole antifungal therapy is an option. Various regimens have been reported in pediatric patients. Disseminated childhood histoplasmosis has been treated successfully with itraconazole for 3 to 12 months, as well as with parenteral amphotericin B followed by oral ketoconazole, itraconazole, or voriconazole.<sup>187,193,195</sup> In patients with acquired immunodeficiency syndrome (AIDS) and severe histoplasmosis, amphotericin B is indicated, whereas itraconazole may be appropriate therapy for mild to moderate disseminated disease.<sup>196</sup> Fluconazole is less effective than the other azole antifungal agents, and clinical data on the newer azoles, voriconazole and posaconazole, are limited.<sup>190,192</sup>

## OPPORTUNISTIC MYCOSES

With the spread of AIDS and advancements in cancer chemotherapy, bone marrow and solid-organ transplantation, and both routine and intensive medical care, certain patient populations who are vulnerable to potentially fatal deep fungal infections have emerged. These organisms are generally nonpathogenic but in certain at-risk individuals who have an alteration or breakdown of host defenses may result in severe disseminated infection. The opportunistic mycoses to be discussed here include aspergillosis, cryptococcosis, fusarium, and mucormycosis. Risk factors for opportunistic mycoses are listed in Table 17-3.<sup>197</sup>

### Aspergillosis

Aspergillosis is an uncommon opportunistic fungal disease of the respiratory tract and other sites caused by a variety of *Aspergillus* species. Although *Aspergillus fumigatus* is the most commonly identified pathogen, *Aspergillus niger*, *Aspergillus flavus*, and an increasing number of other species have been reported in recent years. Invasive aspergillosis is most often seen in patients with prolonged neutropenia and in transplant recipients.<sup>198</sup>

**Table 17-3** Risk Factors for Opportunistic Mycoses/Invasive Fungal Disease

Factor	Comment
Neutropenia	Usually prolonged, severe
Hematologic malignancy	And associated chemotherapy
Transplant recipient	Primarily BMT/HSCT
HIV infection/AIDS	Especially cryptococcosis
High-dose corticosteroids	Often in setting of GVHD therapy
Broad-spectrum antibiotics	
Alterations of oropharyngeal and gastrointestinal mucosae	Via chemotherapy
Altered skin integrity	Catheter sites, skin breakdown or occlusion, burns, wounds
Presence of catheters	Vascular, urinary
Extremes of age	Premature infants, elderly persons
Prolonged hospitalization	ICU
Diabetes mellitus	Specific to mucormycosis
Total parenteral nutrition	

Modified from Gutierrez Paredes EM, Gamez Perez L, Gonzalez Rodriguez AJ, et al. Disseminated fusariosis in immunocompromised patients. Eur J Dermatol 2011;21(5):753–5, and Pfaller MA, Pappas PG, Wingard JR. Invasive fungal pathogens: current epidemiologic trends. Clin Infect Dis 2006;43:S3–14.

AIDS, Acquired immunodeficiency syndrome; BMT, bone marrow transplantation; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; HSCT, hematopoietic stem cell transplantation; ICU, intensive care unit.

*Aspergillus* species are ubiquitous and are normally nonpathogenic. When pathogenic, they primarily cause infection in the lung, although the skin, eyes, CNS, bones, gastrointestinal tract, liver, spleen, lymph nodes, nasopharynx, and genitourinary tract may also be affected. In children, the highest risk groups are those with AIDS, leukemia, corticosteroid or immunosuppressive therapy, chronic granulomatous disease, and severe combined immunodeficiency.<sup>199</sup> Neonates, especially premature ones, appear to be another population at risk for disseminated aspergillosis.<sup>200</sup> Other neonatal aspergillosis risk factors include corticosteroid use, prolonged hospitalization, and skin trauma from tape adhesive in relation to prolonged use of arm boards.<sup>201</sup> Despite aggressive therapy, invasive aspergillosis in children is associated with a mortality rate as high as 85%.<sup>202</sup> Cutaneous aspergillosis has also been reported in immunocompetent adults and children, typically after intravenous-catheter site occlusion or trauma.<sup>203–205</sup>

One of the most common characteristic manifestations of aspergillosis is the pulmonary intracavitary fungus ball. This is composed of colonies of *Aspergillus*, inflammatory exudate, cells, and fibrin in the form of a sphere that may measure from 1 to 5 cm in diameter. Although it occasionally causes hemoptysis, most patients with fungus balls are asymptomatic. Another form of pulmonary disease is invasive pulmonary aspergillosis, which may be necrotizing and is often associated with multiorgan dissemination.

Cutaneous aspergillosis may occur in two forms: primary or secondary. Primary cutaneous aspergillosis usually occurs at sites of skin injury such as intravenous-catheter insertion sites, burns, surgical wounds, or sites covered by various products including occlusive dressings and tape. Secondary cutaneous aspergillosis occurs with direct extension to the skin from underlying soft-tissue infection or hematogenous dissemination.<sup>206</sup> Less commonly, an opportunistic infection of the paranasal sinuses may result in mucopurulent or blood-tinged nasal discharge, headache, periorbital neuralgia, and rhinitis. With extension of this process, the face may become erythematous, swollen, warm, and tender, suggesting a diagnosis of cellulitis or erysipelas.

Cutaneous aspergillosis may initially present as nondescript erythematous macules, papules, or plaques. Common secondary findings include hemorrhagic bullae and necrosis (Fig. 17-52), which may extend rapidly. Eschar formation is often seen. In patients with hematogenous dissemination, embolic lesions present as widespread erythematous to purpuric macules and papules with ulceration and necrosis and may simulate the lesions of ecthyma gangrenosum (caused by *Pseudomonas aeruginosa*). Pustules overlying an erythematous patch are a common finding in the early cutaneous lesions of neonates and often progress to ulceration, necrosis, and eschar formation.<sup>207</sup>

The diagnosis of cutaneous aspergillus can be confirmed by tissue biopsy for histopathology and fungal culture. A deep-skin biopsy is

**Figure 17-52** Cutaneous aspergillosis. Erythematous plaque with necrosis and eschar formation in a young female with immunosuppression and disseminated *Aspergillus fumigatus* infection.

desirable in order to visualize the dermal and subcutaneous blood vessels given the angiotropic nature of *Aspergillus* species. Fungal stains applied to the biopsy material will reveal large fungal hyphae with "acute-angle" branching, and this method will enable a more rapid diagnosis than awaiting results of the fungal culture. Blood cultures are rarely positive. ELISA and PCR testing are available in some centers and may offer a more rapid and reliable means of diagnosing disseminated aspergillosis, especially in immunocompromised children.<sup>199</sup> The galactomannan antigen assay appears to be sensitive in diagnosing invasive aspergillosis in children, although the cutoff thresholds for this population continue to be studied.<sup>208–210</sup>

The treatment of aspergillosis depends on the underlying immune status of the patient and risk factors for disseminated infection. In most cases, systemic therapy is indicated. Occasionally, surgical approaches may suffice (i.e., primary cutaneous aspergillosis in a burn patient without underlying risk factors for disseminated disease). Although amphotericin B has been the mainstay of systemic therapy for years, in some patients this agent is associated with untoward side effects and in others it may result in a suboptimal response.<sup>198</sup> Azole antifungal agents such as itraconazole have also been used with mixed results. The newer broad-spectrum triazole, voriconazole, has been evaluated and demonstrated effective in adults and children with invasive aspergillosis, although the numerous drug interactions may limit its usefulness in some patients.<sup>198,211,212</sup> Caspofungin therapy has also been studied in salvage therapy for invasive aspergillosis, and a body-surface area dosing calculation is preferred over a weight-based regimen for treating children with this agent.<sup>213</sup>

### Cryptococcosis

*Cryptococcus neoformans* is a ubiquitous encapsulated fungus capable of causing severe disease in immunocompromised individuals, especially those with AIDS. Disseminated disease has been rarely observed in immunocompetent children.<sup>214</sup> Whereas it is well established as the most common cause of life-threatening fungal infection in adults with HIV infection, infection in children with HIV may occur in up to 1% of those with AIDS.<sup>215</sup> The organism has been found in various fruits, soil, pigeon excreta, and cow's milk. It is believed to be acquired via inhalation of aerosolized particles from the environment, and recent data suggest that *C. neoformans* may infect many immunocompetent children early in life, resulting in either asymptomatic infection or nonspecific "viral" symptoms.<sup>216</sup> The incidence of cryptococcosis has declined in the past decade, largely because of the improvements in HIV care and the use of highly active antiretroviral therapy (HAART).<sup>217</sup> *Cryptococcus laurentii* is a rare species that may also result in cutaneous lesions, although it is most often implicated in pulmonary, ocular, and disseminated infections.<sup>218</sup>

Cryptococcal infection most commonly presents as meningitis, meningoencephalitis, or sepsis. Infection may be localized to the lungs, producing focal pneumonia, patchy infiltrates, solitary nodules, abscesses, or pleural effusion. Pulmonary symptoms, however, may be absent or minimal, and although pulmonary involvement may be progressive, in most instances CNS manifestations predominate and infection is detected only after dissemination, which may include the skin. Cutaneous lesions may present months before other signs of systemic infection.<sup>219</sup> They may occasionally occur after trauma or extension from bony involvement but are usually the result of hematogenous spread from a pulmonary focus.

Skin lesions, which occur in 6% to 15% of patients with systemic infection, present most commonly on the head and neck, where they may often mimic the lesions of molluscum contagiosum. They begin as painless, firm, pink to red papules, pustules, or acneiform lesions. The molluscum-like lesions may be umbilicated or contain a tiny central hemorrhagic crust and may be multiple.<sup>219</sup> Surrounding inflammation is usually absent. As the lesions enlarge they may form infiltrated plaques, nodules, abscesses, or ulcers, often with raised papillomatous borders. In patients with primary inoculation cutaneous cryptococcosis, the clinical findings most often observed are ulcers, abscesses, or cellulitis.<sup>220</sup>

The diagnosis of cryptococcosis is confirmed by demonstration of the characteristic organism (surrounded by a polysaccharide capsule and with characteristic budding seen in India ink preparations) in cerebrospinal fluid, skin lesions, sputum, or tissue sections. Definitive

diagnosis relies on isolation of the organism from biopsy tissue or bodily fluids.<sup>221</sup> Serologic studies, immunoblotting, and ELISA or latex agglutination assays for the cryptococcal polysaccharide are other diagnostic modalities. The recommended therapy for cryptococcosis is amphotericin B with 5-flucytosine or fluconazole, because combination therapy appears to be superior to amphotericin monotherapy.<sup>222</sup> Fluconazole suppression is recommended after completion of the primary therapy.<sup>221</sup>

### Fusarium Infection

*Fusarium* species are molds that are normally found in soil and the air and may result in localized infections in the nail (fusarium onychomycosis or paronychia) or in burn sites or surgical wounds. However, invasive *Fusarium* infection (or fusariosis) is an increasingly prevalent, serious opportunistic fungal infection that occurs especially in patients with hematologic malignancy undergoing cytotoxic chemotherapy or bone marrow transplantation. Prolonged neutropenia seems to be the main risk factor for this infection. Skin lesions are common in patients with disseminated *Fusarium* infection and may serve as the portal of entry for more widespread involvement. Cutaneous involvement may be mistaken for aspergillosis given the potential clinical overlap in presentation. Disseminated fusariosis is considered to be the second most common opportunistic infection in neutropenic patients after *Aspergillus* and appears to be the most common agent resulting in fungemia with cutaneous lesions.<sup>223,224</sup>

Immunocompromised patients with *Fusarium* infection may have refractory fever, skin lesions, sinusitis, myalgias, or pneumonia. Endophthalmitis may occur from hematogenous seeding as opposed to the fusarial endophthalmitis that occurs in immunocompetent hosts as a complication of advanced keratitis or after ophthalmologic surgery.<sup>225</sup> Fungemia with multiorgan involvement is possible, and the organism is more often cultured from the blood than is *Aspergillus*. Disseminated infection is often notable for skin lesions, which occur in up to 80% of these patients.<sup>226</sup> Skin lesions of fusariosis may include paronychia, tinea pedis, onychomycosis, digital ulcers, or widespread lesions most often involving the extremities. The disseminated lesions present most often as painful, red to gray macules or papules, with purpura, necrosis, and eschar formation.<sup>227</sup> They may mimic the lesions of ecthyma gangrenosum.<sup>228,229</sup> Pustules, cellulitis, abscesses, bullae, and subcutaneous nodules may also occur, and "target lesions" have been described.<sup>229,230</sup> Less common manifestations may include panniculitis, sporotrichoid lesions, and intertrigo.<sup>224</sup>

Fusariosis is usually diagnosed via microscopic examination of skin biopsy specimens with confirmation by fungal culture of tissues and/or blood. Treatment is difficult and includes regular or lipid formulations of amphotericin B, itraconazole, and correction of the neutropenia with granulocyte colony-stimulating factor (G-CSF)– or granulocyte-macrophage colony-stimulating factor (GM-CSF)–stimulated granulocyte transfusions.<sup>229</sup> Newer antifungal agents such as voriconazole or posaconazole may also have a role in the treatment of this serious infection.<sup>230,231</sup>

### Mucormycosis

Mucormycosis (also known as *zygomycosis* or *phycomycosis*) is an opportunistic fungal infection caused by a group of organisms in the order Mucorales (of the class Zygomycetes). Infection of the immunocompetent host is extremely rare despite continual exposure to these organisms. Mucormycosis occurs mainly in immunocompromised individuals and in patients with debilitating diseases (i.e., diabetes mellitus, anemia, heart or liver disease, burns, leukemia, or lymphoma) and is among the most acute, fulminant, and fatal of all fungal infections.<sup>232</sup> It may also occur with increased incidence in patients exposed to hospital construction activity. It may involve any organ of the body but most commonly affects the skin, lungs, meninges, gastrointestinal tract, and structures of the head and neck. Up to 10% of cases of mucormycosis may occur in immunocompetent individuals without identifiable predisposing factors.<sup>233</sup> In children, mucormycosis is associated with many of the risk factors outlined in Table 17-3; in addition, prematurity, low birthweight, malnutrition, and use of wooden tongue depressors and cotton stockinettes have also been reported in association with this infection.<sup>234</sup> Whereas the incidence of mucormycosis may be increasing in adults, a

retrospective 7-year study at a large tertiary children's hospital suggested no such trend in pediatric patients.<sup>235</sup>

The causative fungi of mucormycosis include species of *Mucor*, *Rhizopus*, *Absidia*, *Cunninghamella*, and *Rhizomucor*. The most common cause of zygomycosis is *Rhizopus oryzae* (*arrhizus*). These organisms are saprophytic and grow in soil and on decaying organic materials such as vegetation, fruit, and bread.<sup>236</sup> The portal of entry for these infections varies with the site of the disease. Rhinocerebral mucormycosis is the most common form and affects primarily patients with diabetes as well as patients with immunocompromise.

Cutaneous or subcutaneous infections occur most often in diabetics with recurrent acidosis or in patients with a history of skin trauma or severe burns. This form of infection is characterized by hemorrhagic or necrotic papules and plaques, chronic indolent ulcers, and slowly enlarging dusky nodules. The initial lesion is often a small area of macular discoloration or dusky erythema that gradually enlarges and ulcerates. Necrosis may be marked, and there may be a foul-smelling purulent exudate. A gangrenous form results in rapid ulceration and necrotizing fasciitis-like tissue destruction. The skin lesions of cutaneous mucormycosis are not pathognomonic and may be confused with lesions of ecthyma gangrenosum, aspergillosis, deep fungal infections, other soft-tissue infections, pyoderma gangrenosum, or vasculitis.<sup>232,237</sup> The skin lesions may be primary or secondary, in which case they are related to hematogenous dissemination of the organism from a primary infection in another organ.

The rhinocerebral form is usually characterized by a suppurative necrotizing infection of the paranasal sinuses with periorbital pain, swelling, edema, proptosis, extraocular muscle paresis, and decreased visual acuity. This form is uniformly fatal within weeks when there is extensive involvement, and combined treatment with surgical debridement/resection and systemic antifungals is warranted.<sup>238</sup> Other reported forms of mucormycosis include gastrointestinal, pulmonary, and disseminated. An angioinvasive form of mucormycosis

has been described in neonates, usually those with the risk factors of prematurity, low birthweight, broad-spectrum antibiotic or corticosteroid therapy, and history of local skin trauma.<sup>239</sup> However, the most common types to occur in premature neonates appear to be the gastrointestinal and cutaneous forms.<sup>240</sup>

The diagnosis of mucormycosis relies on tissue biopsy and histologic examination. Broad, nonseptated, thick-walled hyphae are seen and may be noted to be invading cutaneous blood vessels. Fungal culture is confirmatory. Therapy is difficult and often requires a combination of surgical debridement, treatment of the underlying disease process, removal of the source of infection (when possible), and intravenous amphotericin B. Lipid formulations of amphotericin B appear to be more efficacious in treating CNS mucormycosis.<sup>241</sup> Posaconazole may be a reasonable option for those who are resistant to or intolerant of amphotericin.<sup>241</sup>

# 18 Infestations, Bites, and Stings

Parasites are a fascinating and important cause of skin disease in children. They produce their effects in various ways: mechanical trauma from bites or stings, injection of pharmacologically active substances that induce local or systemic effects, allergic reactions in a previously sensitized host, persistent granulomatous reactions to retained mouth parts, direct invasion of the epidermis, or transmission of infectious disease by blood-sucking insects.

## Arthropods

Arthropods are elongated invertebrate animals with segmented bodies, true appendages, and a chitinous exoskeleton. Those of dermatologic significance are the eight-legged arachnids (mites, ticks, spiders, and scorpions) and the six-legged insects (lice, flies, mosquitoes, fleas, bugs, bees, wasps, ants, caterpillars/moths, and beetles).

### ARACHNIDS

The term *mite* refers to a large number of tiny arachnids, many of which live at least part of their lives as parasites upon animals or plants or in prepared foods. Of greatest clinical significance are itch mites (*Sarcoptes scabiei*), grain mites, and harvest mites (chiggers). Avian mite dermatitis has also been recognized with increased incidence in recent years. Mites attack humans by burrowing under or attaching themselves to the skin, where they inflict trivial bites and cause associated dermatitides.

### Scabies

Scabies is a common skin infestation caused by the mite *S. scabiei*. This mite is an obligate human parasite residing in burrowed tunnels within the human epidermis. Mites of all developmental stages may burrow into skin, depositing feces in their tracks. The female mite also lays eggs in these burrows, which serves to further propagate the infestation. The adult female mite has a lifespan of around 15 to 30 days, measures around 400 µm, and lays 1 to 4 eggs per day, which hatch in 3 to 4 days.<sup>1,2</sup> After hatching, the larvae mature into adult mites in 10 to 14 days, and the duration of the whole life cycle is 30 to 60 days.

Scabies is transmitted most often by direct contact with an infested individual, although acquisition from fomites such as bedding and clothing is also possible. The survival time for a mite separated from the human host is estimated at several days. It is estimated that 15 to 20 minutes of close contact time is required for the transmission of scabies from one person to another. Scabies disproportionately affects women and children, as well as individuals with certain predisposing conditions, including immunocompromise, severe mental or physical handicap, and human immunodeficiency virus (HIV) infection. Scabies is seen worldwide in infants and children, and in the United States there seems to be a fairly high incidence in foreign-born adoptees, especially those from Asia or Latin America.<sup>3,4</sup> This latter observation is likely related to the high incidence of infestation seen in orphanages. Scabies continues to be a significant public health issue in the developing world, with a disproportionate burden of disease noted in children who live in overcrowded, lower socioeconomic tropical regions. High endemic rates of scabies are noted in closed communities and institutional environments.<sup>5</sup> In institutions, risk factors for scabies include institution type (with long-term care facilities and larger-sized institutions having higher incidence), extensive physical contact between patients and care workers, movement of patients, delay in diagnosis, and poor implementation of infection control or treatment.<sup>6</sup>

The incubation period for classic scabies is around 3 weeks, with reinfection resulting in more immediate symptoms.<sup>7</sup> The initial symptom of scabies is usually pruritus, which is often evident well before the clinical signs become apparent. Patients with scabies usually complain of worsening pruritus during nighttime hours. Infants and young children may also experience irritability and poor feeding. The skin findings include papules, nodules, burrows, and vesiculopustules (Figs. 18-1 through 18-5). The most common locations for scabies lesions are the interdigital spaces, wrists, ankles, axillae, waist, groin, palms, and soles. Burrows on the palms may reveal a pattern of scale reminiscent of the wake left on a water surface by a moving boat and has been termed the *wake sign*.<sup>8</sup> In infants, lesions may also be seen on the head (Fig. 18-6), which is rarely involved in older patients. Infants commonly have involvement of the palms, soles, and axillae. In older children and adolescents, the most common sites of involvement are the wrists, interdigital spaces, and waist. Although bullous lesions are uncommon in scabies, vesicles are often found in infants and young children, owing to the predisposition for blister formation seen in this age group. Occasionally the Darier sign may be positive, and hence the diagnosis of urticaria pigmentosa may be considered.<sup>9</sup> Genital involvement presenting as papules, crusted papules, or nodules (Figs. 18-7 and 18-8) and areolar lesions are other classic presentation patterns. Excoriations are commonly noted.

Scabies nodules are red-brown nodules (Figs. 18-9 and 18-10) that represent a vigorous hypersensitivity response of the host. They occur most commonly on the trunk, axillary regions, and genitalia and are seen primarily in infants. Although they eventually resolve, scabies nodules may be present for several months. They are occasionally misdiagnosed (both clinically and histologically) as signs of a neoplastic disorder (i.e., leukemia or lymphoma cutis).

Crusted, or Norwegian, scabies is a form of the disorder that presents as scaly, dermatitic papules or plaques. Crusted scabies may be localized or generalized and occurs primarily in immunocompromised patients (especially those with HIV infection) and in those who are mentally retarded or physically incapacitated.<sup>7</sup> The lesions of this disorder may mimic eczema (Fig. 18-11), psoriasis, warts, or a drug reaction, and nail dystrophy may be present. Crusted scabies is commonly misdiagnosed and mismanaged.<sup>10</sup> A delay in the diagnosis of crusted scabies may lead to the inadvertent exposure of multiple physical contacts. The lesions may become heavily crusted and hyperkeratotic and often are minimally pruritic. Crusted scabies is extremely contagious, given the large numbers of mites (thousands) that may be present. In classic scabies, only around 12 mites on average are present. Patients with crusted scabies are often the source for large epidemics within hospitals, given the lack of recognition and subsequent diagnostic delay.

Complications of scabies are generally mild. They include secondary bacterial infection, impaired skin integrity, pain, and rarely debilitation related to limitations in movement secondary to pain. Secondary infection is most commonly the result of *Staphylococcus aureus* or group A β-hemolytic streptococci and presents as crusting, oozing pustules or vesiculopustules. Bullous lesions have been described primarily in older adults, which on occasion may simulate (or possibly evolve into) the autoimmune blistering disorder, bullous pemphigoid.<sup>11,12</sup> Necrotizing vasculitis in the presence of lupus anticoagulant has also been reported.<sup>13</sup>

Animal-transmitted scabies, which is *Sarcoptes* infestation transmitted from domestic animals, usually results in a short-lived infestation with spontaneous resolution in the human host. The close relationship of humans with dogs makes the canine form of animal scabies

**Figure 18-1** Scabies. Erythematous papules with crusting in an infested male infant.

**Figure 18-2** Scabies. Erythematous papules and burrows involving the palm and wrist. Scrapings of lesions from the palmar creases have a high yield on microscopic examination.

**Figure 18-3** Scabies. Curvilinear burrow of the lateral hand.

(*S. scabiei* var. *canis*) the most common type transmitted to humans.<sup>14,15</sup> Canine scabies, or sarcoptic mange, causes patchy loss of hair with scaling in the dog. It is seen most commonly in undernourished, heavily parasitized puppies, and a presumptive diagnosis can be made on the basis of exposure to a pet with a pruritic eruption, alopecia, and the characteristic mouse-like odor of animals with extensive sarcoptic infestation. In children with canine scabies the papular

**Figure 18-4** Scabies. Crusted papule of the abdomen in an infant with scabies.

**Figure 18-5** Scabies. Erythematous papules and linear burrows of the plantar surface of the foot.

eruption most commonly involves the forearms, lower region of the chest, abdomen, and thighs. The distribution differs from that of human scabies in that it tends to spare the interdigital webs and the genitalia, and burrows are absent. The mite of canine scabies does not reproduce on human skin, and therefore the infestation is usually self-limited, clearing spontaneously over several weeks.

The diagnosis of scabies is suggested in the child with pruritus, a papular or papulovesicular eruption with burrows, and the characteristic distribution pattern. However, the differential diagnosis may be broad and includes atopic dermatitis, contact dermatitis, seborrheic

**Figure 18-6** Scabies. Erythematous papules and crusted papules of the scalp in an infant.

**Figure 18-7** Scabies. Erythematous papules of the penis with crusting of the glans penis. These findings are highly suggestive of scabies infestation.

dermatitis, Langerhans cell histiocytosis, impetigo, pyoderma, viral exanthem, papular urticaria, arthropod bites, and acropustulosis of infancy. The latter, which may represent a postscabetic hypersensitivity response, is discussed in detail in Chapter 2. A definitive diagnosis of scabies is made via mineral-oil examination (Box 18-1) with the microscopic identification of mites (Fig. 18-12) or their eggs or feces (scybala) (Fig. 18-13). Ideal skin lesions for sampling include burrows and fresh papules. In young patients in whom skin scrapings might be difficult, obtaining samples from adult contacts (i.e., parents) with lesions is a consideration. Skin biopsy is rarely necessary. A disposable skin curette (an instrument used for the destructive skin procedure, curettage) may be substituted for the scalpel blade if available and may be less frightening for young children and thereby minimize the risk of injury when performing the procedure in a very young or uncooperative child.<sup>16</sup> High-magnification video dermatoscopy is a noninvasive technique that has been reported for diagnosing scabies.<sup>17</sup>

Therapeutic options for scabies are listed in Table 18-1, and a few are discussed here in more detail. The treatment of choice for scabies

**Figure 18-8** Scabies. Nodules of the penis and inguinal regions in a young male recently treated for scabies.

**Figure 18-9** Scabies nodules. These infiltrative nodules persisted for 6 months after effective treatment for scabies.

**Figure 18-10** Scabies nodules. Early scabies nodules developing at sites of crusting; these lesions persisted long after adequate therapy for the infestation.

is 5% permethrin cream, which is applied from the neck down and left on for 8 to 14 hours and followed by thorough rinsing. Permethrin, a synthetic pyrethroid, is a neurotoxin and an excellent scabicide with low potential for toxicity. There appears to be little, if any, resistance of scabies to permethrin, and overall the response rate to treatment is

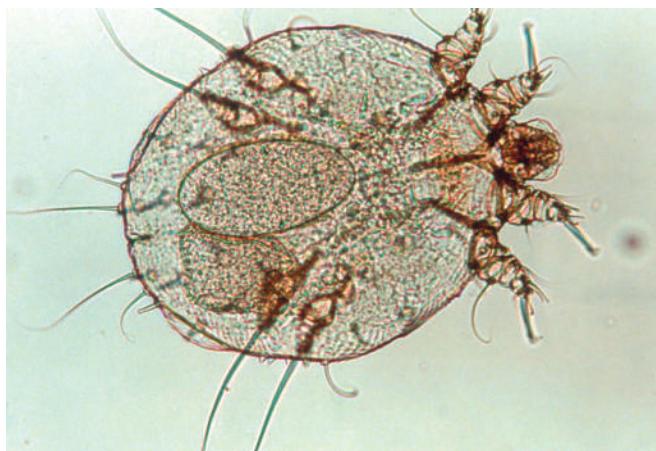

**Table 18-1** Treatment Options for Scabies

Name	Instructions for Use	Comment
Permethrin 5% cream (Elimite, Acticin)	Apply from neck down; rinse in 8–14 hours	Not for use under 2 months of age; may repeat in 1 week if necessary; treat scalp in infants
Lindane 1% lotion	Apply from neck down; rinse in 8–12 hours	Not recommended for infants; not first-line therapy; potential CNS toxicity
Sulfur 6% ointment	Apply from neck down for 3 consecutive nights; rinse 24 hours after last application	Older therapy; malodorous; compounded in petrolatum; safe in infants, pregnant females
Crotamiton cream (Eurax)	Apply from neck down for 2 consecutive nights; rinse 48 hours after last application	High failure rate; may require up to 5 applications
Benzyl benzoate	Apply nightly or every other night for 3 applications	Not available in the United States
Ivermectin (Stromectol)	200 µg/kg per dose given orally for 2 doses, 2 weeks apart	Off-label use; consider for severe infestations, crusted scabies, IC patients, scabies epidemics; should not be used under 5 years of age

CNS, Central nervous system; IC, immunocompromised.

**Figure 18-11** Crusted scabies. This heart-transplant recipient had eczematous, crusted plaques in a widespread distribution that was resistant to topical corticosteroid therapy. Mineral-oil preparation revealed many live scabies mites.

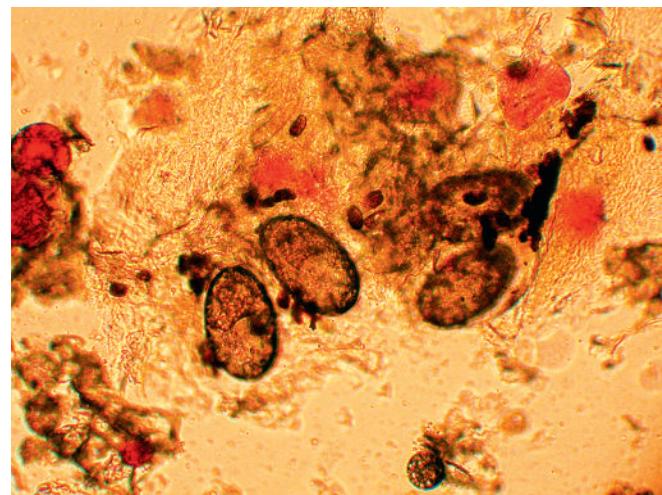

**Figure 18-12** Scabies mite. Note the eggs within the body of the mite. (Live scabies mite,  $\times 40$  magnification.)

excellent. A second treatment with permethrin 1 week after the first is often recommended, although studies suggest a relatively high cure rate after a single application.<sup>1,18</sup> Treatment of all close contacts is also recommended in an effort to minimize ongoing propagation of the infestation. In a systematic review and meta-analysis of scabies therapies, permethrin was demonstrated to be the most effective treatment.<sup>19</sup>

#### Box 18-1 Performing a Mineral-Oil Examination for Scabies

1. Apply a drop of mineral oil to the lesion(s) to be scraped.
  2. Scrape through the lesion with a number 15 scalpel blade (a small amount of bleeding is expected with appropriately deep scrapings).
  3. Smear contents of scraping on a clean glass slide.
  4. Add a few more drops of mineral oil.
  5. Place cover slip over oil and examine under microscope at low power.
- Criteria for a positive mineral oil examination:
- Scabies mite
  - or
  - Ova (eggs)
  - or
  - Scybala (feces)

**Figure 18-13** Scabies preparation. This mineral-oil preparation (performed on scrapings from the patient in Fig. 18-5) reveals multiple eggs (larger, oval bodies) and smaller fecal pellets ("scybala," the dark brown circular concretions).

Permethrin should be applied in a thin, even coat and rubbed in well to all skin surfaces. In infants, application should include the scalp and face, with care to avoid the regions around the eyes and mouth. Special attention should be paid to applying the medication to web spaces, the umbilicus, the genitals, and the gluteal cleft. Fingernails and toenails should be trimmed short and the medication applied as well as possible to the region under the nail edge. Permethrin is not recommended for infants younger than 2 months of age or for pregnant (pregnancy class B) or nursing women. It is vital for patients and

parents to understand that after appropriate therapy, signs and symptoms of scabies may not clear for 2 to 6 weeks after successful treatment, because the hypersensitivity state does not cease immediately after eradication of the infection.<sup>20</sup> The family should have this information before starting therapy, and it may be useful to provide a topical corticosteroid and oral antihistamine for symptomatic relief during this period.

Lindane 1% lotion was, for years, the primary therapy for scabies before the development of permethrin and escalating reports of lindane-related toxicities. Lindane is applied to the skin for 8 to 12 hours with reapplication in 1 week. Although the majority of untoward effects attributed to the use of lindane have been associated with inappropriate, prolonged, or repetitive use, true toxicity potential does exist and becomes more relevant in infants and small children, owing to a relatively greater skin surface and possibly higher blood level accumulations in this age group. When *in vitro* percutaneous absorption of 5% permethrin was compared to 1% lindane, it was shown that human skin was 20-fold more permeable to lindane. In addition, *in vivo* guinea pig blood and brain levels of lindane were fourfold greater than permethrin levels after a single application.<sup>21</sup> Reactions attributed to the use of lindane have included eczema, urticaria, aplastic anemia, alopecia, muscular spasms, and central nervous system toxicity manifested by irritability, nausea, vomiting, amblyopia, headache, dizziness, and convulsions.<sup>22–29</sup> Lindane-resistant scabies has also been an increasing problem in the United States and Central America. This agent, which is recommended as a second-line therapy, is banned in California. Other topical agents utilized in some areas for the treatment of scabies include 10% to 25% benzyl benzoate, 10% crotamiton, 0.5% malathion, and 2% to 10% sulfur ointment.

Ivermectin has been reported with increasing incidence as an off-label treatment option for scabies (it is not approved for this indication in the United States). This agent has been used extensively in veterinary medicine since 1981 for a wide variety of parasitic infestations in farm and domestic animals.<sup>30</sup> Oral ivermectin (Stromectol) is approved for the treatment of *Strongyloides* and onchocerciasis in adult humans. It is also effective for the treatment of loiasis and bancroftian filariasis.<sup>31</sup> Ivermectin acts by blocking chemical transmission across invertebrate nerve synapses that utilize glutamate or  $\gamma$ -aminobutyric acid (GABA), resulting in paralysis and death. It has selective activity against human parasites because of its high affinity for the channels found in the peripheral nervous system of invertebrates.<sup>32</sup> Several studies have evaluated the role of ivermectin in the treatment of scabies and found it very effective in either a single- or two-dose regimen of 200  $\mu\text{g}/\text{kg}$  per dose. Many recommend that this agent be given in two doses when used for classic scabies, separated by 1 to 2 weeks, because it is not ovicidal. Ivermectin is especially useful in immunocompromised patients with scabies and patients with crusted scabies, where it may be used alone or in combination with topical scabicides or keratolytic agents. When it is used in crusted scabies, ivermectin may need to be administered in three to seven doses, depending on the severity of the infection.<sup>33</sup> Topical 1% ivermectin, which is not readily available, has reportedly been effective as well.<sup>34,35</sup>

Regardless of the treatment used for scabies, environmental decontamination is important given the possibility of spread of scabies from fomites. Clothing, bed linens, and towels should be machine washed in hot water and dried using a high-heat setting. Clothing or other items (i.e., stuffed animals) that cannot be washed may be dry cleaned or stored in bags for 3 days to 1 week, because the mite will die when separated from the human host. In addition, systemic antibiotic therapy should be given if secondary bacterial superinfection is present. Scabies nodules can be treated symptomatically with topical or intralesional corticosteroids.

### Other Mites

Mites are small arachnids with mouthparts capable of puncturing and feeding on host tissue fluids. A variety of food and animal mites may result in pruritic dermatoses in exposed humans, and may also be vectors of infectious diseases. Mite bites should be considered in the patient with an unexplained, itchy papular skin eruption.

Harvest mites (chiggers, jiggers, "red bugs") are a member of the American harvest mite family and are commonly found in the

**Figure 18-14** Chigger bites. Multiple itchy, edematous, urticarial papules. Some revealed a small hemorrhagic punctum.

southern United States. Also known as *Trombicula alfreddugesi*, the chigger is distinct from other mites in that only the larva is parasitic to humans and animals. The eight-legged adult and nymphal stages are spent in a nonparasitic existence. Chiggers live in grain stems, in grasses, or in areas overgrown with briars or blackberry bushes, where they exist and feed on vegetable matter, minute arthropods, and insect eggs. The six-legged larva clings to vegetation awaiting the passage of an unsuspecting host and then attaches to the skin when the host brushes against the foliage.<sup>36</sup> The mite then injects an irritating secretion that causes itching and then drops to the ground to molt (or is scratched off) within a few days. The lesions of chigger bites present as urticarial, erythematous papules (Fig. 18-14). They occasionally reveal a hemorrhagic punctum, and in some patients there may be more diffuse erythema, vesicles, or bullae. Pruritus tends to be intense. The "summer penile syndrome" refers to a seasonal acute hypersensitivity reaction to chigger bites and presents with penile swelling, pruritus, and occasional dysuria.<sup>37</sup> Most patients have a history of recent exposure to woods, parks, or lawns.

Treatment of chigger bites consists of antihistamines, cool baths or compresses, and topical corticosteroids. Secondary infection should be treated with systemic antibiotics. Household vinegar (5% acetic acid) has been suggested as a useful measure for postexposure prophylaxis and treatment of pruritus.<sup>36</sup> Chiggers may be disease vectors for scrub typhus, hemorrhagic fever with renal syndrome, hantavirus pulmonary syndrome, and ehrlichiosis.<sup>38</sup>

Grain mites (straw itch mite, *Pyemotes ventricosus*) feed on the larvae of insects, seeds, grains, and plant stems. Persons coming into contact with infested straw and grain are particularly susceptible to this form of dermatitis.<sup>39</sup> This seasonal eruption presents as severely pruritic, pale pink to bright red macules, papulovesicles, or pustules followed by urticarial wheals. Occasionally, a purpuric eruption develops. In severe cases, constitutional symptoms and fever may be present, and the presentation may be mistaken for acute varicella. The eruption is self-limited and treatment, as with chigger bite reactions, is supportive.

Avian mites (fowl mites, bird mites) are divided into two genera, *Dermanyssus* and *Ornithonyssus*. They are known to infest humans accidentally, resulting in a pruritic, widespread papular dermatitis. *Gamasoidosis* is the term used to describe the human skin disorder resulting from nonburrowing, blood-sucking mites from birds and other animals.<sup>40</sup> The diagnosis of avian mite dermatitis is often overlooked because of lack of awareness and the small size of the mites.<sup>41</sup> Common causes include *Dermanyssus gallinae* (chicken mite), *Dermanyssus americanus* (American bird mite), *Ornithonyssus sylviarum* (northern fowl mite), and *Ornithonyssus bursa* (tropical fowl mite). *D. gallinae*, the most common cause, infects various birds including chickens, parakeets, pigeons, canaries, and starlings. Although the mite remains on the bird at night, during the day it may migrate to the nest and can survive without feeding for several months. When

**Figure 18-15** Avian mite dermatitis. Multiple papules and papulovesicles were very pruritic. Upon investigation, a bird's nest was noted near the window in this patient's bedroom and was believed to be the source of the infestation.

birds leave their nest in the spring or early summer, the mites search for other hosts, and human infestation may be the result. Clinical examination reveals papules (Fig. 18-15), vesicles, and urticarial lesions without burrows, because the mite does not burrow into the skin. The diagnosis of avian mite dermatitis is confirmed by identification of the mites found in pillows, bed sheets, clothing, nests, birds, and only rarely humans. Special attention should be given to potential sites for nesting, such as porches, attics, eaves, air conditioning systems, and ventilation ducts. Pet gerbils were the source for *O. sylviarum* and *D. gallinae* in one report.<sup>42</sup> Treatment for avian mite dermatitis, as with other mite bites, is symptomatic.

Other mites may result in similar, nonspecific, pruritic papular eruptions in the human host. The rat mite, *Ornithonyssus bacoti*, is found in rats, and extermination is often necessary for eradication.<sup>43</sup> It has also been reported in pet hamsters.<sup>44</sup> *Cheyletiella* mites are large, animal-specific nonburrowing mites that include *Cheyletiella blakei* (found on cats), *Cheyletiella yasguri* (found on dogs), and *Cheyletiella parasitovorax* (found on rabbits). When these mites are in close proximity to a human host, they bite quickly and run, returning to their animal host.<sup>45</sup> They are very difficult to visualize with the human eye. Skin lesions include grouped pruritic papules, urticarial wheals, and bullous lesions. Pets infested with *Cheyletiella* exhibit patches of fine, powdery scale ("walking dandruff"). Other mites of potential human concern include house-dust mites (*Dermatophagoides* species), the snake mite (*Ophionyssus natricis*), and the house-mouse mite (*Liponyssus sanguineus*).

*Demodex* mites are present normally in adult human hair follicles and sebaceous glands of the face, where they are considered to be "commensal ectoparasites."<sup>46</sup> They are less commonly present in childhood skin. The two species are *Demodex folliculorum* and *Demodex brevis*. "*Demodex folliculitis*" presents as a very itchy papular and pustular eruption on the face, usually in children with leukemia or HIV infection.<sup>46,47</sup> There may be an accentuation in the perioral regions. Reported topical therapies have included 5% permethrin, metronidazole, sulfur, and sodium sulfacetamide.

### Ticks

Ticks are large, globular arachnids with short legs, hard leathery skin, and mouthparts adaptable for sucking blood from mammals, birds, and reptiles. They are important vectors of diseases such as relapsing fever, rickettsial infections (Rocky Mountain spotted fever, Mediterranean spotted fever, Q fever, and ehrlichiosis; see Chapter 16), Lyme disease (see Chapter 14), babesiosis, Colorado tick fever, and tularemia. Although tick bites may be painful, the majority are painless and may go unnoticed.

Ticks are classified into three family groups: hard ticks (Ixodidae), soft ticks (Argasidae), and Nuttalliellidae.<sup>48</sup> They are found in grass,

**Figure 18-16** Tick bite. **(A)** This tick was found on clinical examination of the scalp of this 9-year-old male, who came to the office for an unrelated matter. He had been playing in a forested area in Michigan 3 days previously. **(B)** The tick, after gentle manual removal.

shrubs, vines, and bushes, from which they attach themselves to dogs, cattle, deer, and humans. Ticks penetrate the human epidermis with distal mouthparts called *chelicerae* (Fig. 18-16) and then insert another part called the *hypostome*, through which they feed on blood and deposit a variety of agents including anticoagulant and anti-inflammatory agents. Both acute and chronic dermatoses may result from tick bites. Acute changes include erythema, papules, nodules, bullae, ulceration, and necrosis. Multiple pruritic papules caused by infestation with tick larvae have also been reported.<sup>49</sup> Chronic changes include granulomas, alopecia, and secondary bacterial infection. Localized foreign-body-type reactions may result from retained mouthparts or improper tick removal and occasionally persist for months to years. T- or B-cell cutaneous lymphoid hyperplasia may also be noted, often with copious numbers of eosinophils when tissue biopsies are analyzed histologically. The B-cell type may be difficult to distinguish from true B-cell lymphoma.<sup>50</sup>

Nondermatologic findings that may result from tick bites include anaphylaxis, fever, headache, flu-like symptoms, abdominal pain, and vomiting. Tick paralysis is a reversible disorder characterized by ascending motor weakness and flaccid paralysis. It is believed to be caused by a salivary neurotoxin injected into the victim while the tick is engorging, and it appears that the tick must feed for several days before paralysis occurs. Tick paralysis occurs more commonly in young girls, possibly owing to their longer hair, which may augment tick attachment and hiding.<sup>51</sup> The classic clinical presentation includes an unsteady, ataxic gait followed by ascending symmetric paralysis, usually starting within 2 to 6 days of tick attachment. Upper extremity weakness and cranial nerve involvement (which may present as

dysphagia, drooling, facial weakness, and dysphonia) may occur. If intervention does not occur, involvement may extend to the respiratory musculature, resulting in respiratory failure and subsequent death. Most cases of tick paralysis occur in children, and the mainstay of treatment is tick removal, which usually results in rapid resolution of the signs and symptoms.<sup>51,52</sup>

Various methods of prevention for tick-borne diseases have been advocated. Avoidance of tick habitats may reduce risks, but this is not always feasible. Recommendations for clothing include wearing light-colored, long-sleeved clothes and footwear, tucking pants into socks and taping exposed edges.<sup>48</sup> Insect repellents containing N,N-diethyl-3-methylbenzamide (DEET) or picaridin applied to exposed areas of skin and permethrin applied to clothing are both effective parts of prevention (see below). Frequent examination of skin for ticks is also important in high-risk areas and during high-risk seasons.

Prompt tick removal is also important in reducing the transmission of disease. The entire tick must be removed completely, including the mouthpart and the cement the tick secretes to secure attachment.<sup>53</sup> A variety of commercial tick-removal devices are available and are quite successful. Manual extraction of a tick is performed with blunt, medium-tipped forceps. The tick is grasped as close to the skin as possible, and perpendicular traction is used to gradually extract the entire tick, taking care not to twist the forceps.<sup>53</sup> Should a portion of the tick be retained, a cutaneous punch biopsy will effectively remove it.

### Spiders

Spiders, because of their menacing appearance, are often blamed for more damage than they actually create. Virtually all of the serious spider bites on the North American continent are caused by the black widow spider and the brown recluse spider. Bites of the former tend to have milder outcomes, whereas bites of the latter often result in more severe sequelae.<sup>54</sup> Children are more vulnerable to the effects of spider bites. Patients reporting spider bites are often diagnosed in emergency departments as having skin or soft-tissue infection.<sup>55</sup> The gold standard for diagnosing spider bites is collection and proper identification of the biting spider, although this rarely occurs.

The black widow spider, or *Latrodectus mactans*, is a potentially dangerous spider found mainly in southern Canada, the United States, Cuba, and Mexico. It is recognized by its coal-black color and globular body (1 cm in diameter) with a red or orange hourglass marking on the underside of its abdomen (Fig. 18-17). A web spinner (in contrast to burrowing spiders), it lives in cool, dark places in buildings and little-used structures, woodpiles, and garages, and often spins its web across outdoor furniture. Consequently, a significant number of bites in the southern United States occur around the genitalia and buttocks.

The black widow spider bites humans only in self-defense. The female spider is more dangerous than the male as a result of her larger size and more potent neurotoxin.<sup>56</sup>  $\alpha$ -Latrotoxin, the potent black

**Figure 18-17** Black widow spider. Note classic red hourglass marking on the underside of the abdomen. (Courtesy of Dirk M Elston, MD.)

widow neurotoxin, triggers synaptic vesicle release from presynaptic nerve terminals and results in its effects via exocytosis of neurotransmitters.<sup>57</sup> Two red, punctate marks and local swelling are often seen, and burning or stinging with intense pain develops at the site of the envenomation. This is followed, usually within 10 minutes to an hour, by severe cramping abdominal pain and spasmodic muscular contractions, which peak in around 3 hours. Irritability, sweating, anxiety, and agitation are also common. Priapism may occur. Hypertension within the initial hours after the bite occurs in 20% to 30% of patients,<sup>56</sup> and although it may be severe, it is often asymptomatic in children.<sup>58</sup> Although the bite may be fatal, most children recover spontaneously in 2 to 3 days.

Treatment options for black widow spider bites include analgesics, benzodiazepines, calcium gluconate, and specific antivenin. Diazepam is the most commonly utilized benzodiazepine. Intravenous opioids are also utilized and seem very effective in providing symptomatic relief.<sup>59</sup> Antivenin therapy has been demonstrated useful, even when given as late as 90 hours after the bite.<sup>60</sup> Although specific antivenin may not be available in some parts of the world, redbuck-spider (*Latrodectus hasselti*) antivenin has also been shown to be effective in neutralizing *L. mactans* venom in mouse models.<sup>61,62</sup> Indications for the administration of *Latrodectus* antivenin are shown in Table 18-2, although use of this agent remains controversial in the United States. Potential reactions to antivenin include anaphylaxis and serum sickness.

Spiders of the *Loxosceles* genus cause cutaneous and subcutaneous injury primarily via the enzyme sphingomyelinase D (SMD) (see below). There are roughly 100 species of *Loxosceles* spiders, with 80% of them being found in the Western hemisphere.<sup>63</sup> The brown recluse spider, or *Loxosceles reclusa*, is the one of the most dangerous spiders in the United States. This spider is indigenous to the area spanning eastward from southeastern Nebraska and the eastern half of Texas to the western part of Georgia.<sup>64</sup> The northern boundary includes southern Missouri, Illinois, Indiana, and Ohio, and the southern boundary is the Gulf of Mexico. In nonendemic areas, such as the western United States, physician overdiagnosis of brown recluse bites (also known as *loxoscelism*) is common.<sup>65</sup>

The brown recluse spider has an oval, tan to dark brown body, about 1 cm in length and 4 to 6 mm in width. A dark-brown violin-shaped marking extends dorsally from the eyes back to the distal cephalothorax (Fig. 18-18), and there are three pairs of eyes, rather than the four seen in other spiders. The brown recluse spider thrives in human-altered environments such as attics, basements, and boxes.<sup>64</sup> When in the house, the spider is often found in storage closets (among clothing); when outdoors, it generally resides in grasses, rocky bluffs, woodpiles, and barns. Because of its normal shyness and predilection for dark recesses, it bites only in self-defense when approached.

The venom of *L. reclusa* contains numerous enzymes, most notably SMD2, as well as alkaline phosphatase, esterase, adenosinetriphosphatase (ATPase), and hyaluronidase. SMD may result in many effects, including lysis of red blood cells, complement activation, platelet activation, and thrombosis.<sup>66</sup> Activation of neutrophils results in the classic cutaneous necrosis seen and is a result of neutrophil secretion with subsequent endothelial damage, thrombosis, and ischemia. The local effect on tissues seems to be directly related to the amount of venom injected.

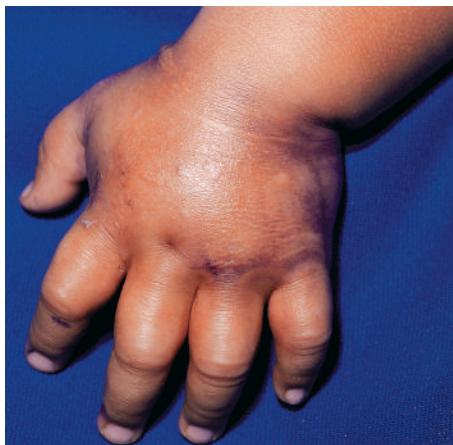

**Table 18-2** Indications for Administration of *Latrodectus* Antivenin

Indication	Comment
Hypertension	If uncontrolled
Pregnancy	
Comorbid conditions	Coronary artery disease, chronic obstructive pulmonary disease
Intractable pain	
Respiratory difficulty	

Modified from Quan D. North American poisonous bites and stings. Crit Care Clin 2012;28:633–59.

**Figure 18-18** Brown recluse spider. Note the brown, violin-shaped marking on the dorsal surface. The adjacent penny gives a size reference. (Courtesy of Dirk M Elson, MD.)

**Figure 18-19** Brown recluse spider bite reaction. Swelling and mild erythema are noted early in the course after a brown recluse spider bite.

The clinical presentation of loxoscelism begins within 6 hours of the bite, usually with pruritus, pain, and/or erythema at the site. These bites, however, may be relatively painless, and patients may be unaware of them occurring, which accounts for the rarity of spider identification in diagnosing these bites.<sup>67</sup> Within 24 hours, a red ring develops around the bite site and is followed by blue-purple discoloration (Fig. 18-19), occasional hemorrhagic blisters, and an increase in pain. Ultimately, gangrenous ulceration with necrosis and eschar formation occurs (Fig. 18-20), occasionally with bulla formation. Anesthesia is often present in the center of the affected area. A generalized petechial or morbilliform eruption may also be present.<sup>63</sup> Systemic findings may include chills, fever, nausea, and joint pain. Rare

**Figure 18-20** Brown recluse spider bite reaction. Massive deep ulceration with eschar formation. (Courtesy of Brooke Army Medical Center teaching file.)

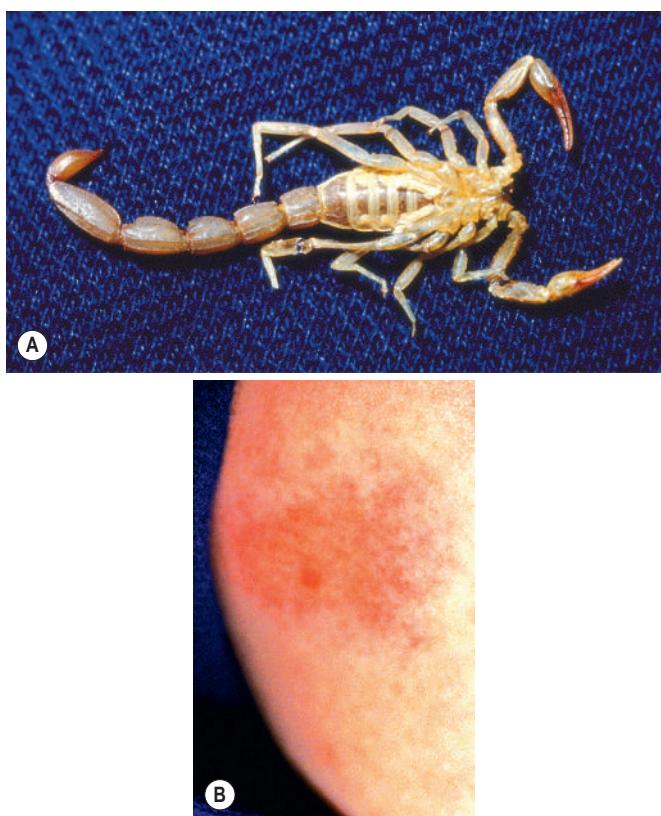

findings include severe hemolysis, renal failure, and pulmonary edema. Necrotizing fasciitis has also been reported.<sup>68</sup> Lymphangitis is not uncommon when the bite occurs on an extremity. In mild cases, *L. reclusa* bites may result only in a mild urticarial reaction. Systemic loxoscelism is uncommon overall (but when it occurs, it appears to be more common in children), and symptoms may include fever, malaise, vomiting, headache, and acute hemolytic anemia with jaundice. Renal failure rarely occurs.

Brown recluse spider bites heal very slowly, and scarring often results. Progression to pyoderma gangrenosum-like ulcers has been reported but is rare. For the majority of small, uncomplicated bite reactions, spontaneous healing is the rule. Conservative treatment measures for these patients include rest, ice compression, and elevation (RICE) of the affected area. Antibiotics should be considered if secondary bacterial infection is suspected. Aspirin, antihistamines (most notably cyproheptadine), and tetanus vaccination may be considered, and dapsone therapy has been utilized but must be closely monitored given the toxicity profile.<sup>64</sup> Dapsone is felt by some to be effective when administered early in the course of the bite reaction and may have its therapeutic effects via suppression of neutrophil chemotaxis. However, side effects including dose-related hemolysis, agranulocytosis, cholestasis, and methemoglobinemia limit its widespread use. When systemic signs and symptoms are present, fluid support should be given and systemic corticosteroids may be considered. Other reported therapies have included hyperbaric oxygen, vaso-dilators, heparin, nitroglycerin, electric shock, curettage, and surgical excision.<sup>63</sup> *Loxosceles* antivenin is available in some countries.

### Scorpions

Scorpions are tropical photophobic arachnids that hide by day and hunt by night. They differ from other arachnids in that they have an elongated abdomen ending in a stinger (Fig. 18-21, A). Scorpions are found worldwide, particularly in the tropics, and in North America they are generally seen in the southwestern United States and Mexico. The Buthidae family are the most toxic of scorpions and are found mainly in India, Spain, the Middle East, and northern Africa.<sup>56</sup> The major scorpion offender in the United States is *Centruroides exilicauda* (also known as *Centruroides sculpturatus* or the "bark scorpion").

Although the majority of scorpion stings in the United States are not severe and do not warrant significant medical therapy, children seem to be at greater risk of developing severe scorpion envenomation. Hence stings in children should be watched carefully, particularly during the first 4 hours, to assess for a more serious reaction. Most symptoms have their onset within 15 minutes after envenomation. The venom apparatus of the scorpion is carried in its curved stinger at the tip of the tail, which is swung over the scorpion's head to penetrate the victim's skin. During the day scorpions hide in shoes, closets, clothing, and crevices. Some species of ground scorpions, however,

**Figure 18-21** Scorpion (A) and scorpion sting, early reaction (B). Painful burning and erythema was present shortly after the sting.

may burrow and hide in gravel or children's sandboxes. They rarely attack humans but will do so when accidentally disturbed, brushed against, or stepped upon. The effect of the sting depends upon the amount of envenomation and the age and size of the individual. The majority of published reports of severe or fatal envenomation have been in children younger than 10 years of age.<sup>69,70</sup>

During a sting, the scorpion releases two noxious agents: a localized hemolytic toxin and a dangerous neurotoxic venom. The hemolytic toxin may cause a painful burning sensation with pronounced redness (Fig. 18-21, B), swelling, discoloration, severe necrosis, lymphangitis, and in some patients, disseminated intravascular coagulation or renal failure. The neurotoxic venom, which reaches the systemic circulation primarily via the lymphatics, may produce local numbness and a severe generalized reaction consisting of sweating, salivation, tightness in the throat, abdominal cramps, cyanosis, muscle jerking, tongue fasciculations, convulsions, and particularly in small children, respiratory paralysis and death. Tachycardia and hypertension are common and may persist for several hours. Pulmonary edema, with or without hemoptysis, and shock may develop. Local cutaneous reactions may vary and include erythema, petechiae, purpura, bullae, edema, induration, necrosis, and ulceration.<sup>71</sup> The diagnosis of scorpion sting is a clinical one, and experienced clinicians who practice in endemic regions can often recognize the clinical symptom pattern.<sup>72</sup>

Treatment for scorpion envenomation is difficult and without consensus on one gold standard of care. Immediate measures include application of a tourniquet above the area of the sting and the application of ice or cold water. *Serotherapy*, which refers to administration of scorpion antivenin, has been advocated by some but has been found ineffective by some investigators, and does not prevent the development of cardiac problems.<sup>56,73–75</sup> Antivenin *Centruroides* (scorpion) equine immune F(ab')<sub>2</sub> (Anascorp) has been approved by the United States Food and Drug Administration (FDA) as an orphan drug and has been shown to be associated with more rapid resolution of envenomation symptoms, decreased use of sedative-hypnotics, and lower levels of plasma venom levels.<sup>72,76</sup>

**Figure 18-22** Head louse. Note the elongated body, three pairs of legs, and nits (eggs) within the body of the louse.

Fluid resuscitation, sedation, and treatment of hypertension may be indicated after scorpion stings. Prazosin therapy has been shown to decrease the development of acute pulmonary edema.<sup>77</sup> A large series of severe scorpion envenomation in children suggested that the beneficial effects of antivenin and/or prazosin is questionable when hospital admission is delayed.<sup>70</sup> Continuous intravenous midazolam infusion has also been utilized to control agitation and involuntary motor activity.<sup>78</sup> Opioid analgesics may be required for pain relief. Although intravenous high-dose corticosteroid therapy was once recommended, it appears to offer no significant benefit in terms of mortality, duration of hospital stay, or cost.<sup>79</sup>

## INSECTS

Insects are the class of arthropods characterized by division into three parts (a head, thorax, and abdomen). Noxious insects are ubiquitous, affecting all humans in some manner at one time or another. The insects of medical significance include lice, mosquitoes, flies, fleas, bed bugs, bees, wasps, ants, caterpillars/moths, and beetles.

### Lice (*Pediculosis*)

Lice have plagued humans since ancient times. Infection is most common during times of stress, such as war, or in crowded environments such as schools, camps, or institutions. After widespread use of dichlorodiphenyltrichloroethane (DDT) after the end of the Second World War, there were relatively few reports of pediculosis in the United States. Subsequent restrictions on the use of DDT in the United States since 1973, however, resulted in an increase in the number of cases, particularly pediculosis capitis and pediculosis pubis. Lice occur wherever there are humans. They spend their entire life as ectoparasites depending on human blood for sustenance. Their existence independent of humans is generally not possible. All lice feed by pressing their mouth against the host's skin, piercing the surface, and injecting an anticoagulant to facilitate the blood flow during feeding.

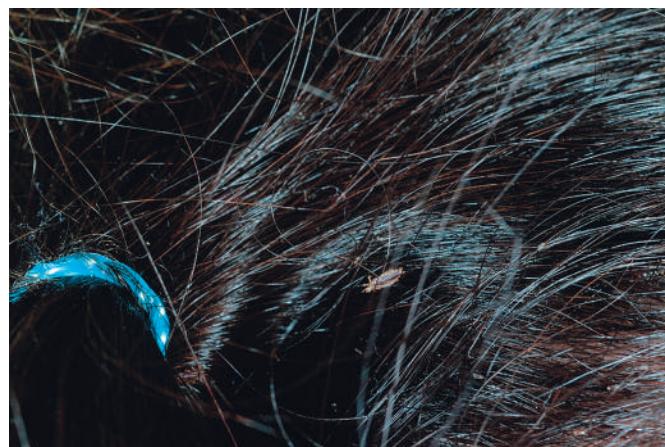

Lice are small, six-legged, wingless insects with translucent, gray-white bodies that become red when engorged with blood. They measure 1 to 4 mm in size, and are visible to the naked eye on close inspection. Three species of lice infest humans:

1. *Pediculus humanus corporis* (the body louse)
2. *Pediculus humanus capitis* (the head louse)
3. *Phthirus pubis* (the pubic or "crab" louse).

Body lice and head lice (Fig. 18-22) are very similar in appearance, with elongated bodies and three pairs of claw-like legs. Pubic lice, on the other hand, have short bodies and resemble crabs in appearance. The body louse is the only louse that can carry human disease, including louse-borne relapsing fever, trench fever, and epidemic typhus. Body and head lice are transmitted by close contact or occasionally via fomites including clothing (body louse) and combs, brushes, and hats or other headgear (head louse). Pubic lice are transmitted by intimate physical contact and are considered in most cases to be a sexually transmitted disease. Nonsexual transmission of pubic lice may occur, though, and probably accounts for most cases of

**Figure 18-23** Nits. These eggs are seen as tiny, gray-white specks attached firmly to hair shafts.

**Figure 18-24** Pediculosis capitis. Note the live head louse, easily seen with the naked eye.

itself is rarely observed on the skin. It obtains its nourishment by clinging to the patient's clothing and intermittently piercing the skin. The primary lesion is a small, red macule, papule, or urticarial wheal with a hemorrhagic central punctum. Primary lesions may be difficult to visualize owing to excoriations related to scratching, and secondary impetiginization may be present. The diagnosis of body lice is confirmed by finding lice or nits in clothing, often in seams. Treatment consists primarily of thorough deinfestation of all clothing and bedding. Treatment of the patient with 5% permethrin cream or lindane 1% lotion may also be useful, because an occasional louse may remain and return to feed.

Pediculosis pubis (pubic lice, crab lice) involves primarily the pubic area but may also involve the scalp, eyebrows and eyelashes, beard, and other hairy areas. Blepharoconjunctivitis may be the presenting signs when eyelashes are involved, and this pattern has been reported in infants and children.<sup>82</sup> Live lice and nits are usually seen. Itching may be the initial symptom, but in persistent cases eczematization or secondary infection may occur. A characteristic skin finding is maculae ceruleae, which are gray-blue macules on the abdomen and thighs. They are felt to represent hemosiderin deposition in the deep dermis as a result of the bites. Treatment of pubic lice is generally similar to that used for head lice (see below), as well as laundering of all clothing and bed linens. Eyelash involvement is usually treated with an occlusive agent such as petroleum jelly.

P. capitis (head lice) is by far the most common form of lice to affect children and usually affects those between 3 and 12 years of age. As mentioned, it is spread primarily through head-to-head contact and less commonly via fomites including headgear, combs, brushes, towels, and upholstery. The transmission from fomites may contribute to the increasingly challenging cycle of head-louse infestation. However, because most transmission occurs from direct contact with the head of an infested individual, the focus of control activities should be primarily on reducing the number of lice on the head and decreasing head-to-head contact.<sup>83</sup> All socioeconomic groups are affected, although African-Americans are less often infested with head lice, possibly related to the diameter, shape, or twisted nature of their hair shafts (which makes grasping of the shaft more difficult for the louse).<sup>80,84–86</sup> The clinical findings consist primarily of pruritus, with secondary excoriation and occasional secondary bacterial infection. Cervical and suboccipital lymphadenopathy may be present. Head lice do not transmit other infectious disease agents. The diagnosis is confirmed by finding live lice (Fig. 18-24) or viable nits on the scalp. In patients in whom the diagnosis is based only on nits, their viability can be confirmed by mounting them on a glass slide and performing microscopic evaluation at low power. Viable nits have an intact operculum (cap) on the nonattached end and a developing louse within the egg (Fig. 18-25).

Although the clinical syndrome of head lice infestation is not serious, it is a cause of significant psychosocial distress, embarrassment, and lost school and work days. The annual cost to society for

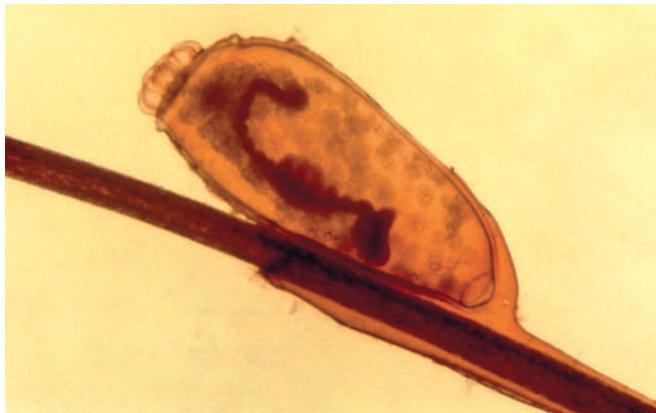

**Table 18-3** Differential Diagnosis of Nits

Diagnosis	Comment
Nits	Firmly adherent to hair shaft; not easily removed with fingers
Seborrheic dermatitis (dandruff)	Diffuse scalp scaling; scales occasionally adhere to hair but easy to remove; scalp erythema may be present
Hair casts	Keratin protein that encircles hair shaft; easily removed
Piedra	Fungal infection of hair; firm nodules attached to hair shafts, white or black in color
Psoriasis	Thick silvery scales, often present overlying red plaques on the scalp
Hair products	i.e., hairspray, mousse, gel

infestation involving the eyebrows and/or eyelashes in children, although the possibility of sexual abuse should always be considered in this setting.

Lice egg cases are called *nits* and are firmly attached to the hair shaft with a cement that makes them difficult to remove. They are gray to yellow-white in color and are seen as tiny pinhead specks measuring 0.3 to 0.8 mm (Fig. 18-23). The nits of head lice are attached to the hair shaft at a more acute angle than those of pubic lice.<sup>80</sup> Head-louse nits are usually laid within 1 to 2 mm of the scalp and, in general, attached nits further from the scalp are more likely to be nonviable. Nits are usually easily distinguished from hair casts or dandruff by the inability to remove them from the hair shaft and, if necessary, microscopic evaluation. The differential diagnosis of nits is shown in Table 18-3. Nits incubate for about 1 week, and then young lice hatch, passing through several nymph stages and growing into adult lice over 1 to 2 weeks. *P. corporis* (body lice) most commonly occurs in homeless individuals, refugees, victims of wars and natural disasters, and those living in crowded conditions.<sup>81</sup> The nits of the body louse attach firmly to clothing fibers, where they may remain viable for weeks. The louse

head lice in the United States is extremely high and includes costs for prescription and over-the-counter therapies, clinical appointments, school nursing time, and time lost from work for caregivers.<sup>87</sup> Since nonviable nits may persist on hair shafts for several months, the potential exists for misdiagnosing active infestation when in fact there is none. It has been tradition in some communities for “no nit” policies to be enforced, in which children with nits are excluded from school until they are adequately treated and all visible nits have been removed.

**Figure 18-25 Nit.** This  $\times 40$ -magnification light microscopy image shows a nit firmly attached to the hair shaft by a cement-like substance. Note the intact cap (operculum) and the developing louse within the egg.

Such policies may lead to unnecessary exposure to pediculicidal agents, missed school, and loss of parental work time.<sup>88</sup> The American Academy of Pediatrics recommends against no-nit policies, because they have not been effective in controlling head-lice transmission.<sup>89</sup> Misidentification of nonlice, non-nit debris (such as dandruff, fibers, dirt, scabs, hair casts) may also result in the overdiagnosis and consequent mismanagement of head lice.<sup>90</sup> Pediculicidal agents should be used only when viable nits or live lice are observed. In general, nits located close to the scalp are viable and unhatched, although in warmer climates, viable ones may be found several inches away from the scalp.

Treatment options for head lice are summarized in **Table 18-4**. Head-lice therapy is recommended for individuals diagnosed with an active infestation, and prophylactic therapy is recommended for bedmates and immediate members of the household of the infested index patient. The standard of care is application of 1% permethrin cream rinse to mildly damp hair, followed by rinsing 10 minutes later. Although permethrin is both pediculicidal and ovicidal, many physicians recommend a second treatment 7 to 10 days after the initial therapy. This agent is FDA approved for children as young as 2 months of age and is recommended as first-line therapy by the American Academy of Pediatrics.<sup>89</sup> Increasing resistance concerns have been reported with permethrin (see below).

Lindane (or  $\gamma$ -benzene hexachloride) is a slow-acting pesticide that has been used often in the past. This agent is stored in fat and nerve tissues, and concerns regarding absorption and neurotoxicity have resulted in many recommending against its use, although most reported toxicities occurred with incorrect usage. Lindane use has been banned in the state of California since 2002.<sup>91</sup> The synergized pyrethrins (i.e., pyrethrin + piperonyl butoxide) include extracts from the *Chrysanthemum* family. These agents are pediculicidal only, and

**Table 18-4** Treatments for Pediculosis Capitis (Head Lice)

Name	Instructions for Use	Comment
Permethrin 1% cream rinse (Nix)	Apply to damp hair after shampooing; leave on for 10 minutes, then rinse	Pediculicidal and ovicidal; repeat treatment in 7–10 days; OTC
Pyrethrin + piperonyl butoxide (RID, Pronto, A-200)	Apply to dry hair; leave on for 10 minutes, then rinse	Pediculicidal only; repeat treatment in 7–10 days; derived from chrysanthemum (do not use in patients with chrysanthemum or ragweed sensitivity); OTC
Lindane 1% shampoo (Kwell)	Shampoo into hair; leave on for 4 minutes and then rinse	Stored in nerve/fat tissue; possible CNS toxicity (although usually observed with incorrect usage) and resistance concerns; low ovicidal activity; not recommended as first choice therapy; repeat therapy in 9 days; Rx
Benzyl alcohol 5% lotion (Ulesfia)	Apply to dry hair; leave on for 10 minutes, rinse	Approved for children 6 months and older; pediculicidal only; kills lice by asphyxiation; contains no neurotoxic pesticide; repeat treatment in 7 days; Rx
Malathion 0.5% lotion (Ovide)	Apply to dry hair; rinse after 8–12 hours	Approved for children 6 years and older; ovicidal and pediculicidal; not first-line therapy; flammable; repeat therapy in 7–10 days, if needed; Rx
Spinosad 0.9% suspension (Natroba)	Apply to dry hair; rinse after 10 minutes	Approved for children 4 years and older; pediculicidal and ovicidal; repeat therapy in 7 days, if needed; Rx
Ivermectin 0.5% lotion (Sklice)	Apply to dry hair; rinse after 10 minutes	Approved for children 6 months and older; pediculicidal only; Rx
Trimethoprim-sulfamethoxazole (Bactrim)	8–10 mg/kg per day, divided, twice daily for 10 days	Occasionally used off-label (not FDA-approved for lice); purportedly kills symbiotic bacteria in louse gut; risk of severe allergic reactions; Rx
Ivermectin, oral (Stromectol, 3 or 6 mg tablets)	200 $\mu$ g/kg single dose; repeat in 1–2 weeks	Occasionally used off-label for resistant cases or crusted scabies; FDA-approved for strongyloidiasis, onchocerciasis; side effects include headache, dizziness, nausea, vomiting; not recommended in children weighing <15 kg; Rx
Manual nit removal	Comb with fine-toothed nit-removal comb	Difficult, tedious (see text); recommended by some in conjunction with pediculicides
Permethrin 0.5% spray (RID)	Spray on inanimate objects	For furniture and bedding; not for use on skin; OTC
Occlusive agents (petrolatum, olive oil, mayonnaise, liquid cleanser, others)	Applied and typically left on overnight, then rinsed out; blow-drying with hand-held dryer reported as useful in conjunction with liquid cleanser	Therapeutic goal is suffocation of lice; potentially limited by ability of lice to temporarily close breathing spiracles; no evidence-based data to support efficacy; none are FDA-approved for this indication

treatment failures are more common. Lindane is available as a 1% shampoo that is left in the hair for 4 minutes and then rinsed out.

Malathion is a weak organophosphate cholinesterase inhibitor that had been unavailable in the United States for several years. This agent was reintroduced in 1999 as a 0.5% lotion and approved for use in children 6 years of age and older. It is not considered a first-line therapy. Malathion is both pediculicidal and ovicidal, and resistance is quite rare, although it is occurring in some parts of the world.<sup>92</sup> The isopropanol-containing vehicle contributes to its effectiveness but also its flammability.<sup>80</sup> Malathion 0.5% lotion is applied to dry hair and rinsed after 8 to 12 hours. A single application is sufficient for most patients, but repeat treatment in 7 to 10 days is recommended if live lice are again noted.

Benzyl alcohol 5% lotion is FDA approved in children 6 months of age and older. This agent is a nonneurotoxic product that kills lice via blockage of their respiratory mechanism. Although head lice have evolved the ability to temporarily close their breathing spiracles (holes), benzyl alcohol 5% lotion stuns the spiracles open while the mineral-oil vehicle obstructs them, killing the lice via asphyxiation.<sup>93</sup> This product provides an alternative for parents who are concerned about the use of neurotoxic pediculicidal agents. Repeat therapy is necessary, and benzyl alcohol 5% lotion is not ovicidal.

Spinosad 0.9% suspension is a pediculicide approved in children 4 years of age and older. It originates from the fermentation of the *Saccharopolyspora spinosa* bacteria, which is normally found in soil, and it results in paralysis and death of the louse. It was found to have better efficacy than permethrin in one report.<sup>94</sup> Spinosad has pediculicidal and ovicidal activity and is applied to dry hair and rinsed off after 10 minutes. Therapy is repeated in 7 days if live lice are again noted. In a meta-analysis, Spinosad therapy was associated with superior efficacy (defined as being free of lice 14 days after the last treatment) compared with permethrin.<sup>95</sup>

Ivermectin 0.5% lotion is approved in children 6 months of age and older and is derived from the fermentation of the bacteria *Streptomyces avermitilis*. The oral form (see below) is used to treat disorders such as onchocerciasis and strongyloidiasis (and off-label occasionally for head lice and scabies). It is applied to dry hair and rinsed after 10 minutes. The manufacturer recommends against repeat therapy without discussing first with the healthcare provider. In a clinical trial of 78 patients with head lice, a single application of 0.5% ivermectin lotion was effective at eradicating lice in three fourths of patients through to day 15 after therapy.<sup>96</sup>

Other less conventional therapies have been used with variable success. These include 5% permethrin, oral trimethoprim-sulfamethoxazole, oral ivermectin, greasy preparations (i.e., olive oil, mayonnaise, and petroleum jelly, which are believed to work via occlusion of the respiratory spiracles of the adult louse), and styling gels.<sup>80,86,97</sup> None of these agents have been studied scientifically, and their true effectiveness remains unclear. Trimethoprim-sulfamethoxazole is believed to kill symbiotic bacteria present in the louse gut and was shown in one study to work synergistically with 1% permethrin cream rinse when the two were used in combination.<sup>98</sup> The potential for severe allergic reaction to this agent makes it less desirable as a lice therapy. Ivermectin has been used as an off-label oral therapy and has typically been dosed at 200 µg/kg (single dose, followed by a second dose in 7 days if persistent infestation is present), similar to when it is used for scabies.<sup>99</sup> In a prospective randomized trial, oral ivermectin (at a higher dose of 400 µg/kg) was found to be superior to 0.5% malathion lotion in children with difficult-to-treat infestations.<sup>100</sup> Thirty-minute applications of hot air have been studied as a potential therapy for head lice.<sup>101</sup>

Manual lice, and especially nit, removal is a tedious task that is unlikely to prevent spread of the infestation unless performed by professional nit-removing salons. Nits, given their firm adherence to the hair shaft, remain in place long after the viable louse has left the casing. It should be recalled that viable nits are deposited on hair close to the scalp (usually within 1 to 2 mm), and most nits that are further out than 5 to 7 mm are no longer viable. However, in some instances nit removal is desirable, such as for esthetic purposes or in response to societal pressures. This is accomplished with manual removal and with fine-toothed nit combs, which are widely available and occasionally packaged with pediculicidal agents. Wet combing refers to use of

the nit comb on damp hair, which is believed to slow down live lice and facilitate removal of nits. A variety of agents have been used in an effort to loosen the cement that attaches the nit to the hair shaft. These include vinegar, 8% formic acid (Step 2<sup>TM</sup>), and a variety of vinegar-based products.

The issue of drug resistance has emerged over the years and clearly appears to be a significant consideration in certain communities. Before assuming true drug resistance, however, other reasons for therapeutic failure should be considered. These include incorrect diagnosis, repeat infestation, and noncompliance with therapy. True resistance has been documented to permethrin, lindane, synergized natural pyrethrins, and malathion.<sup>102–106</sup> Malathion appears to be the agent with the least documented resistance, especially in the United States.<sup>102,103</sup> Lack of susceptibility to pyrethroid insecticides (permethrin, pyrethrins) is usually attributed to an amino acid substitution in a protein that confers "knockdown resistance" (termed the *kdr-like gene*), which subsequently desensitizes cholinergic nerves to the activity of these toxins.<sup>107,108</sup> However, the presence of this mutation has not correlated with clinical treatment failures with permethrin or pyrethrin in some series, suggesting the need for further study in identifying the exact mechanism(s) of resistance in these populations.<sup>92,109</sup>

Regardless of the method of therapy, other family members and close contacts should be examined, and those with evidence of infestation should also be treated. Play areas and furniture can be vacuumed, and bedding, clothing, and headgear should be machine washed in hot water and dried on a high-heat setting. Items that cannot be washed may be dry-cleaned or placed in sealed plastic bags for 2 weeks. Hats, combs, brushes, grooming aids, towels, school lockers and hooks, and other items that come into contact with the head or head coverings should not be shared. Combs and brushes may be coated with the pediculicide for 15 minutes or soaked in rubbing alcohol for 1 hour followed by washing in hot soapy water. Alternatively, these items can be discarded and replaced with new ones.

Information for patients regarding management and control of head lice is available from the National Pediculosis Association at [www.headlice.org](http://www.headlice.org).

## Mosquitoes and Flies

Flies and mosquitoes belong to the order Diptera. One of the largest orders of insects, it includes the two-winged biting flies, gnats, and mosquitoes. Of these, mosquitoes are the most important from the standpoint of human health. They are seen worldwide and may be vectors of many important diseases such as encephalitis (including West Nile encephalitis), malaria, yellow fever, and filariasis. In the United States, the most common insect bites of infants and children are those of mosquitoes.

Mosquitoes are attracted to bright clothing, heat, humidity, and human odors, particularly those of young children. Carbon dioxide, released mainly in the breath but also from the skin, is a long-range attractant for mosquitoes and can be detected from up to 36 meters away.<sup>110</sup> In unsensitized individuals, the ordinary mosquito bite produces only mild, local irritation. This manifests as a slight stinging sensation and a small, pruritic erythematous papule. In sensitized individuals, however, mosquito bites produce itching, urticarial wheals that may last for several hours to several days, or firm papules or nodules (Fig. 18-26) that may persist for longer periods. Occasionally, and particularly in the young, mosquito bites may produce blisters or hemorrhagic lesions. Excoriation of these lesions may result in secondary eczematization and impetiginization. Systemic Arthus-type reactions and anaphylaxis are rare but do occur. Hypersensitivity to mosquito bites has also been associated with Epstein-Barr virus-associated lymphoproliferative disorders.<sup>111,112</sup>

Although the diagnosis of insect bites is often obvious, differentiation from other papular, vesicular, and pruritic eruptions may also be suggested by the characteristic grouping of lesions, a central punctum when present, the acute nature of most reactions, and their seasonal incidence. Treatment of mosquito bites includes oral antihistamines, cool compresses, and topical antipruritic agents such as calamine lotion and topical corticosteroids. When topical corticosteroids are used, stronger preparations (i.e., class II through V) are most effective, with caution exercised not to apply these agents to the face, groin, or

**Figure 18-26** Severe mosquito bite reaction. An indurated, firm, edematous plaque with secondary petechiae from rubbing.

fold areas. Topical diphenhydramine should be avoided given risks of allergic contact sensitization. Cetirizine or loratadine taken prophylactically have both been shown to decrease immediate whealing and pruritus as well as delayed pruritus.<sup>113,114</sup>

Prevention is most effectively accomplished by the use of insect repellents (see below). Another important measure, especially during high-risk activities or exposure times, is the use of protective clothing (hats, socks and shoes, and long-sleeved shirts tucked into pants). Scented hairsprays, pomades, soaps, lotions, powders, colognes, and perfumes may attract all forms of stinging insects and should be avoided unless necessary. Although some have suggested that thiamine hydrochloride taken orally may help to repel insects, this measure remains unproven. Efforts at reducing mosquito populations include ultrasonic electronic devices for use by the consumer and insecticide spraying programs, which have been adopted by several communities.

Various species of biting flies (sandflies, gnats, black flies, deerflies, horseflies) are known to attack the exposed areas of the face, neck, arms, and legs, with the production of painful or pruritic papules or nodules, often with vesiculation. Although lesions often disappear in a few hours, they may persist for several days and can be quite annoying, particularly in small children. Treatment consists of the prophylactic use of insect repellents and treatment of symptoms with acetaminophen, antihistamines, calamine lotion, or topical corticosteroids.

Nonbiting flies, including common houseflies, tend to feed at open wounds, exudates, and cutaneous ulcers and may produce myiasis, a far less common but significant skin disorder. Myiasis is usually a travel-associated dermatosis and is caused most often by infestation with *Dermatobia hominis* (human botfly). It is most common after travel to Central and South America.<sup>115</sup> In this disorder, the adult female lays eggs on other arthropods (flies, mosquitoes, ticks), and this vector then transmits the larvae to the skin of the human host. The larvae penetrate skin, mature in the dermis and subcutaneous tissues, and eventually reach such a size (Fig. 18-27) that they are unable to spontaneously emerge. Clinically, patients present with furuncular nodules (Fig. 18-28) that may drain and often have a central opening (sinus tract), which serves as a site for respiration and excretion. The patient may report a sensation of "crawling in the skin." The lesions occur most commonly on the head and other exposed areas of the body, and small black spiracles may be seen through the overlying skin punctum.<sup>116</sup> Oral myiasis resulting in oral and maxillofacial mutilation have been reported in children living in tropical regions.<sup>117</sup> Treatments include extraction of the larvae through suffocation (petroleum jelly, butter, pork fat, paraffin, oil) or surgical extraction.<sup>115,116,118</sup>

Myiasis caused by *Cochliomyia hominivorax* (New World screw-worm) may occur in persons living in Central and South America or travelers to those regions and result in more tissue destruction. The third larval stage of these maggots contain powerful oral hooks at the

**Figure 18-27** Botfly larva. Note the posterior spines and odd shape of the second stage larva, which makes it difficult to dislodge through the overlying tiny skin orifice.

**Figure 18-28** Myiasis. A furuncular nodule with a small, central opening. Note the visible tip of the larva within the opening.

forepart, which enable burrowing into deeper tissues and significant destruction (Fig. 18-29).<sup>119,120</sup> These screwworms have a predilection for the eyes and nasal and oral mucosae. Mechanical removal of maggots, tissue debridement, and treatment for secondary sequelae (i.e., bacterial infection) are the mainstays of treatment, and topical and oral ivermectin have been utilized as adjunctive therapy.<sup>121,122</sup>

### Fleas

Fleas (Siphonaptera) exist universally among animals and humans. Those that most commonly attack humans in the United States are the human flea (*Pulex irritans*), the cat flea (*Ctenocephalides felis*), and the dog flea (*Ctenocephalides canis*). The eruption produced by a flea bite in a sensitized individual is an urticarial wheal or papule (Fig. 18-30) often with a centrally located hemorrhagic punctum. In highly susceptible individuals, particularly young children, wheals may progress and develop into tense bullae (Figs. 18-31 and 18-32). Flea bites are often multiple and grouped together in linear or irregular clusters on the arms, forearms, or legs or on areas where clothing fits snugly (thighs, buttocks, waist, and lower abdomen). Bites in a linear configuration (the "breakfast, lunch, and dinner" sign; Fig. 18-33) are common and relate to their tendency to jump and crawl but not fly. Treatment is similar to that described for mosquito bites.

Elimination of fleas by treatment of suspected animal carriers and cleaning/spraying of carpets, floors, crevices, and other potentially infested areas should be considered. It should be noted that for every flea seen on the pet there are many more in the environment, that flea collars are not completely effective, and that animal flea sprays and

**Figure 18-29** Myiasis caused by *Cochliomyia hominivorax*. Almost 50 of these larvae were extracted from the small, well-demarcated scalp ulcer of a 13-year-old girl with Darier disease, who contracted the infestation while hiking in Peru.

**Figure 18-30** Flea bites. Multiple excoriated, clustered red papules.

powders, if used, must be repeated every 2 weeks during the summer months to be effective.<sup>123</sup>

Tungiasis is a skin infestation caused by the gravid sand flea, *Tunga penetrans* (chigoe flea, jigger flea). It is endemic in South and Central America, parts of Africa, India, and Pakistan. Tungiasis is rare in the United States and usually seen in those who have traveled to an endemic region.<sup>124</sup> In tungiasis, the female flea attaches herself to the warm-blooded host, burrows through the epidermis into the dermis, and gradually enlarges. Clinical lesions are red nodules with a central punctum or ulceration, occasionally resembling an abscess. Treatment consists of flea removal, wound care, tetanus prophylaxis, and when necessary, treatment of secondary bacterial infection.<sup>124</sup>

**Figure 18-31** Bullous flea-bite reaction. Tense bulla and surrounding crusted papules in a patient with a hypersensitivity to flea bites.

**Figure 18-32** Bullous flea-bite reaction. Multiple tense bullae and secondary bacterial impetiginization in a patient with flea-bite hypersensitivity.

### Bed Bugs

Bed bugs are a member of the order Hemiptera, which also includes reduviid bugs. The most common species to parasitize humans is *Cimex lectularius*. Bed bugs are red-brown, blood-sucking, nocturnal insects that are 3 to 5 mm in size. They are wingless, with flattened oval bodies and three pairs of legs (Fig. 18-34). The female bug deposits eggs on rough surfaces, cracks, and crevices. They avoid light, hiding out during the day in cracks in walls and floors and in furniture and responding to warmth and carbon dioxide (which are both present in sleeping humans) at night. Bites present as erythematous papules, and the breakfast, lunch, and dinner sign may again be present. Bullous lesions may also occur.<sup>125</sup> Bed-bug bites most commonly occur on exposed areas of the face, neck, arms, or hands.

Systemic reactions which may possibly be attributable to bed-bug bites include urticaria, angioedema, asthma, and anaphylaxis. The bed bug is capable of traveling long distances in search of food, often from one house to another, and has been known to survive without food for up to 6 months to a year. It has been suggested that bed bugs may be vectors for hepatitis B, HIV, plague, yellow fever, tuberculosis, relapsing fever, leprosy, leishmania, filariasis, or trypanosomiasis, although there is little evidence to support that they are vectors for any communicable diseases.<sup>126–128</sup> Importantly, methicillin-resistant *S. aureus* and vancomycin-resistant *Enterococcus faecium* were recovered from bed bugs collected from an impoverished community in Vancouver, British Columbia, suggesting that more studies are required to determine their potential to serve as vectors for transmission.<sup>129</sup> Since

**Figure 18-33** Flea bites. The classic linear configuration of flea bites (the breakfast, lunch, and dinner sign) caused by the tendency of fleas to jump and crawl rather than fly.

**Figure 18-34** Bed bug (*Cimex lectularius*). Note the flattened, oval body and three pairs of legs. The family that brought it in had been complaining of itchy, red bite reactions for several months.

In the late twentieth century, bed-bug infestations have been observed increasingly in homes, apartments, hotel rooms, bed and breakfasts, dormitories, hostels, trains, aircrafts, cruise ships, nursing homes, and hospitals.<sup>128,130,131</sup> Although the exact basis for the increased bed-bug resurgence is unclear, some have attributed it to increased worldwide travel, altered insecticide management, or increasing pesticide resistance.<sup>129</sup>

Treatment is directed at elimination of the bug from the environment with insecticides and eliminating potential hiding sites. Although individual lesions require no direct therapy, oral antihistamines, topical corticosteroids, or calamine lotion may be used for symptomatic relief. Systemic corticosteroids have occasionally been utilized. Preventive measures that have been advocated for bed-bug bites include wearing pajamas that cover the majority of skin, covering bedposts with petroleumatum, and manual inspection of hotel headboards and mattresses.<sup>132</sup> Once infestation has occurred, useful measures for

eradication may include vacuuming of exposed hiding locations, washing all linens in hot water and drying on low heat, steam cleaning, use of mattress and box spring encasements, discarding of furniture, placement of insect-growth regulators, and pesticide spraying.<sup>128,132</sup> Carbon-dioxide fumigation has also been demonstrated effective against bedbugs.<sup>133</sup>

### Bees, Wasps, and Ants

Bees, wasps, and ants belong to the order Hymenoptera, a large order of insects that contains about 100 000 species. Like most other insects, they have three pairs of legs and four wings and are recognized by the narrow isthmus separating the abdomen from the thorax. These insects have stingers that can result in local or systemic reactions in susceptible individuals. Hymenoptera venom allergy can result in life-threatening anaphylactic reactions and is responsible for at least 40 deaths per year in the United States.<sup>134,135</sup> The three families of stinging insects in the order Hymenoptera include Vespidae (yellow jackets, wasps, and hornets), Apidae (honey bees and bumble bees), and Formicidae (stinging ants).

Bees, the only insects that produce food eaten by humans, live in almost every part of the world except the North and South Poles. Honey bees live and work together in large groups and do not sting unless frightened or injured. Africanized ("killer") honeybees are hybridized honeybees (from interbreeding of African and domestic honey bees in South America) that tend to attack in swarms and have gradually been migrating into the United States. Wasps, among the most interesting and intelligent of insects, may live together in cooperative fashion, as seen with the so-called "social wasps" (hornets and yellow jackets), or may live as solitary insects. Most wasps are beneficial to humans, because they destroy large numbers of flies, caterpillars, and other insects that may be harmful. As with bees, wasps ordinarily do not sting humans unless they are bothered or frightened. However, yellow jackets and hornets tend to be quite aggressive, especially when near their nest or if disturbed.<sup>135</sup> Wasps are capable of multiple stings, because their stingers are smooth and retractable; bees, on the other hand, usually eviscerate themselves after a single sting, given the barbed nature of their stingers.<sup>136</sup>

Symptoms of bee or wasp stings vary from mild local pruritus, pain, and edema to general anaphylactic reactions with associated difficulty in breathing and swallowing, hoarseness, slurred speech, gastrointestinal disturbances, abdominal pain, dizziness, weakness, confusion, generalized edema, cardiovascular collapse, and occasionally sudden death.

Ants, like bees and wasps, have large glands at the tip of the abdomen from which they introduce venom into wounds produced by their bites. The majority of ants are not aggressive and rarely sting large organisms.<sup>137</sup> However, there are two groups that are considered medically important in the United States. The fire ant (*Solenopsis richteri* and *S. invicta*) is originally from South America and has spread rapidly in the southern United States, where it has become an agricultural pest and a health hazard.<sup>138</sup> It produces a venom more potent than that of other members of the order Hymenoptera. The fire ant was named for the extreme burning pain inflicted by its sting and tends to attack without warning.<sup>139</sup> During one bite cycle, the fire ant may inflict seven to eight stings in a circular pattern. The immediate reaction is characterized by a painful wheal and flare response, with vesicles developing over several hours. Pustular changes eventually occur, and some patients develop large, local erythematous reactions. Anaphylaxis is a common cause of significant morbidity and may be fatal. The harvester ant (*Pogonomyrmex* species), which also has a significant presence in the United States and is considered a stinging ant, is found primarily in the Southwestern states.

The treatment of ordinary bee, wasp, or ant stings consists of local application of antipruritic shake lotions (i.e., calamine lotion), cool compresses or cool baths, and oral antihistamines. A papain solution made of one part meat tenderizer to four parts water may help to relieve local symptoms of pain or discomfort. Severe allergic reactions are treated with epinephrine, antihistamines, oxygen, and systemic corticosteroids. Patients known to be at risk for severe systemic reactions to bee, wasp, hornet, yellow-jacket, or fire-ant stings should be given an epinephrine pen kit and be educated in its proper use in an emergency. Preventative techniques include education on practical

avoidance measures and referral to an allergist for consideration of allergen testing and immunotherapy.

Allergen immunotherapy is an effective form of prevention for certain individuals at risk for severe insect-sting reactions. Commercial venoms for both skin testing and immunotherapy are available for yellow jackets, white-faced hornets, yellow hornets, wasps, and honey bees, and the complementary deoxyribonucleic acid (cDNA) of most major allergens of bee and vespid venoms has been cloned and is available in a recombinant form.<sup>134,135</sup> Sequential bee-sting challenge tests can be used as a diagnostic tool to assess the need for venom immunotherapy in children who are allergic to bee venom.<sup>140</sup> Because the stinging insect cannot always be reliably identified, it is suggested that the testing physician include all geographically relevant insects when choosing the test panel.<sup>141</sup> Venom immunotherapy should be considered for any patient with a history of a systemic allergic reaction to a Hymenoptera sting. For fire-ant immunotherapy, imported fire-ant whole-body extract is the main reagent used.<sup>139</sup> The therapeutic goals of immunotherapy are to prevent life-threatening reactions, reduce morbidity from such stings, and decrease insect-sting anxiety.

### Blister Beetles

Blister beetles (*Cantharis vesicatoria*, order Coleoptera) contain cantharidin, a vesicant most concentrated in the beetles' genitalia, and the active principle of the purported aphrodisiac Spanish fly.<sup>142</sup> The lesions produced accidentally by crushing blister beetles, by discharge of their body fluid on the skin, or by external therapeutic use of cantharidin (as in the treatment of molluscum contagiosum; see Chapter 15) consist of slowly forming blisters that involve the outer layers of the skin. Treatment depends on the extent and location of lesions. Simple aseptic drainage of large bullae and cool compresses generally give adequate relief of symptoms. If vesicles are not traumatized, they usually resolve in 3 to 4 days with subsequent desquamation and healing. Blister-beetle ingestion, when reported, may result in oral mucosal blistering, abdominal pain, vomiting, hematuria, oliguria, and renal failure.<sup>143</sup> "Blister-beetle dermatitis" may also occur after exposure to cantharidin (or another vesicant, pederin, found in the genus *Paederus*) and may mimic shingles, herpes infection, allergic contact dermatitis or impetigo.<sup>144</sup>

### Papular Urticaria

Papular urticaria is a common condition of childhood characterized by a chronic or recurrent papular eruption caused by hypersensitivity to a variety of bites, including those of mosquitoes, fleas, bed bugs, and mites. It is often pruritic and uncomfortable, and the resultant scratching may result in open erosions and secondary bacterial superinfection. One of the most challenging aspects of papular urticaria is convincing parents that the lesions are related to a bite reaction and identifying and eradicating the source of the offending insect.<sup>145</sup>

Papular urticaria presents with multiple urticarial, 3- to 10-mm papules (Figs. 18-35 and 18-36). Lesions are commonly grouped or

**Figure 18-35** Papular urticaria. These edematous, red papules would intermittently swell and become itchier.

clustered in a fashion similar to acute bite reactions. They may be excoriated or crusted, and a central punctum may be visible overlying each papule. Papular urticaria is most common in the summer and late spring, and flea bites are the most common cause. Individual lesions tend to resolve over 1 to 2 weeks and may heal with postinflammatory erythema or hyperpigmentation (Fig. 18-37). Recurrent episodes are common, especially if there is ongoing exposure to the offending insects.

The differential diagnosis of papular urticaria includes ordinary urticaria, pityriasis lichenoides et varioliformis acuta (PLEVA), papular acrodermatitis of childhood (Gianotti-Crosti syndrome), and lymphomatoid papulosis. Histopathologic examination of skin-biopsy specimens reveals spongiosis (epidermal edema), subepidermal edema, and a mixed inflammatory infiltrate that often includes eosinophils.<sup>146</sup> Skin biopsy is useful both in confirming the diagnosis and in persuading the parents regarding the nature of the condition. Symptomatic treatment includes oral antihistamines and topical corticosteroids, as well as topical antipruritic preparations containing menthol, camphor, or pramoxine. Environmental control measures are also desirable when feasible.

### Insect Repellents

Protection from insect bites includes several measures such as avoiding infested areas, wearing protective clothing, and controlling insect populations when possible. However, the most effective avoidance measure in most situations is the application of insect repellent to the

**Figure 18-36** Papular urticaria. These edematous, pruritic red papules continued to intermittently enlarge for many months.

**Figure 18-37** Papular urticaria. These recurrent papules would heal with postinflammatory hyperpigmentation, only to recur with erythema, edema, and pruritus in the same locations.

### Box 18-2 Guidelines for the Safe Use of Insect Repellents in Children

Do not apply to infants under 2 months of age.  
 Read and follow all package directions and precautions.  
 Use just enough repellent to lightly cover the skin; do not saturate the skin.  
 Apply only to exposed skin; do not use on clothing or apply under clothing.  
 Apply sparingly to the face, and avoid contact with the eyes and mouth.  
 Do not apply to the hands of small children.  
 Do not allow young children to apply products themselves.  
 Do not use sprays in enclosed areas or near food.  
 If self-applied, rinse palms to avoid inadvertent contact with eyes and mouth.  
 Do not use on open skin, cuts, wounds, or inflamed areas.  
 Once inside, wash all treated areas with soap and water.  
 Keep repellents out of the reach of children.  
 Use a separate sunscreen; avoid using combined insect repellent-sunscreen products, because clinical data are limited.

skin. Several types of repellents are commercially available and include both synthetic chemicals and plant-derived essential oils.

DEET (formerly N,N-diethyl-m-toluamide) has traditionally been the most effective and most widely used repellent.<sup>147</sup> DEET is a broad-spectrum insect repellent that is effective against mosquitoes, biting flies, chiggers, fleas, and ticks.<sup>148</sup> Higher concentrations of DEET result in longer-lasting protection, although these effects seem to plateau at concentrations higher than 50%. In the United States, DEET is available in variable concentrations in multiple vehicles, including solutions, lotions, creams, gels, pump sprays, sticks, roll-ons, wristbands, and impregnated towelettes.<sup>110,147</sup> The mechanism of action of DEET is to provide a vapor barrier that deters the biting insect from coming into contact with human skin.<sup>149</sup> Firm guidelines or recommendations for choosing an appropriate DEET concentration are not available. However, it is generally accepted that products with 10% to 35% DEET will provide adequate protection in most circumstances.<sup>110</sup> Some general recommendations for the use of DEET-containing products are listed in Box 18-2.

The use of DEET in young children has been a source of some concern, given rare reports of potential neurologic toxicity. Small amounts of DEET may be absorbed through the skin yet seem to be completely eliminated (along with its metabolites) within 4 hours of application in adults.<sup>150</sup> Although the pharmacokinetics are not as well understood in children, reports of neurologic toxicity are rare, and, in fact, in one study of data collected by the American Association of Poison Control Centers, infants and children had lower rates of severe adverse events than did adults.<sup>151</sup> Many of the reports of DEET-related toxicity involved long-term, heavy, frequent, or whole-body application of DEET, and in some, the product was orally ingested.<sup>148,152</sup> In 1998 the Environmental Protection Agency (EPA) completed a reregistration eligibility decision for DEET, and in this process included a review of acute, subacute, and chronic toxicity data. The agency concluded that normal use of insect repellents containing DEET poses no significant risks to children or adults, that product labeling would be modified to include recommendations for safe use, and that child safety claims on labels were prohibited, given the lack of appropriate scientific data to support such claims.<sup>148,152,153</sup> Human-health risk assessments were conducted for DEET and picaridin (see below), and found no significant toxicological risks from typical use of these repellents.<sup>154</sup> Over a 6-year period of data collection as part of the DEET Registry, seizures were the most common neurologic symptom reported with a possible temporal relationship to DEET exposure. However, children were not disproportionately represented; there was no apparent relationship between DEET concentration and the severity of outcome; and the reports of neurologic events (when considered relative to the number of annual DEET applications in the United States) were quite low overall.<sup>155</sup> The American Academy of Pediatrics, in the Red Book discussion of mosquito bite prevention, recommends repellents with DEET concentrations not exceeding 30% and following such practical application guidelines as those outlined in Box 18-2.<sup>156</sup> The Centers for Disease Control and Prevention

recommends DEET at concentrations up to 50% for both adults and children over 2 months of age.

DEET-containing insect repellents should be carefully applied, because they may damage plastics, rayon, leather, spandex, and other synthetic fabrics. They are not damaging, however, to cotton or wool. In addition, it should be remembered that DEET-containing products are flammable. Combination products containing DEET and sunscreen are not recommended, given the potentially decreased effectiveness of the sunscreen and the different recommended application frequencies of these two products. Questions about the safety of DEET can be addressed by the EPA-sponsored National Pesticide Telecommunications Network at [www.ace.orst.edu/info/nptn](http://www.ace.orst.edu/info/nptn).

Picaridin is an insect repellent that is effective against mosquitoes, biting flies, and ticks. It is usually used in a concentration of up to 20%. Picaridin is reportedly of similar efficacy to DEET, is odorless, and will not damage plastics or fabrics.<sup>149</sup> Before its launch in the United States, picaridin was used fairly extensively in Europe and Australia. No serious adverse events have been reported to date. Another synthetic insect repellent available in the United States and Europe is IR3535, which fared poorly in an “arm-in-cage” study when compared to DEET.<sup>148</sup>

Plant-derived repellents may have repellent activity, but none compare to the effectiveness and duration of action of DEET.<sup>110</sup> These products usually contain essential oils from any of several plants, including citronella, cedar, eucalyptus, lemongrass, and soybean. Citronella is the active ingredient in most “natural” repellents marketed in the United States. It has a lemony scent and is available in an oil and in candles. However, in areas with epidemics of mosquito-borne diseases (such as West Nile virus) or in high-risk settings, these products should not be relied upon as the sole protection from bites. When compared to DEET, a blend of the top three performing essential oils was found to offer some protection against various species of mosquitoes but significantly less so than the chemical repellent.<sup>157</sup>

Other approaches to mosquito repellency include ingested garlic or vitamin B<sub>1</sub> and treated wristbands, each of which has less consistently demonstrated effectiveness. Permethrin, marketed in a 0.5% concentration (Permanone, Duranon, Cutter Outdoorsmen Gear Guard, Sawyer Clothing Tick Repellent, 3M Clothing and Gear) as a tick repellent, is also available and is sprayed on tents, clothing, and sleeping bags. This product is also effective against mosquitoes, flies, and chiggers and works as a contact insecticide, resulting in central nervous system toxicity to the insect.

### Caterpillars and Moths

Caterpillars represent the larval stage of butterflies and moths of the order Lepidoptera. The hairs of certain moths and caterpillars are known to produce dermatitis that can be severe and incapacitating to both children and adults. Dermatitis related to these insects has been known as *caterpillar dermatitis* and *lepidopterism*. In the United States, the most commonly seen and most irritating of these are those caused by the hairs of the brown-tail moth (usually seen in the northeastern part of this country) and the puss caterpillar (the larvae of the “flannel” moth, *Megalopyge opercularis*), seen from Virginia southward to the states bordering the Gulf of Mexico.<sup>158–160</sup> Contact with the oak processionary caterpillar (*Thaumetopoea processionea*), found especially in oak forests in European countries, may result in multiple symptoms including pruritus, dermatitis, conjunctivitis, pharyngitis, and respiratory distress.<sup>161</sup> In some instances, affected individuals did not have direct contact with the caterpillar but only with another individual who had experienced contact, suggesting the possibility of human-to-human transmission of the relevant substance(s).<sup>162</sup>

Reactions produced by contact with the hairs and spines of these moths and caterpillars may be associated with the release of histamine and other vasoactive substances or from mechanical irritation by caterpillar hairs that become imbedded in the pores of affected individuals. The precise mechanisms for these reactions are unclear, however, and may be related to irritant reactions, hypersensitivity reactions, or toxic envenomation.<sup>163</sup> They may be focal or more widespread. Examination typically reveals erythematous macules and papules, eczematous dermatitis, vesicles, urticaria, or even necrosis. Other reactions may include severe local pain, nausea, fever, swelling, numbness, muscle cramps, headache, seizures, and shock. The

diagnosis of moth or caterpillar dermatitis can be confirmed by microscopic examination of tape strippings or scrapings of involved areas with demonstration of offending hairs. Although the disorder is self-limiting, relief can be obtained with the use of oral antihistamines, topical corticosteroids, ice packs, and topical antipruritic agents. In patients with severe reactions, fluid support, narcotics, and systemic corticosteroids may be necessary.

## Other Cutaneous Parasites

### CUTANEOUS LARVA MIGRANS (CREEPING ERUPTION)

Cutaneous larva migrans (CLM; creeping eruption) is a self-limited skin eruption caused by the larval stages of the dog and cat hookworms, *Ancylostoma caninum* and *Ancylostoma braziliensis*, respectively. *Uncinaria stenocephala* has also been implicated. CLM is one of the most common skin diseases among travelers returning from tropical countries.<sup>164</sup> In the United States, most cases of CLM are contracted in the southeastern states, most notably Florida and Georgia.<sup>165</sup> Worldwide the disorder is most common in Mexico, Central and South America, Africa, Southeast Asia, and the Caribbean.<sup>165,166</sup> The adult hookworms release eggs while in the intestines of their definitive hosts (dogs or cats), and these eggs are passed along with stool onto sandy, warm soil. Humans become incidental hosts when larvae burrow through intact skin that comes into contact with the infested soil. The disorder is quite common in children because of high-risk behaviors (i.e., playing in the sand) seen in this age group. It occurs sporadically or in small epidemics in high-income countries and in tourists who have visited the tropics.<sup>167</sup> The most commonly involved areas are the extremities (especially feet), buttocks, and genitalia. The incubation period for CLM may be prolonged for weeks to months.<sup>168</sup> Preventative measures may include wearing shoes or sandals and sitting on a towel or chair while on sandy beaches.<sup>169</sup>

In the human host, the hookworm larvae are unable to complete their natural life cycle and remain confined to the upper levels of skin, wandering aimlessly and producing the characteristic cutaneous findings. Initially, skin findings may be limited to one or a few erythematous papules. Ultimately, serpiginous, raised, sharply demarcated plaques develop (Figs. 18-38 and 18-39) and may advance up to 1 to 2 mm per day. Follicular involvement with folliculitis (hookworm folliculitis) may also occur.<sup>164,170</sup> Vesicular or bullous lesions are rare. Without treatment, the larvae eventually die, but this may take several months. The lesions of CLM are extremely pruritic and may be complicated by pain and secondary bacterial infection. Although systemic dissemination of the parasite does not generally occur, eosinophilia is common and pneumonitis (Löffler syndrome) may occasionally be present.

The differential diagnosis of CLM may include other larval infestations such as *Strongyloides stercoralis* and *Gnathostoma spinigerum*. Scabies, jellyfish stings, and phytophotodermatitis may also mimic CLM.<sup>166</sup> Treatment options for creeping eruption include liquid nitrogen cryotherapy (which was a traditional mainstay of treatment) and oral anthelmintic agents. Cryotherapy is rarely effective and is traumatic for most young children; hence it should be avoided for this indication. Oral agents demonstrated to be effective include thiabendazole, albendazole, and ivermectin. Thiabendazole is given at a dose of 25 mg/kg per day divided into two doses for 2 to 5 days. Potential side effects include headache, dizziness, and gastrointestinal upset. Alternatively, topical thiabendazole (500 mg/5 mL) can be applied four times daily and is often effective. Oral albendazole seems to be one of the most effective and well-tolerated therapies. It is given at a dose of 200 to 400 mg twice daily for 5 to 7 days.<sup>171-173</sup> Side effects are rare with this agent, which has been used in nematode and cestode infestations. Use of these agents in young children has not been well studied. Ivermectin, an agent used primarily for onchocerciasis and other nematodes, has also been anecdotally reported as effective in open-label studies.<sup>164</sup> It is given as a single dose (200 µg/kg) and repeated in 1 to 2 weeks if necessary. In one series of 56 patients with CLM treated with single-dose ivermectin, the response rate was 98%.<sup>174</sup>

**Figure 18-38** Cutaneous larva migrans. A serpiginous, migratory plaque on the dorsal foot.

**Figure 18-39** Cutaneous larva migrans. The plantar surface of this young boy revealed a very itchy, linear plaque that was noted to continuously extend over the several days before diagnosis.

### CERCARIAL DERMATITIS (SWIMMER'S ITCH)

Cercarial dermatitis (swimmer's itch) is an itchy, inflammatory dermatosis that results from penetration of human skin by nonhuman schistosome parasites. It occurs after swimming or wading in freshwater lakes, especially in the midwestern United States and has also been demonstrated in the southwestern United States.<sup>175</sup> Cercarial dermatitis can also be acquired in the sea or brackish waters.<sup>176</sup> The most clinically relevant organisms are the *Trichobilharzia* species. The adult schistosomes reside in the mesenteric blood vessels of birds and mammals, and after passage from the blood to the intestine, eggs are deposited in water along with the host feces. Subsequently, miracidiae hatch and penetrate the intermediate host, usually snails.<sup>177</sup> Within the snail they develop into cercariae, which leave the snails and reside in the upper levels of lakes until they can again infect the definitive host. However, they may also infect accidental hosts such as humans.

Swimmer's itch occurs on exposed areas of skin, which are the sites most readily available to the cercariae. Because humans are not the

definitive host, the cercariae die within hours after skin penetration, and the host immune response results in the clinical eruption.<sup>178</sup> Often the initial infestation does not result in a reaction but causes sensitization, which results in the clinical eruption after subsequent exposures.<sup>177</sup> Examination of the skin usually reveals nonspecific, erythematous papules and papulovesicles (Figs. 18-40 and 18-41). Excoriation may be present, and secondary bacterial superinfection is an occasional complication. Postinflammatory hyperpigmentation is common.

The distribution of the lesions combined with the history of exposure to a freshwater lake will combine to suggest the diagnosis of swimmer's itch. Activities that involve more extensive contact with lake water (i.e., wading, working on the dock, and swimming) are more likely to be associated with the disorder than other activities like boating, skiing, and tubing.<sup>178</sup> Aquariums containing snails may also be a source of swimmer's itch.<sup>177,179</sup> Water analysis via filtration and polymerase chain reaction (PCR) detection may be useful if

**Figure 18-40** Cercarial dermatitis. Multiple pruritic, excoriated papules and papulovesicles on exposed surfaces of the skin. The patient had been swimming in a freshwater lake along with family members, several of whom developed similar lesions.

**Figure 18-41** Cercarial dermatitis. Itchy, excoriated papules and papulovesicles, occurring on exposed areas of skin.

confirmation is required and snails cannot be found.<sup>180</sup> Treatment is supportive and consists of topical corticosteroids, topical antipruritic agents, oral antihistamines, and rarely systemic corticosteroids for severe cases.

## Seabather's Eruption

Seabather's eruption, also known as *sea lice*, is not a true parasitic infestation but is commonly confused with cercarial dermatitis and is therefore included in this chapter. It results from a hypersensitivity reaction to the stinging nematocyst of a cnidarian (planula) larva, which includes jellyfish, Portuguese man-of-war, sea anemone, or fire coral (see below).<sup>181</sup> Most often it has been associated with exposure to the larval form of the thimble-sized jellyfish, *Linuche unguiculata*.<sup>181,182</sup> Seabather's eruption occurs most commonly in marine saltwaters off of Florida, in the Gulf of Mexico, and in the Caribbean. (A discussion of traditional jellyfish stings can be found in the following section.)

The skin lesions of seabather's eruption tend to be limited to areas covered by the swimming garment; the swimwear tends to act as a filter, draining water and maintaining contact of the planulae against the skin.<sup>183</sup> Skin findings may include erythematous papules, pustules, and papulovesicles (Figs. 18-42 and 18-43). Urticarial plaques may also be present, and pruritus is usually severe. Other symptoms may include fatigue, fever, chills, headache, abdominal pain, diarrhea, and nausea; these symptoms appear to be more common in children or in those who have severe envenomation.<sup>184</sup> Many patients recall having seen "thimble-sized" jellyfish in the waters, or tiny "black dots" along the water surface.<sup>181</sup> Symptoms may begin while in the water or when exiting, although in the majority of patients they begin several hours later. Longer swim times appear to increase the risk of seabather's eruption; in one report of 38 patients, the median duration of water exposure was 2.5 hours (range 1 to 8 hours).<sup>184</sup> Because freshwater is known to stimulate nematocyst discharge of toxins (via osmotic pressure change), removal of the bathing garment is recommended before rinsing, especially in areas where seabather's eruption warnings are posted.

The diagnosis of seabather's eruption is primarily a clinical one. It should be suspected in the patient with an itchy, papulovesicular eruption limited to covered areas of skin and occurring after exposure to saltwater. Skin biopsy<sup>181</sup> and serologic assays<sup>181,185</sup> have been used but are generally unnecessary. Treatment is symptomatic, as discussed earlier for swimmer's itch.

## Jellyfish Stings

Cnidarians (phylum Cnidaria) are a group of aquatic animals that includes jellyfish, corals, sea anemones, and hydras. The cnidarian

**Figure 18-42** Seabather's eruption. These edematous, erythematous papules were limited to sites covered by the swimming garment.

**Figure 18-43** Seabather's eruption. Erythematous papules and papulovesicles limited to sites covered by the swimming garment, following a vacation in the Caribbean.

body consists of a gastrovascular cavity with a single opening through which food is ingested and waste is released. Cnidarians have tentacles encircling their mouth and bodies that are radially symmetrical. The phylum Cnidaria consists of four classes: Hydrozoa (Portuguese man-of-war), Scyphozoa (true jellyfish), Cubozoa (box jellyfish or sea wasps), and Anthozoa (sea anemones and corals).

Jellyfish are marine invertebrates that are found both in the ocean and in fresh water. They are responsible for the most common ocean-related envenomations acquired by humans, which may result in three types of responses, including immediate allergic, immediate toxic, and delayed allergic reactions.<sup>186</sup> The surface of jellyfish bodies and tentacles is covered in specialized cells called *cnidoblasts* that contain in their cytoplasm a nematocyst, or a capsule filled with a toxic fluid that is injected into human skin at the time of contact.<sup>187</sup> Cutaneous reactions to jellyfish stings may include urticarial wheals, burning, pruritus, and tenderness. Papules and papulovesicles often occur in linear and wispy patterns, and more chronic postinflammatory pigmentary changes, scarring (including keloids), and

lichenification may occur. Occasionally observed findings include thrombophlebitis, tender regional lymphadenopathy, angioedema, papular urticaria, and distant hypersensitivity-type skin reactions (i.e., an id reaction). Fatal anaphylactic reactions are rare but when they occur are more common in children.<sup>188</sup> Other reported sequelae include a persistent lichen planus-like eruption and Guillain–Barré syndrome.<sup>186,189</sup> *Seabather's eruption* refers to a papulovesicular eruption occurring in covered areas of skin in response to contact with nematocysts from thimble-sized jellyfish larvae (see previous section).

Treatment for jellyfish stings is supportive, and traditional considerations include pain control, compression, application of vinegar (thought to help in deactivation of the nematocysts), avoidance of fresh water exposure (which may trigger firing of nematocysts), oral antihistamines, and manual removal of tentacles when visible. One systematic review of jellyfish-sting therapy suggested that vinegar may cause pain exacerbation or further nematocyst discharge unless the envenomation is believed to be from the bluebottle (*Physalia*), in which case it may be helpful; other authors, however, firmly believe in the benefit of topical vinegar in this setting.<sup>190,191</sup> Medical attention should be sought after a jellyfish sting, despite there being a lack of consensus on the most appropriate treatment regimen among emergency medicine physicians.<sup>192</sup> Cardiopulmonary resuscitation and use of an epinephrine pen (when available) may be necessary if anaphylaxis occurs. Useful preventive measures include wearing protective swim- or diving-wear and avoidance of areas known to be infested with jellyfish.

Sunlight emits a wide spectrum of radiation energy, extending from radio waves through infrared, visible, and ultraviolet (UV) light, to X-rays.<sup>1</sup> The wavelength range of visible light is 400 to 800 nm and is relatively harmless, except for individuals with photosensitivity disorders, such as porphyria, solar urticaria, and polymorphous light eruption (PMLE). The infrared range is 800 to 1800 nm. It is the UVA and UVB wavelengths (290 to 400 nm) that cause most cutaneous reactions, including in normal individuals who are exposed to sunlight, tanning booths, and an ever-expanding number of photosensitizers in the environment. Wavelengths less than 220 nm are absorbed by atmospheric gases, including oxygen and nitrogen, and those less than 290 nm are absorbed by the atmospheric ozone layer. The remaining middle wavelength (UVB, 290 to 320 nm) and long wavelength (UVA1, 340 to 400 nm; UVA2, 320 to 340 nm) UV radiation can reach the earth and be absorbed by biologic molecules. The skin is quite effective at protection from UV penetration, but the depth of penetration depends upon the wavelength. UVA easily reaches the deeper dermis, whereas UVB is absorbed in the epidermis and little reaches the upper dermis.

UV light also reaches the skin through reflection from snow (80% to 85%); sand (17% to 25%); water (5%, but up to 100% when the sun is directly overhead); sidewalks, and turf. UV light exposure also increases by 4% for every 1000-foot elevation above sea level. On a bright, cloudy day with thin cloud cover, it is possible to receive 60% to 85% of the amount of UV radiation present on a bright clear day. Hats and parasols provide only a moderate degree of protection, and surfaces with reflectivity greatly increase sunlight exposure.

## Tanning and Sunburn Reactions

The visible short-term effects of UV light exposure are sunburn (Fig. 19-1; see Fig. 26-15) and tanning. The ability to cause sunburn markedly declines with increasing wavelength. UVA light at 360 nm is 1000-fold less effective in causing skin erythema (sunburn) than UVA light at 300 nm. Thus UVB light is largely responsible for sunburn, with peak induction 6 to 24 hours after exposure. Sunburns gradually fade during the next 3 to 5 days, as the skin starts to desquamate. Reactivity to UVB light may range in severity from a mild asymptomatic erythema to a more intense reaction, with redness accompanied by tenderness, pain, edema, and, at times, vesiculation and bulla formation, particularly the day after the sunburn first appears. If the sunburned area is extensive, constitutional symptoms may include nausea, malaise, headache, fever, chills, and even delirium. Sunburn during childhood correlates with a higher risk of developing melanocytic nevi,<sup>2</sup> as well as UV light-induced skin cancers.

Tanning is also wavelength-dependent and is biphasic. Immediate pigment darkening results primarily from exposure to UVA light, is caused by alteration and redistribution of melanin, and fades in 6 to 8 hours. Delayed tanning usually results from exposure to UVB and peaks at about 3 days after exposure. Fair skin is only able to tan with UVB dosages about the erythema threshold (i.e., a sunburn is required on type II skin; type I skin cannot tan; Table 19-1). In contrast, darker skin types (i.e., type III and higher) can tan significantly without burning (at suberythemogenic doses). Sunburn causes apoptosis (cell death) of keratinocytes ("sunburn cells") or, if the dosage is high enough, induces cell cycle arrest, allowing the cell to undergo repair of their deoxyribonucleic acid (DNA) template before proliferating. Sunburn also depletes the protective Langerhans cells, causes epidermal thickening (which reduces exposure of the basal keratinocytes to UV radiation) as a protective mechanism, stimulates

release of inflammatory cytokines, and induces the formation of anti-oxidative enzymes (which reduce oxidative DNA damage). The tan induced by UVB involves increased melanin synthesis, increased numbers of melanocytes, and increased transfer of melanosomes to keratinocytes.

The long-term effects of chronic sun exposure include photoaging, photocarcinogenesis, and immunosuppression. Given its potential to penetrate more deeply into the dermis, UVA light is thought to play a particularly important role in photoaging. UVA light, but not UVB light, is able to penetrate through window glass, even if tinted.<sup>3</sup> Thus individuals who sit in offices exposed to UVA light through windows or drive cars extensively can show significant asymmetry in UVA damage on the face.<sup>4</sup> An exception is the laminated glass of windshields (as opposed to the nonlaminated glass on the sides of cars), which blocks most UVA light (up to 380 nm). Window films can be applied to block UVA radiation but allow vision.

UVA light is also the light used in indoor tanning, a practice prevalent particularly among older female adolescents.<sup>5,6</sup> This practice promotes skin damage, leading to an increased risk of both melanoma and nonmelanoma skin cancer and photodamage, but no increased protection against sun exposure.<sup>7,8</sup> The danger of using tanning facilities has led to legislation to control use by minors and limitations of exposure in several states. Nevertheless, the prevalence of use of a tanning salon by college-aged students was 60.4% in 2009, with 33.1% using tanning salons more than five times a year.<sup>9</sup> Many facilities now offer "safe" tanning, and these self-tanners are also available commercially. With all of these self-tanners, an artificial tan is produced by dihydroxyacetone (DHA), a sugar that interacts with the stratum corneum proteins to produce a brown pigment made of polymers called *melanoidins*, which resist washing.<sup>10</sup> Approximately 10.8% of adolescents have used a self-tanner, especially older Caucasian adolescents with a high to moderate level of sun sensitivity.<sup>11</sup> Self-tanners, unfortunately, provide minimal and transient sun protection, and their use is often in conjunction with tanning salon use rather than as a substitute.<sup>12</sup>

Prevention of sunburn depends primarily on the utilization of measures that reduce exposure to strong sunlight. This is especially important for fair-skinned individuals, particularly blue-eyed persons, redheads, blonds, and those with freckles who withstand actinic exposure poorly, burn easily, and, over the years, tend to suffer chronic effects of light exposure. Prophylactic measures to reduce the impact of harmful UV rays include timing of outdoor activities to avoid peak UV light exposure between 10:00 AM and 3:00 PM in the warmer seasons of the year; wearing broad-rimmed hats, sun protective clothing, and sunglasses; and staying in the shade. Light-textured materials such as T-shirts (especially when wet) give only partial protection.<sup>3</sup> Clothes with a tighter weave are commercially available (e.g., [www.coolibar.com](http://www.coolibar.com); [www.solumbra.com](http://www.solumbra.com)), or clothes can be laundered with a chemical (Tinosorb FD), which provides sun protection (e.g., Sun Guard).

Sunscreens occupy an important position in the management of UV light exposure.<sup>13-15</sup> The lifetime use of sunscreen and sun avoidance has been calculated to reduce the lifetime risk of developing UV light-induced skin cancer by 78%,<sup>16</sup> although whether use of sunscreens reduce the development of nevi remains controversial.<sup>17</sup> Promoting routine sunscreen use in the pediatric population is important, including among adolescents whose behaviors escape parental influence.<sup>18,19</sup> In order to be effective, adequate amounts of sunscreen must be applied to all areas exposed to UV light, and the sunscreen must be reapplied every few hours. It is critical that individuals continue sensible sun protection by means other than sunscreens and not increase their exposure because of sunscreen availability.

**Figure 19-1** Sunburn. This adolescent became more sensitive to ultraviolet light exposure while taking isotretinoin.

**Table 19-1** Skin Types and Photosensitivity

Skin Type	Reactivity to Sun	Examples
I	Very sensitive: always burns easily and severely, tans little or not at all	Individuals with fair skin, blond or red hair, blue or brown eyes, and freckles
II	Very sensitive: usually burns easily, tans minimally or lightly	Individuals with fair skin; red, blond, or brown hair; and blue, hazel, or brown eyes
III	Moderately sensitive: burns moderately, tans gradually and uniformly	Average white individuals
IV	Moderately sensitive: burns minimally, tans easily	Individuals with dark brown hair, dark eyes, and white or light brown skin
V	Minimally sensitive: rarely burns, tans well and easily	Brown-skinned (Middle Eastern and Hispanic) individuals
VI	Deeply pigmented: almost never burns, tans profusely	Blacks and others with heavy pigmentation

The most common sunscreen components and their absorbance capacity are listed in **Table 19-2**. Inorganic sunscreens (titanium dioxide and zinc oxide) protect skin by reflecting and scattering UV and visible light (290 to 700 nm); often, both of these agents are usually included in an inorganic sunscreen. Organic sunscreens absorb light at particular wavelengths into specific chemical UV filters and reemit the energy as insignificant quantities of heat. Newer organic sunscreen components now absorb in both the UVA and UVB spectrum, thus providing protection against the damaging effects of the broad spectrum of UV light. These newer sunscreens are photostable (in contrast to avobenzene, an earlier generation component), and include bis-ethylhexyloxyphenol methoxyphenol triazine (anisotriazine [Tinosorb S]), drometrizole trisiloxane (silatriazole [Mexoryl XL]), methylene-bis-benzotriazolyl tetramethylbutylphenol (Tinosorb M), and terephthalylidene dicamphor sulfonic acid (Mexoryl SX). Unfortunately only avobenzene and Mexoryl SX are FDA-approved, so other newer sunscreen ingredients are not available in the US. Ideally, organic sunscreens should be applied 20 to 30 minutes before the onset of sun exposure, so that there is adequate time to bind to the stratum corneum and show effectiveness. The inorganic sunscreens can be applied immediately before sun exposure.<sup>20</sup> Sunscreens should be reapplied after swimming, periods of excessive perspiration, and washing or showering; water resistance for 40 minutes is specified on labeling. Oral sunscreens containing antioxidants (e.g., lycopene, vitamins C and E) and botanicals (e.g., polyphenols, such as green tea and flavonoids such as genistein) are now commercially available. They provide some protection against acute sun damage, but they are not as effective as topical sunscreens in preventing sunburns, their long-term protective effects are not clear, and they should not replace other forms of photoprotection for children.

Sunscreen labels in the United States are now required to reveal both the sun protection factor (SPF) and the capability of broad spectrum UVA protection.<sup>21</sup> The SPF rating can be determined by dividing the least amount of time it takes to produce erythema on sunscreen-protected skin by the time it takes to produce the same erythema without sunscreen protection. Thus individuals using a sunscreen with an SPF of 15 who normally burn after unprotected sun exposure, can theoretically stay out 15 times longer before getting the same degree of erythema, and thus only informs about protection against sunburn from UVB light. The additional benefit from use of a sunscreen with an SPF above 30 is small compared with the incremental benefit at lower SPF numbers, but higher SPF may be important for individuals with high photosensitivity or in intense sunlight. Furthermore, it should be recognized that the SPF is tested with a concentration of 2 mg/cm<sup>2</sup>, which is more than the majority of individuals apply. The designation "broad spectrum" provides information about the ability of the sunscreen to protect again nonerythema effects, especially from UVA light, including immune suppression, photoaging, and skin cancer.

The degree to which a person sunburns or tans depends on genetic factors and the natural protection of the skin. Skin types, accordingly, are ranked from skin type I, the most sensitive, to skin type VI, the least sensitive to sun damage (see **Table 19-1**). Because sun damage begins in children and is cumulative, it is strongly recommended that everyone adopt a program of sun protection and daily sunscreen use, preferably with an SPF of 15 or greater, from infancy on. Because increased melanin is not totally protective, even darker skinned individuals can burn and should use sunscreen.

Considerable media attention has focused on the need for UV light-induced vitamin D synthesis in the skin as a rationale for sun exposure. Indeed, UVB light induces the synthesis of vitamin D<sub>3</sub> in epidermal cells, and this vitamin D<sub>3</sub> is then hydroxylated in the liver (to 25-OH-vitamin D<sub>3</sub>) and kidney (to 1,25-OH-vitamin D<sub>3</sub>). However, the UV light exposure that stimulates vitamin D<sub>3</sub> production in the skin is inseparable from UV light exposure that is carcinogenic. Although vigorous sunscreen use may reduce the capacity of skin to produce vitamin D (and greater vitamin D deficiency has been linked to darker skin color), sunscreen use has not been linked with deficiency and oral administration of vitamin D likely suffices. The American Academy of Pediatrics recommends a minimum daily intake of vitamin D for infants, children, and adolescents to 400 IU/day, beginning shortly after birth.<sup>22</sup> Patients who require strict photoprotection as treatment should be monitored for possible vitamin D deficiency and provided dietary supplementation.<sup>23</sup>

Treatment of sunburn consists of cool compresses or cool tub baths in colloidal oatmeal (such as Aveeno), baking soda, or cornstarch; topical formulations with pramoxine or menthol; mild topical corticosteroid formulations; an emollient cream; and systemic preparations with analgesic and anti-inflammatory properties, such as nonsteroidal anti-inflammatory drugs (NSAIDs). When symptoms are severe, a short course of systemic corticosteroids (oral prednisone, or its equivalent, in dosages of 1 mg/kg per day, with tapering after a period of 4 to 8 days) will abort severe reactions and afford added relief.

Certain disorders predispose individuals to the adverse effects of UV light. For example, children with alopecia totalis (see Chapter 7),

PABA, Paraaminobenzoic acid; UVA, ultraviolet A light; UVB, ultraviolet B light.

\*UVB = 290 to 320 nm, UVA2 = 320 to 340 nm, UVA1 = 340 to 400 nm, visible light = 400 to 800 nm.

<sup>†</sup>Only organic UVA blockers in US.

just as adults with androgenetic alopecia and balding at the vertex, have a higher risk of developing skin cancer at the exposed site if not protected. Patients with diminished or absent melanin, as in oculocutaneous albinism (see Chapter 11), or with defective DNA-repair mechanisms, as in xeroderma pigmentosum (XP), have an increased tendency to develop UV light-induced DNA damage and cutaneous malignancy. Individuals with nevoid basal cell carcinoma syndrome (see Chapter 9), which predisposes to the early onset of numerous basal cell carcinomas, have mutations in the *PTCH* gene, a gene that can also be mutated by UV light exposure in sporadic basal cell carcinomas. Sunlight can also exacerbate or trigger certain dermatoses, among them acne (see Chapter 8); herpes simplex infection (see Chapter 15); lupus systematus, neonatal lupus, and dermatomyositis (see Chapter 22); Darier disease (see Chapter 5); pemphigus and bullous pemphigoid (see Chapter 13); and lichen planus and psoriasis (see Chapter 4).

## Photodermatoses

**Photosensitivity** is a broad term used to describe abnormal or adverse reactions to sunlight energy in the skin.<sup>24</sup> Photodermatoses must be distinguished from reactions to sunlight from exaggerated exposure, which is a normal response. Photodermatoses have been classified into four groups: 1) immunologically mediated; 2) drug- or chemical-induced; 3) with defective DNA repair; and 4) photoaggravation of existing conditions.<sup>25</sup>

Photosensitivity in a child should be suspected if the child develops a sunburn reaction, swelling, or intense pruritus after limited exposure to sunlight or shows a rash or scarring predominantly in sun-exposed areas (face, V of the neck, and dorsal surface of the arms and hands).<sup>26,27</sup> The history in a patient with a photosensitivity disorder is of great importance in determining the cause (Table 19-3). Examina-

**Table 19-3** Evaluation for Potential Photosensitivity Disorders

History	Age of onset; exposure to potential photosensitizers; season of the eruption; time of onset after exposure to the sun; duration of eruption; effect of window glass and exposure to other light sources, including tanning booths; history of atopy and other medical problems; response to medications and use of sunscreens; family history
Examination	Distribution and morphology
Phototesting	Action spectrum, time to onset, minimal urticarial dose, inhibition and augmentation spectra
Photopatch testing	If photoallergy is suspected
Laboratory	Complete blood count, metabolic panel, erythrocyte sedimentation rate, autoantibodies, esp. antinuclear antibody, porphyrins
Biopsy	Useful for lupus and possibly porphyrias, but not for other photodermatoses Fibroblast cultures for XP testing

XP, Xeroderma pigmentosum.

tion should focus on the distribution of lesions, including the areas of sparing.<sup>28</sup> In a photosensitivity disorder, the upper eyelids, postauricular and submental areas, nasolabial and neck folds, volar aspect of the wrist, and the antecubital fossae generally tend to be spared. The morphology of the lesions may be helpful as well (urticarial versus papular

versus vesicular, and the presence of lichenification, which suggests chronicity.

Phototesting can be helpful in determining the cause of an acquired photodermatoses. Exposure to UV light of different wavelengths may replicate the lesions, offering the opportunity to see morphology that may not be present at the time of the examination, confirming the suspicion of photosensitivity, and determining the UV range that triggers the disorder.<sup>29</sup> Further laboratory investigations, such as antibody testing for suspected collagen vascular disease (such as antinuclear antibodies [ANAs], anti-ds DNA, anti-Ro, and anti-La antibodies), blood and 24-hour urine porphyrin levels, and photopatch testing in patients with suspected photoallergy, may be necessary. Performing a biopsy is rarely useful, except for suspected lupus erythematosus.

## IMMUNOLOGICALLY MEDIATED PHOTODERMATOSES

### Solar Urticaria

Solar urticaria accounts for less than 1% of type I immunoglobulin (Ig) E-mediated type of sensitivity reactions and is characterized by a sensation of pruritus or burning and erythema.<sup>30-34</sup> Typically affected areas are the arms, legs, and upper chest; areas with regular sun exposure, such as the hands and face, are less commonly involved. It usually appears within 5 to 10 minutes of sunlight exposure and is followed almost immediately by a localized urticarial reaction confined to the exposed areas and an irregular flare reaction that may extend onto unexposed skin. Within 24 hours, lesions tend to resolve (usually in 1 to 3 hours); new lesions will not develop for 12 to 24 hours, even if subsequent exposure to sunlight occurs. Fixed solar urticaria, characterized by recurrent eruptions on the same body parts, is rare and less severe than typical solar urticaria.<sup>35</sup> Delayed fixed solar urticaria, occurring 6 hours after exposure, has been described.<sup>36</sup> Although the reaction is generally transient, scratching and rubbing may lead to secondary eczematization with persistent cutaneous changes. The disorder usually does not manifest until the third or fourth decade of life, and females are affected three times more often than males. It has been reported, however, as early as 1 week of age.<sup>37,38</sup> The condition persists for more than a decade in the majority of affected individuals and often for a lifetime. Systemic signs have occasionally been reported in association, including headache, nausea, wheezing, dizziness, syncope and rarely shock.

The cause of solar urticaria is unclear, but the pathogenesis involves interaction of a cutaneous photoallergen with IgE-specific mast cells, leading to mast cell degranulation. Often phototesting can confirm the diagnosis and determine the wavelength range that causes the photosensitivity. If positive, whealing generally occurs within minutes. In some patients, the sensitivity involves the UVB range through the visible light range; the majority of patients react within the range of 290 to 480 nm. A negative phototest occurs in many patients and does not exclude the diagnosis. In patients with mild forms of solar urticaria (those in whom the threshold is high), the disorder may be controlled simply by appropriate sunscreens and avoidance of prolonged unprotected sun exposure. Those individuals highly sensitive to sunlight, however, must completely avoid daytime exposure.

Nonsedating antihistamines,<sup>39</sup> antimalarials, corticosteroids, intravenous Ig (IVIG), and plasmapheresis have been beneficial. Omalizumab may be an option for patients with high levels of IgE who fail antihistamine therapy and has been successful in several (but not all) adult patients.<sup>40,41</sup> In some individuals, sun tolerance may be established by carefully metered, increasing exposures ("hardening") to natural or artificial light or the oral administration of a psoralen followed by UVA (PUVA) light.

### Polymorphous Light Eruption

Polymorphous light eruption (PMLE) is the most common of the immune-mediated disorders associated with photosensitivity.<sup>42,43</sup> It is predominantly a disorder of females in the second and third decades of life, and is estimated to occur in 10% to 15% of the US population. It occurs more often in individuals with lighter skin types. Although its etiology remains only partially understood, PMLE has been hypothesized to involve resistance to UV light-induced immune suppression and subsequently cell-mediated immune reactivity to a cutaneous

photoantigen. An autosomal dominant inherited form of PMLE has been described in Native Americans of both North and South America.<sup>44</sup> Onset of this hereditary form is in childhood, and female patients outnumber male patients 2:1.

Often referred to as *sun allergy* or *sun poisoning*, the clinical eruption consists of a group of polymorphic lesions that usually occur 1 to 2 days after intense sunlight exposure, often while on vacation. In some individuals, the eruption is first seen in the spring and persists with continued sun exposure, but may improve later in the summer as the skin "hardens" from UV light exposure. The lesions may range from small papular (Fig. 19-2), urticarial (Fig. 19-3), vesicular, or eczematous reactions to large papules, plaques,<sup>45</sup> or patterns resembling erythema multiforme. A "pinpoint" variant that resembles lichen nitidus clinically and histologically occurs more often in individuals with darker skin colors.<sup>46,47</sup> The areas of the body most commonly involved include the face, the sides of the neck, and sun-exposed areas of the arms and hands. In children, it most commonly begins on the face as an acute, erythematous, eczematous eruption with small papules. Pruritis may be severe. Lesions usually involute spontaneously in 1 to 2 weeks, provided no additional exposure to sunlight occurs.

Juvenile spring eruption is considered a subset of PMLE, and is characterized by photo-induced, dull-red edematous papules that are largely confined to the helix of the ears (Fig. 19-4).<sup>48</sup> Lesions may become vesicular and crusted, and occasionally appear on the dorsal aspects of the hands and on the trunk. Juvenile spring eruption occurs more commonly in boys than in girls, and particularly between the ages of 5 and 12 years. Protuberant ears and lack of hair cover have been strongly associated,<sup>49</sup> but skin color and use of sunscreen have not. Lesions heal within a week, without scarring, unless secondary

**Figure 19-2** Polymorphous light eruption. Papular lesions occurred 2 days after intense sun exposure.

**Figure 19-3** Polymorphous light eruption. Urticarial form.

**Figure 19-4** Juvenile spring eruption. Tiny papules and vesicles on the helix of the ears after sun exposure. Note that sun-shielded area behind the ear is uninvolved.

infection develops. Lesions are more difficult than PMLE to reproduce by exposure to UV light.<sup>50</sup>

The diagnosis of PMLE is suggested by the character of the lesions, their distribution, and their relationship to sun exposure. Although often unnecessary, PMLE can be confirmed by provocative light testing, which involves exposing the same site for about 4 consecutive days; it is important to use a site that has previously reacted but to perform the test early in the spring before hardening has occurred. The reaction, in contrast to that of solar urticaria, occurs within hours rather than minutes, lasts for days rather than hours, and is not urticarial. Some patients with systemic lupus erythematosus (SLE) acquire sun-induced lesions indistinguishable from those of PMLE, and serologic testing should be performed (see Chapter 22). In addition, erythema multiforme may be photodistributed and thus confused with PMLE;<sup>51</sup> in contrast with erythema multiforme, PMLE skin samples have shown no evidence of herpes simplex virus.

Prevention of PMLE consists of sunscreens with good coverage of the UVA spectrum (when applied adequately with 2 mg/cm<sup>2</sup>), sun-protective clothing, and the avoidance of midday sun exposure. Hardening or desensitization of skin by gradually increasing exposure 2 to 3 times weekly to narrowband UVB or PUVA light for 4 to 6 weeks before exposure helps the majority of treated patients. The addition of oral flavonoids (especially polypodium leucotomos given for 12 weeks) or antioxidants in sunscreens has shown benefit in preventing PMLE.<sup>52,53</sup> If patients severely affected by this disorder anticipate temporary intense or prolonged sun exposure, a short course of systemic corticosteroids can be administered. Topical steroids may provide relief in mild cases. Recent evidence suggests that topical vitamin D<sub>3</sub><sup>54</sup> or topical liposomal DNA-repair enzymes<sup>55</sup> may be of value. Antimalarials, β-carotene, and nicotinamide are of limited effectiveness.

### Actinic Prurigo

This photosensitivity disorder, also called *hydrea aestivale* and *Hutchinson summer prurigo*, is most commonly seen in the Indian and mestizo (mixed ancestry) populations of Mexico and other regions of Central and South America, although it has been described in the Caucasian and Asian populations.<sup>56-59</sup> It has been seen in many children in the United States and Canada but is rare in Europe. Most cases begin in childhood before puberty.<sup>60</sup> The condition is characterized by intensely itchy papules, plaques, and nodules, along with excoriations and scars (Figs. 19-5 and 19-6). Some patients can be very uncomfortable and show secondary eczematization and lichenification. Actinic prurigo predominantly affects exposed sites on the face and distal extremities, but may involve covered areas as well, particularly the sacrum and buttocks. Healed facial lesions leave minute linear or pitted scars. Seasonal exacerbation at the beginning of spring with improvement in the fall is common, although the lesions commonly do not clear during the winter; greater seasonal change occurs with higher latitudes. The oral or ocular mucosae are involved in 30% to 50% of cases. Cheilitis alone is seen in 28% of patients, but 83% of patients

**Figure 19-5** Actinic prurigo. Intensely itchy papules with excoriations in this mild case with secondary eczematization.

**Figure 19-6** Actinic prurigo. Note the excoriations and residual scars.

experience pruritus, tingling, and pain of the vermillion.<sup>61</sup> Ocular findings most commonly include photophobia and conjunctivitis.<sup>62</sup>

The diagnosis is generally based on the clinical appearance. Biopsy of skin is generally not useful, although histologic evaluation of lip and conjunctival biopsies shows the characteristic well-formed lymphoid follicles.<sup>63</sup> The presence of the eruption on both exposed and covered sites, its occurrence in winter, mucosal and conjunctival involvement, persistence beyond 4 weeks, and residual scarring of skin distinguish actinic prurigo from PMLE. Photosensitivity testing for minimal erythema dose is abnormal in up to two-thirds of patients. Human leukocyte antigen (HLA) DRB1\*0407 is found in 60% to 70% of patients with actinic prurigo, but only in 4% to 8% of DR4+ controls<sup>64-66</sup>; HLA DRB1\*0401 is present in up to 20% of affected individuals with actinic prurigo. Although individuals with PMLE do not show these associations, 35% of patients with typical actinic prurigo

have a history that suggests coexistence of actinic prurigo and PMLE or transition from one to the other.<sup>67</sup> Although the etiology of actinic prurigo is unknown, the strong association with HLA markers suggests a role for major histocompatibility complex (MHC)-restricted antigen presentation in the pathomechanism of the condition.

The disorder often has a chronic course that persists into adulthood; however, spontaneous resolution may occur during late adolescence. Vigorous sun protection and use of topical anti-inflammatory agents for the pruritus lead to improvement in the majority of patients. Short courses of systemic steroids can be helpful, but antimalarials and other immunosuppressive medications have not had much effect. Complete resolution may require the addition of thalidomide (usually 50 to 100 mg/day),<sup>68</sup> which results in rapid clearing.<sup>69</sup> The gradual introduction of exposure to narrow band UVB light has also helped some patients. Oral cyclosporine and azathioprine have had some success in a few refractory cases.

### Hydroa Vacciniforme

Hydroa vacciniforme (HV) is a rare disorder that is now known to result from chronic Epstein–Barr virus infection.<sup>70</sup> The classic lesions tend to appear each summer in children on uncovered parts of the body after exposure to sunlight. Boys are more often affected than girls. Rare familial cases have been described. The mean age of onset is 8 years.<sup>71</sup> Most patients show sensitivity to UVA light in monochromator phototesting, which may induce papulovesicular lesions.<sup>71</sup>

The primary lesion is a pruritic edematous papule, vesicle, or bulla that occurs within hours or days on uncovered surfaces exposed to sunlight.<sup>33</sup> Itching and burning, as well as mild constitutional symptoms may occur a few hours before the outbreak of the cutaneous lesions. Lesions tend to appear on the face, the sides of the neck, and extensor surfaces of the extremities, and are arranged symmetrically over the nose, cheeks, ears, and dorsal surfaces of the hands. The vesicles or bullae usually develop on an erythematous base and initially are rather tense. These are followed by central necrosis and umbilication that leads to healing with individual or confluent varioliform scarring within 1 to 2 weeks (Fig. 19-7). Mild conjunctivitis or keratitis may be associated. The disease usually flares after sun exposure, and, in most instances, involves spontaneously by the late teenage years with a mean duration of 9 years.<sup>71</sup>

A more severe and persistent vesiculonecrotic HV-like skin eruption is likely to be lymphoma (HV-like), which is associated with higher titer latent Epstein–Barr virus infection and monoclonal T-cell receptor gene rearrangements<sup>72–75</sup> (see Chapter 10). Patients have marked facial edema, hemorrhagic bullae, atrophic scarring, and severe disfigurement in both sun-exposed and sun-protected sites. Fever, hepatosplenomegaly, abnormal liver function testing, lymphadenopathy, hemophagocytosis, and hypersensitivity to mosquito bites may be associated.<sup>76</sup> HV-like T-cell lymphoma occurs primarily in pediatric patients from Central and South America and Asia.

**Figure 19-7** Hydroa vacciniforme. Varioliform scarring on the nose in an adolescent who had severe episodes when younger.

The diagnosis can be confirmed histologically. Treatment of HV consists of strict sun protection, including broad-spectrum sunscreens (SPF at least 30), protective clothing, and avoidance of midday sun exposure. No intervention has been uniformly successful. Antimalarial drugs, β-carotene, oral fish oils,<sup>77</sup> and “hardening” by treatment with narrowband UVB light have been used with some therapeutic success.<sup>78</sup> Low-dose prophylactic narrowband UVB light during spring months may also reduce disease severity. The psychosocial and emotional impairment of HV on quality of life is significant, given the extensive disfigurement from scarring and the effect on daily life of strict sun avoidance.<sup>79</sup> Because of the potential risk of HV progression to HV-like lymphoma, patients should be closely monitored for at least 10 years after diagnosis.

## Photosensitivity Induced by Exogenous Sources

Photosensitivity reactions may be phototoxic (photoirritant) or photoallergic (Table 19-4).<sup>80–83</sup> Exogenous photosensitizers may reach the skin by topical or systemic routes. The clinical course is brief, and elimination of the offending drug or sunlight exposure usually results in improvement. In rare cases, however, the photosensitivity may persist for months after the last known exposure to the offending chemical. Such individuals are known as persistent light reactors and the eruption (chronic actinic dermatitis) ranges from a chronic dermatitis initially restricted to sun-exposed surfaces to thickened hyperpigmented plaques. This rare disorder generally affects men and not pediatric patients.

### PHOTOTOXICITY

Phototoxic reactions are common and can be likened to a primary irritant reaction. A phototoxic reaction refers to a nonimmunologic exaggerated sunburn or sunburn-like reaction characterized by erythema (and at times swelling and blistering), occurring within a few minutes to several hours (usually within a period of 2 to 6 hours) after exposure to UVA light and followed by hyperpigmentation and desquamation confined to the exposed areas. This type of sensitivity usually occurs with the first exposure to the photosensitizing substance, when the systemic or percutaneous absorption of the sensitizing substances is in high enough concentration to result in a photo-induced cutaneous reaction.

Plant-induced photosensitivity (phytophotodermatitis) is the most common phototoxic reaction of children.<sup>84–87</sup> The large majority are phototoxic reactions caused by the presence of furocoumarin compounds (psoralens) found widely in such plants as Rutaceae (e.g., limes and lemons); Umbelliferae (e.g., parsnips, carrots, dill, parsley, meadow grass, common rue, giant hogweed, and celery, most often celery infected with a fungus that causes pink rot disease); and Moraceae (e.g., fig). Psoralens can also reach the skin after ingestion, as has been noted after ingestion of contaminated celery and subsequent outdoor and tanning salon UV light exposure. With systemic ingestion, all sun-exposed areas are susceptible to reaction. Psoralens have also been used therapeutically in topical or oral formulations in combination with UVA light (PUVA therapy) as treatment of psoriasis and vitiligo; given the safety issues with PUVA, this intervention is rarely used in children. Furocoumarins can also be components in Chinese herbal medications.<sup>88</sup> Inhalation of traces of giant hogweed have been reported to cause obstructive pulmonary symptoms, and contact with the eye can lead to blindness.<sup>89</sup>

Phytophotodermatitis usually begins within a day after exposure to the furocoumarin and sunlight, ranges in severity from mild erythema with or without erosion to severe blistering (Fig. 19-8), and eventuates in a characteristic dense inflammatory hyperpigmentation. A bizarre linear streaking configuration of the dermatitis (Fig. 19-9), with subsequent hyperpigmentation, especially on the face, chest, hands, and lower legs of children, is characteristic. At times, only the hyperpigmented streak appears without prior erythema (Fig. 19-10). The purple coloration of skin and bizarre patterning can be mistaken for child abuse and the blistering for herpes simplex infection.<sup>90–92</sup> Streaks on the trunk have been noted after dripping of lime juice (sometimes

**Table 19-4** Medications Most Commonly Associated with Phototoxic and Photoallergic Reactions

Phototoxic Medications	Photoallergic Medications
<b>Antibiotics</b>	<b>Antimicrobials (topical)</b>

used as a hair rinse or in drinks), and thumbprint-shaped macules on the lateral aspects of the trunk may be described after a parent with furocoumarins on the fingers picks up a child. Usually no treatment is necessary once the diagnosis is made, and the often-intense hyperpigmentation fades spontaneously over several weeks to months. However, severe burns have been induced in children by contact with phototoxins, especially giant hogweed and prolonged sunlight exposure, and have required debridement and surgical wound closure.<sup>89,93,94</sup>

Phototoxicity may present with a variety of manifestations. For example, sunburn reactions can occur with thiazide diuretics, tetracyclines (Fig. 19-11), retinoids, voriconazole, ciprofloxacin, and others, whereas skin fragility and blisters (pseudoporphyria) are the typical manifestation of exposure to NSAIDs, and telangiectasia results from calcium channel antagonists. Photoonycholysis most commonly occurs after administration of doxycycline<sup>95</sup> (see Chapter 8, Fig. 8-16). The phototoxicity from voriconazole, used to prevent fungal infections in transplant patients, occurs in 20% of treated children overall and in 47% of children treated for more at

**Figure 19-13** Pseudoporphyria. Large bulla in a child receiving peritoneal hemodialysis.

**Figure 19-12** Pseudoporphyria. Blisters and erosions on the face of a child with juvenile idiopathic arthritis taking celecoxib.

least 6 months<sup>96</sup>; a dosage of at least 6 mg/kg twice daily has also been associated with a higher risk of developing voriconazole-induced phototoxicity.<sup>97</sup> The eruption can be confused with graft-versus-host disease in these immunocompromised patients<sup>98</sup> and has been associated with a 4.6% risk of developing nonmelanoma skin cancer in areas that had a phototoxic reaction at a mean age of 15.5 years.<sup>96</sup>

Pseudoporphyria is a non-immunologically mediated phototoxicity reaction characterized clinically by increased cutaneous fragility, vesiculobullae, and histopathologic features similar to those of patients with porphyria, but levels of porphyrins are normal.<sup>99</sup> It has been described in approximately 11% of children taking NSAIDs, especially naproxen sodium (Fig. 19-12, for juvenile idiopathic arthritis<sup>100</sup>) and is especially common in patients with blue/gray eye color and fair skin.<sup>101</sup> The disorder has also been described in individuals receiving other NSAIDs,<sup>102</sup> dapsone, ciprofloxacin,<sup>103</sup> furosemide, imatinib,<sup>104</sup> metformin, nalidixic acid, tetracyclines, retinoids, amiodarone, and voriconazole.<sup>105</sup> A similar, if not identical, disorder has also been described in patients receiving hemodialysis (Fig. 19-13).<sup>106</sup>

A careful history and the presence of normal porphyrin levels in serum, erythrocytes, urine, and feces will generally establish the diagnosis. The cutaneous fragility tends to reverse rapidly upon withdrawal of the causative medication, but may only gradually reverse or even persist with new lesions for up to 1 month after discontinuation of the medication.<sup>107</sup> Pseudoporphyria associated with hemodialysis has responded to treatment with N-acetylcysteine or glutathione. Disfiguring facial scarring is a residua in some affected children.

#### PHOTOALLERGY

Photoallergy is relatively uncommon and presumably is a form of cell-mediated delayed hypersensitivity.<sup>108,109</sup> The individual must first be

sensitized to the allergen, which can require 7 to 10 days. When exposed to UV light, the light is absorbed by the photoantigen, which is thought to cause a change in the molecule. Instead of sunburn-type reactions, photoallergic responses are generally characterized by immediate urticarial or delayed papular or eczematous lesions that are not followed by hyperpigmentation. After the first sensitization, subsequent photoallergic reactions generally appear within 24 hours, even after very brief periods of exposure. Sunscreens with chemical components (especially benzophenones) are the leading cause because of their extensive use, although the risk of reaction with sunscreens containing these agents is less than 1% of that for allergic contact dermatitis.<sup>110,111</sup> In the past, children showed photoallergic reactions to salicylanilides (antimicrobial agents formerly in soaps but now only in industrial cleaners) and fragrances (musk ambrette, oil of bergamot). These chemicals are no longer used in personal products, but children or adolescents have been known to find a cologne with oil of bergamot, apply it to the skin, and develop berloque (berlock) dermatitis after UV exposure.<sup>112</sup> Promethazine hydrochloride cream and topical nonsteroidal anti-inflammatory agents have caused photoreactions.

Suspected photoallergic contact dermatitis may be confirmed by photopatch testing. Photopatch testing is similar to traditional testing for contact dermatitis (see Chapter 3), except that two sets of patch tests are placed on the back. Twenty-four hours later, one set is uncovered and irradiated with UVA light. The following day a comparison is made of the covered and irradiated sites. A positive test reproduces the clinical eczematous lesion at the phototest site. Therapy is treatment with topical anti-inflammatory agents and avoidance of exposure to the offending antigen.

#### Genetic Disorders Associated with Photosensitivity

Photosensitivity is a prominent feature of several genetic disorders, many of which are associated with defective DNA repair. Some of these are described elsewhere in this text, such as Kindler syndrome (see Chapter 13), trichothiodystrophy (see Chapter 7), and ataxiatelangiectasia (see Chapter 12).

#### XERODERMA PIGMENTOSUM

Xeroderma pigmentosum (XP) is a rare autosomal recessive disease characterized by cutaneous photosensitivity, a decreased ability to repair DNA damaged by UV radiation, and the early development of cutaneous and ocular malignancies.<sup>113,114</sup> The disorder is estimated to occur in one in a million individuals in the United States and Europe, and with an incidence in Japan as high as one in 40,000 persons. The risk of developing cutaneous malignancy does not diminish in patients

**Table 19-5** Subtypes of Xeroderma Pigmentosum

Gene/Protein	Protein Function	Incidence	Skin Disease	Neoplasia	Neurologic Change	Comments
XPA	Confirms damage	Especially in Japan	+++	+++	+ to +++	Lowest repair activity
XPB/ERCC3	Helicase	Very rare	++ to +++	+++	+++	CS (two kindreds) One case of TTD
XPC	Detects damage	Most common	++ to +++	++; melanoma	Rare	
XPD/ERCC2	Helicase	20% of cases	++	+	Late onset or none	Tremendous variability in phenotype; TTD; XP/CS
XPE/DDB2	Detects damage	Rare	+	Rare	None or mild	Mild phenotype
XPF/ERCC4	Nuclease	Fairly rare	++	Few to none	Usually none	
XPG/ERCC5	Nuclease	Very rare	+++	Few or none	Cockayne type	CS has been associated
XPV/POLH	Polymerase	30% of cases	++ to +++	Later onset	++ in a few

with darker skin types.<sup>115</sup> Historically, seven complementation groups (XPA through XPG) have been described based on *in vitro* cell fusion studies (Table 19-5), which are now recognized to correlate with mutations in specific genes whose products affect DNA repair.

The basic abnormality is an absence of a component of the nucleotide excision repair complex, a multistep mechanism that includes recognition of the UV light-induced DNA lesion, unwinding of DNA, and then resynthesis and ligation of the DNA. Complementation groups XPC and XPE recognize and bind to damaged DNA.<sup>116-118</sup> XPA may help to assemble the DNA machinery around the damaged DNA site. This binding signals the XPB and XPD proteins to unwind the DNA in the damaged region and to allow DNA transcription. The XPF and XPG nucleases cut the DNA and allow excision of the UV light-induced pyrimidine dimers. DNA repair rates may range from 0% to 50% of normal levels. A variant form has been described (XPV). In the variant group, postreplication repair is defective, but excision repair is normal. More than half of all cases in the United States are caused by mutations in the genes encoding XPC (XPC), XPD (ERCC2), or XPV (POLH), although mutations in the genes encoding XPA and XPF are more common in Japan than in the United States and Europe.

In 75% of cases the first signs appear between 6 months and 3 years of age. The presenting feature of this disorder is photosensitivity to UV light, primarily at wavelengths 290 to 340 nm, but this sunburn after minimal UV light exposure only occurs in 50% to 64% of patients and is not a feature of XP patients with mutations in XPC, XPE, or XPV.<sup>119,120</sup> The sunburn may be severe with vesicles and bullae (Fig. 19-14) and is often accompanied by photophobia with chronic conjunctivitis during the first months of life. The other 40% of cases do not show this sunburn reaction and instead tend to manifest initially with the lentigines (freckle-like pigmentation) that otherwise follow the early sunburns (Figs. 19-15 and 19-16). The skin ages prematurely with atrophy, telangiectasia, mottled hyper- and hypopigmentation, keratoses, and ulcerations, but not wrinkling; these observations likely reflect the sensitivity primarily to UVB rather than to UVA light, which is the primary cause of solar elastosis.<sup>113</sup> With continued exposure, the skin becomes xerotic, leading to the name XP. Areas of skin ordinarily protected by clothing remain relatively normal or may eventually show similar features, but to a lesser degree. Affected children resemble adults with severe actinic damage by early childhood.

Other issues are epithelial neoplasms, severe eye involvement, progressive neurologic degeneration in some patients, and malignancy.<sup>121</sup> Several tumors occur with increased incidence in XP (basal cell and squamous cell carcinomas, angiosarcoma, fibrosarcoma, atypical fibroxanthoma, keratoacanthoma, and melanoma) (Fig. 19-17).<sup>122,123</sup> In patients younger than 20 years of age with XP, the overall risk of developing basal cell and squamous cell carcinomas is 10,000 times that of the normal population (median age 9 years), and of melanoma 2000-fold greater (median age 22 years).<sup>119,124</sup> Interestingly, the melanomas in XP show a high rate of PTEN mutations (mammalian target of rapamycin [mTOR] pathway activation) rather than the typical RAS pathway activation, which may be important in considering choice of small molecule inhibitors.<sup>125</sup> The tendency to develop these

**Figure 19-14** Xeroderma pigmentosum. Sunburn after minimal sun exposure was the clue to diagnosis of xeroderma pigmentosum in a 9-month-old boy. Note the early freckling on the upper cheeks. This boy with XPA developed severe neurologic degeneration (DeSanctis-Cacchione syndrome) despite vigorous sun protection and no evidence of even a premalignant skin lesion by his mid-20s.

neoplasms is a function of exposure to UV light and the subtype of XP (see Table 19-5). The lower risk of developing skin cancer in patients who show early sunburns<sup>119</sup> may reflect the earlier recognition of XP and intense early photoprotection. These tumors and their therapy cause considerable facial distortion. Patients with XP also have an approximately 10- to 20-fold increase in internal malignancies, including of the brain, lungs, hematopoietic system, kidney, and gastrointestinal tract, which may reflect concomitant sensitivity to physical and chemical carcinogens, such as cigarette smoke.<sup>119,126</sup> Although skin cancer is the most common cause of death (34%), internal cancer leads to death of 17% of patients.<sup>119</sup>

Patients also have an increased risk of developing carcinomas of the anterior portion of the tongue<sup>127</sup> and may show leukoplakia.<sup>126,128</sup> The ocular manifestations largely involve the anterior part of the eye that is exposed to UV light.<sup>129</sup> By 3 years of age, most patients show blepharitis, symblepharon, and crusts of the palpebral margins. With

**Figure 19-15** Xeroderma pigmentosum. Note the many black-colored facial lentigines, which should raise concern about the possibility of xeroderma pigmentosum.

**Figure 19-16** Xeroderma pigmentosum. Despite total avoidance of ultraviolet light after diagnosis at 2 years of age, this adolescent boy showed extensive pigmentary changes.

continuing UV light exposure, affected individuals show conjunctival melanosis, scarring, atrophy, entropion or ectropion, trichiasis (irritation caused by the eyelashes), and at times loss of the lower lid. Ocular surface cancer develops in 10% of patients. Corneal opacities and ulcerations, and choroidal melanomas have been described.<sup>130</sup>

Neurologic complications develop in approximately 30% of patients (termed the *DeSanctis–Cacchione syndrome*), most commonly in the XPA group,<sup>131</sup> but also with XPB, XPD, and XPG. These may include microcephaly with developmental delay, poor growth and sexual development, choreoathetosis, hyporeflexia, cerebellar ataxia, and sensorineural deafness. These neurologic changes may have their onset in infancy but may not occur in some patients until the second decade of life. Testing of deep tendon reflexes and routine audiometry are good screening studies.<sup>132</sup> In this subset, it is the neurologic degeneration that leads to death of patients (cause of death in 31% of all patients with XP), and at an earlier age (median age of death with neurodegeneration is 37 years vs. 29 years without neurodegeneration).<sup>119</sup>

**Figure 19-17** Xeroderma pigmentosum. Severe actinic damage in an 18-year-old girl with inadequate sun protection. Note the scarring from removal of several basal cell carcinomas, beginning at 10 years of age.

The neurologic abnormalities and photosensitivity may be seen in individuals with the XP/Cockayne syndrome (CS) overlap (see [Cockayne Syndrome](#) section).<sup>133,134</sup> DNA excision repair defects and UV light hypersensitivity are also seen in a subset of patients with trichothiodystrophy (photosensitivity, ichthyosis, brittle hair, intellectual impairment, decreased fertility, and short stature [PIBIDS]; see Chapter 7).<sup>113</sup> Patients with trichothiodystrophy do not show an increased risk of developing skin cancer, although the reason for this distinguishing feature is unclear. XP and trichothiodystrophy may also coexist.<sup>135</sup>

Suspicion of the diagnosis of XP is made through clinical observation. In the past, confirmation involved UV light sensitivity and DNA repair assays, but genetic analysis is now the preferred testing for confirmation and subtyping, which cannot be determined by clinical features alone. Whole exome sequencing has recently been performed<sup>136</sup> and has the advantage of analyzing the presence of mutation in all possible genes simultaneously. Immunohistochemistry of paraffin-embedded skin sections is a simple way to show absence of XPC.<sup>137</sup> Given the founder mutation in XPA in Japan, rapid genetic analysis for this mutation can easily be performed in individuals of Japanese descent.

All patients with XP require strict lifelong sun protection, including total sun avoidance, application of sunscreens that protect throughout the UVB and UVA spectrum, UV-light shields over windows, sun-protective clothing (a sun suit designed by the National Aeronautics and Space Administration [NASA] is also available), broad-rimmed hats, and sunglasses.<sup>138</sup> Methylcellulose eye drops should be applied to keep the corneas moist, and soft contact lenses should be worn to protect against mechanical trauma in individuals whose eyelids are severely deformed. Corneal transplantation may be required for patients with severe keratitis and corneal opacity. All patients should be given vitamin D supplementation, given the sun avoidance.<sup>139</sup> Patients should avoid cigarette smoke and other environmental carcinogens. Surveillance for skin cancer by dermatologists and ocular complications by ophthalmologists is imperative.

Individual premalignant and malignant tumors should be treated by cryosurgery, application of topical 5-fluorouracil or imiquimod cream,<sup>140,141</sup> and use of these treatments for 3 weeks every 3 to 6 months starting during childhood has been advocated as

prophylaxis.<sup>138</sup> Other interventions are intralesional interferon- $\alpha$ , or surgical removal as appropriate for the neoplasm.<sup>142</sup> Dermabrasion, laser resurfacing, and phenol-based peeling of skin with actinic damage have been helpful in reversing the pigmentary changes.<sup>143,144</sup> High-dose oral isotretinoin decreases the incidence of new skin cancers, but withdrawal of therapy results in reversal of its chemoprophylactic effect.<sup>145</sup> "Readthrough" of premature termination codons by aminoglycosides to restore DNA repair<sup>146</sup> and targeted repair of XPC mutations using transcription activator-like effector (TALE) nucleases<sup>139</sup> have been recently been shown as potential future interventions. XP has been diagnosed prenatally by showing DNA-repair defects in cultured amniotic fluid cells and by DNA analysis. Support groups for families with XP include the XP Society ([www.xps.org](http://www.xps.org)); XP Family Support Group ([www.xpfamilysupport.org](http://www.xpfamilysupport.org)), and the XP Support Group ([www.xpsupportgroup.org.uk](http://www.xpsupportgroup.org.uk)). A camp for families with XP (Camp Sundown) engages affected individuals and their families in daytime indoor activities and outdoor activities at night.

## COCKAYNE SYNDROME

Cockayne syndrome (CS) is a recessively inherited disorder caused by defects in repair of actively transcribed DNA, either ERCC8 (excision-repair cross complementing group 8; CSA) or more commonly ERCC6 (CSB).<sup>147-150</sup> A spectrum of severity for individuals with CS (classified as CS I, II, and III) or its variants (cerebrooculofacioskeletal syndrome [COFS] and UV-sensitive syndrome [UVSS]) has been described and modified criteria have been proposed (Box 19-1).<sup>150</sup> Arthrogryposis and congenital kyphosis are specific features of COFS. Whereas affected individuals with COFS and CS II show features from birth (e.g.,

### Box 19-1 Diagnostic Features and Subclassification in Order of Severity of Cockayne Syndrome and Its Variants

#### Major

Developmental delay  
Progressive microcephaly  
Progressive growth failure

#### Minor

Cutaneous photosensitivity  
Progressive sensorineural hearing loss  
Pigmentary retinopathy/cataracts  
Enophthalmia  
Enamel hypoplasia

Major criteria are required for diagnosis of CS I, CS II, and CS III in addition to at least 3 minor criteria.

#### COFS

Most severely affected:  
Death by infancy

#### CS II

Signs present at birth  
Fulfils diagnostic criteria by infancy  
Death usually 5 to 6 years of age

#### CS I

Signs first present by 2 years of age  
Fulfils diagnostic criteria during childhood  
Death usually in late teenage years

#### CS III

Signs first present at 3 to 4 years of age  
Fulfils diagnostic criteria by early teens  
Death usually at about 30 years of age

#### UVSS

Only presents with photosensitivity  
Survival is likely normal

COFS, Cerebrooculofacioskeletal syndrome; CS, Cockayne syndrome; UVSS, UV-sensitive syndrome.

weak cry, axial hypotonia, and peripheral hypertonia), other children with CS have no signs until infancy or even childhood, but retardation, microcephaly, deafness, and loss of developmental progress are progressive. COFS and CS II most commonly result from mutations in CSB, while most individuals with CSA mutations have a later onset and less severity.

The most common cutaneous change is photosensitivity, a feature in at least 75% of patients. Photosensitivity manifests as sunburn after brief exposure and may occur even after exposure through a windshield.<sup>151</sup> Within the spectrum, however, are patients without photosensitivity<sup>152</sup> or with photosensitivity but no other features (UVSS). Despite the photosensitivity, CS is not associated with sun-induced pigmentation or malignancy. Although this light sensitivity eventually disappears, erythema with telangiectasias characteristic of photosensitivity, mottled pigmentation, scarring, and atrophy of these sites remain as prominent features. Acral cyanosis and edema are another feature seen in about 75% of patients, and nail dystrophy (often subtle), hair abnormalities (sparse, thin, dry and/or pseudo "tiger-tail" appearance), and hypohidrosis have also been described. Associated pruritus without skin inflammation is not uncommon and may be the presenting feature to a dermatologist. Loss of subcutaneous fat and cachectic wasting produces a "bird-like" facies with sunken eyes (Fig. 19-18, A). Patients show a tendency toward progressive ataxia, long limbs in proportion to body length, quick bird-like movements, disproportionately large hands and feet, progressive contractures of the joints, and large protruding ears. A characteristic "salt and pepper" pigmentary retinopathy has been described; optic atrophy and cataracts are not uncommon. Mental retardation can be severe. Affected individuals are generally below the third percentile for height and weight. Other abnormalities may include thickened skull bones and intracranial calcification, especially of the basal ganglia, elevated transglutaminases, and renal disease.

There is no effective treatment for patients with this disorder, and most patients die by the third decade of life as a result of arteriosclerotic vascular disease, profound neurologic deterioration, or both. Patients with CS show defective DNA repair and hypersensitivity to UV light, which accounts for their photosensitivity.<sup>134,153</sup> Patients with CS show spasticity, ataxia, and peripheral neuropathy from demyelination, in contrast to neuronal degeneration in patients with XP. However, patients have been described with features of both XP and CS.<sup>133,154</sup> These patients usually have mutations in a different gene, ERCC5 (XPG), but occasionally in XPB or XPD. They show the short stature, sexual immaturity, and retinal pigmentation of CS, are sensitive to UV light, and develop the pigmentary abnormalities of XP, but not the cutaneous malignancy (Fig. 19-18, B). Administration of daily niacin in a patient with XP/CS led to a dramatic photoprotective effect both clinically and in cultured fibroblasts, reminiscent of improvement in patients with pellagra.<sup>155</sup>

## ROTHMUND–THOMSON SYNDROME

Rothmund–Thomson syndrome is an autosomal recessive disorder that occurs twice as often in boys than in girls.<sup>156</sup> Cutaneous features are seen in the first 2 years and often by 3 to 6 months of age. Most common are diffuse erythema and, at times, edema and vesication of the cheeks, forehead, chin, ears, buttocks, and extensor surfaces of the arms and legs, but sparing of the trunk. As the erythema resolves, the skin begins to show a reticulated pattern of telangiectasia, alterations in pigmentation (both hypopigmentation and hyperpigmentation), and areas of atrophy (poikiloderma) that progress until approximately 3 to 5 years of age (Fig. 19-19). Occasionally affected individuals are born with poikiloderma or develop poikiloderma after the first year of life. Children may develop bullae after sun exposure or spontaneously; this tendency appears to subside as patients grow older. Approximately 30% of patients develop verrucous hyperkeratoses on the hands, feet, knees, and elbows later in childhood or during adolescence. Although photosensitivity is a feature of many cases and exposure to sunlight may extend the distribution of the eruption, UV light is unlikely to be the sole cause of the poikiloderma, since it may be found before UV light exposure and also appears on unexposed areas. Adults with the disorder show an increased risk of development of squamous cell carcinomas at sites of the keratotic

(A)

(B)

**Figure 19-18** (A) Cockayne syndrome II. Note the typical facial features with enophthalmia, microcephaly, and protruding ears as well as growth failure in this 7-year-old girl with mutations in *ERCC6* (CSB). (B) Xeroderma pigmentosum/Cockayne syndrome caused by mutations in *ERCC5* (XPG). Note the facial features of CS but the sun-induced lentigines and photophobia of XP.

and atrophic lesions; melanoma and porokeratosis have also been associated.<sup>157,158</sup>

Patients are commonly short, and most show a history of low birth-weight and length as well as severe growth failure. Some have a characteristic facies with saddle nose, frontal bossing, wide forehead, and narrow chin, giving a triangular configuration to the face. Hypotrichosis with sparse or absent eyebrows or eyelashes (and sometimes involvement of the scalp, face, and body hair) occurs in 50% of patients, and premature graying has been reported. Nail dystrophy has been described in about 30% of patients, and dental abnormalities, caries, and periodontitis in almost 40%.<sup>159</sup>

Cataracts occur in about 6% to 40% of reported cases,<sup>156</sup> generally as bilateral anterior or posterior subcapsular opacities that evolve

**Figure 19-19** Rothmund–Thomson syndrome. Reticulated pattern of telangiectasia and both hypopigmentation and hyperpigmentation on the cheek and ear. (Courtesy of Sarah Chamlin, MD.)

rapidly. Although they are first noted between 3 and 7 years of age in most patients, they have been described in an infant at 4 months of age and may appear as late as 40 years of age. Hypogonadism occurs in one-quarter of patients (female patients may be amenorrheic; male patients may have undescended testes).

Defective bone development is a common characteristic that occurs in up to two-thirds of affected individuals. Most common are absence or hypoplasia of the thumbs, radius, and occasionally the ulna; brachymetacarpophalangy; syndactyly; clinodactyly; and fusion or agenesis of carpal and tarsal bones.<sup>160</sup> Both hyperostosis and osteoporosis with fractures have been described. Osteosarcoma has been described in 32% of patients, approximately half before 15 years of age, and most commonly affects the tibia or femur.<sup>156,161,162</sup> Surveillance for bone pain, swelling, or an enlarging lesion on a limb suggesting a tumor is important. Because of the risk of osteosarcoma, baseline radiologic evaluations of long bones are recommended by 3 years of age. Several other malignancies, aplastic anemia, and myelodysplasia have been described less commonly.<sup>163</sup>

Laboratory tests are usually normal, including assays of unscheduled DNA repair, increased sensitivity to alkylating agents such as mitomycin C, and chromosomes. Mutations in *RECQL4* have been found in 40% to 66% of affected patients<sup>164</sup> and have been associated with an increased risk of developing osteosarcoma.<sup>165</sup> *RECQL4* encodes a DNA helicase that is important for DNA replication, repair of UV light-induced DNA damage, and telomere maintenance.<sup>166,167</sup> Mutations in *RECQL4* also cause RAPADILINO and Baller–Gerold syndromes. RAPADILINO (radial hypoplasia, patellar hypoplasia/aplasia, cleft or high arched palate, diarrhea, dislocated joints, little size and limb malformations, slender nose, and normal intelligence) syndrome is associated with the osteosarcoma risk but not the poikilodermatous changes.<sup>168</sup> Baller–Gerold syndrome prominently features numerous bony defects and the risk of osteosarcoma, but the onset of poikiloderma is later and cataracts have not been described.

The early onset and noncutaneous features allow Rothmund–Thomson syndrome to be distinguished from other disorders with poikiloderma that are not related to *RECQL4* mutations (dyskeratosis congenita, Kindler syndrome, poikiloderma with neutropenia, hereditary sclerosing telangiectasia, Bloom syndrome, Fanconi anemia, XP, and nonhereditary disorders—chronic juvenile dermatomyositis and cutaneous T-cell lymphoma).<sup>169</sup> Any patient with poikiloderma deserves initial evaluation for neutropenia, which can distinguish patients with poikiloderma with neutropenia (Clericuzio type), another autosomal recessive genodermatosis resulting from mutations in the *C16orf57* gene.<sup>170–172</sup>

Individuals with the Rothmund–Thomson syndrome have a normal life span, although the development of cancer may lead to premature death in some patients. The poikiloderma and facial telangiectasia have been treated successfully with laser. Cataract extraction may be necessary.

### BLOOM SYNDROME

Bloom syndrome (congenital telangiectatic erythema) is a rare autosomal recessive disorder characterized by a triad of telangiectatic erythema, photosensitivity, and severe intrauterine and postnatal growth retardation.<sup>173</sup> Some 80% of affected children are male, and 50% are of Ashkenazi Jewish ancestry; the carrier rate among Ashkenazi Jews is 1 in 110 individuals. The disorder results from mutations in *BLM* (or *RECQL2*), a helicase of the RecQ family that participates in normal DNA replication.<sup>174</sup>

Affected patients are born at term with reduced body weight and size.<sup>175</sup> They have small, narrow faces with a prominent nose and ears, and the voice is high-pitched. Although physical growth is stunted, intellectual and sexual development is normal. Erythema of the cheeks in a butterfly distribution, often resembling lesions of lupus erythematosus, appears between the second and third week of life, and typically spreads with exposure to sunlight to involve the nose, eyelids, forehead, ears, and lips. The trunk, buttocks, and lower limbs tend to be spared. Although this light sensitivity eventually disappears, erythema, telangiectasia, mottled pigmentation, scarring, and atrophy of these sites remain as prominent features. Café-au-lait spots and areas of hypopigmentation have been described, especially on the trunk. Patients may show dolichocephaly, polydactyly, clinodactyly, syndactyly, cryptorchidism, shortened lower extremities, and clubbed feet.

Patients often have vomiting and diarrhea during infancy, which may be associated with gastrointestinal infections. The tendency toward recurrent respiratory infections increases the risk of chronic lung disease, the second most common cause of death in patients with Bloom syndrome. With increasing age, however, resistance to infection increases. Diabetes has been noted in 12% of patients<sup>176</sup>; men with Bloom syndrome are usually sterile, and women have reduced fertility.

Of the affected individuals, 20% develop malignancy, most commonly leukemia, at a mean age of 16 years. Lymphomas and leukemias occur 150 to 300 times more often than in normal individuals.<sup>177</sup> Solid tissue tumors of a wide variety of tissues, most commonly Wilms tumor, lymphosarcoma, and carcinomas of the oral mucosa and gastrointestinal tract, are seen at a mean age of 30 years in older, surviving individuals. Wilms tumor and osteosarcoma, however, have been described in the first decade of life. Decreased levels of IgG, IgM, and IgA, dysfunctional helper T cells, and abnormal delayed hypersensitivity have been described and may be related to defective lymphocyte maturation.

The diagnosis of Bloom syndrome can be confirmed by cytogenetic analysis. Patients have a high incidence of chromosomal breakage, sister chromatid exchanges, and quadriradial configurations.

Although there is no specific treatment, avoidance of sun exposure and protection by sunscreens can help prevent some of the cutaneous eruptions associated with photosensitivity. Appropriate antibiotics for gastrointestinal and respiratory tract bacterial infections are commonly helpful in the management of patients with this disorder. Because life expectancy is shortened by malignancy, periodic evaluation for possible neoplastic disease is advisable; however, exposure to ionizing radiation in screening tests should be minimized.<sup>178,179</sup>

### SMITH–LEMLI–OPITZ SYNDROME

Photosensitivity is a feature of Smith–Lemli–Opitz syndrome, an autosomal recessive disorder that results from mutations in the sterol Δ-7-reductase gene, part of the pathway of cholesterol biosynthesis.<sup>180</sup> This syndrome occurs in 1:20,000 births in populations of northern and central European origin. Hypospadias is a prominent feature, so Smith–Lemli–Opitz syndrome is more easily recognized in males. Other features are mental retardation, abnormal sleep

patterns, microcephaly, short or proximally placed thumbs, and congenital cardiac abnormalities, most commonly atrioventricular septal defect. Patients show a typical facies, and 80% show syndactyly of the second and third toes. Severe photosensitivity has been described in 57% of affected individuals<sup>181</sup> and typically occurs within minutes after exposure to UVA light.<sup>182,183</sup> Objective improvement in the photosensitivity has been demonstrated after supplementation with cholesterol.<sup>184</sup>

### HARTNUP DISEASE

Hartnup disease is a rare autosomal recessive, light-sensitive disorder characterized by a pellagra-like cutaneous eruption, neurologic abnormalities, and a specific aminoaciduria (caused by a defect in the cellular transport of a group of monoamino-monocarboxylic acids). The basic defects appear to be a failure in the absorption of tryptophan from the gastrointestinal tract and a renal tubular defect causing inadequate reabsorption of amino acids, including tryptophan. These result in reduced levels of available tryptophan and, accordingly, nicotinic acid, which in turn may be responsible for the pellagra-like photosensitivity. The condition results from mutations in *SLC6A19*,<sup>185</sup> which encodes the neutral amino acid transporter BOAT1.<sup>186</sup>

The biochemical defect (aminoaciduria) is a constant feature of Hartnup disease. Clinical manifestations, however, are intermittent, recurrent, and quite variable. The cutaneous eruption usually appears in the spring and summer. It may be present in early childhood, occasionally during early infancy and, when present, is usually seen in children between 3 and 9 years of age. The cutaneous manifestations consist of a symmetric distribution of erythematous macules that tend to coalesce and eventuate in well-margined red scaling lesions over light-exposed parts of the face, neck, uncovered areas of the arms, inframammary and perineal folds, elbows, knees, dorsal aspects of the hands, wrists, and lower legs. Once these lesions appear, they usually persist for weeks or months.

Acute dermatitis and blistering with secondary crusting and scarring frequently occur following sun exposure. These changes, together with marked postinflammatory hyperpigmentation, are similar to the findings seen in pellagra. Malnutrition and intercurrent infections frequently aggravate the dermatitis. Glossitis, angular stomatitis, vulvovaginitis, diffuse hair loss and fragility, and nail abnormalities (longitudinal streaking) may also be seen. In many patients, the cutaneous manifestations become milder with advancing age and subsequent sun exposure. Hartnup disease with cutaneous manifestations resembling acrodermatitis enteropathica has also been described.<sup>187</sup>

Cerebellar ataxia is the predominant neurologic feature of Hartnup disease. Seen in more than two-thirds of those affected by this disorder, the ataxia seems to occur during periods when the rash is most prominent or after acute episodes of febrile illness. The gait is broad-based and unsteady, and patients have both nystagmus and an intention tremor. Ocular abnormalities include diplopia and ptosis, and some patients have mental retardation, emotional lability, or frank psychosis.

The diagnosis of Hartnup disease is based on the clinical picture and demonstration of specific amino acid and indole excretion patterns (not the total amino acid excretion). Treatment consists of avoidance of sunlight exposure and prolonged oral administration of high doses (40 to 200 mg) of nicotinic acid or nicotinamide. Because nicotinamide does not cause the flushing generally associated with administration of nicotinic acid, the former is generally the drug of choice. Although the eruption and ataxia seem to improve when patients are adhering to this regimen, assessment of therapy is difficult because the natural history of the disorder is one of spontaneous remission and exacerbation.

### Pellagra

Pellagra is a systemic disturbance caused by a cellular deficiency of niacin resulting from inadequate dietary intake of niacinic acid or its precursor (tryptophan) or the ingestion of certain antinicotinic substances, such as phenytoin and isoniazid.<sup>188,189</sup> Niacin is required for the biosynthesis of ceramides and other stratum corneum lipids.

Given the supplementation in foods and vitamins, pellagra rarely occurs except in countries where nutritional deficiency is common.<sup>190</sup> However, it has been described in adolescents with anorexia nervosa, children with malabsorption syndromes, and individuals maintained on diets high in corn<sup>191</sup>; it is more commonly seen in people with chronic alcoholism and malnourished homeless persons.

The disorder is characterized by seasonal recurrences and a classic triad of dermatitis, diarrhea, and dementia.<sup>192</sup> The onset of the disorder, however, may be heralded by weakness, loss of appetite, abdominal pain, mental depression, and photosensitivity. In later stages, nervous symptoms may predominate to such a degree that the cutaneous lesions may be overlooked. These include delirium, dementia, posterolateral spinal cord degeneration, and pyramidal and peripheral nerve involvement.

The most prominent cutaneous lesions of pellagra are precipitated by the sun and, although not always present, begin as asymptomatic or pruritic symmetric erythematous scaling macules on areas exposed to sunlight, heat, friction, or pressure. The usual sites of involvement include the face, neck, dorsal surface of the hands, arms, feet, inguinal region, and, particularly in infants and small children, the diaper area. The eruptions begin as well-margined erythema and superficial scaling on sun-exposed areas resembling sunburn (with or without vesiculation or blister formation) that gradually subside, leaving a dusky brown-red discoloration. In acute cases the lesions may progress to vesiculation, ulceration, exudation, cracking, and, at times, secondary infection. With chronicity, lesions become more livid, thickened, scaly, and ultimately fissured, atrophic, and deeply pigmented. On the lower neck the eruption may appear as a broad collarette of dermatitis known as *Casal's necklace*. In cases in which the "necklace" is incomplete, the lesions maintain their symmetric and otherwise characteristic appearance. The nose has a fairly distinctive appearance with a dull erythema of the nasal bridge, slight scaling, and a powdery appearance. Mucous membrane involvement, when present, consists of painful fissures and ulceration. The lips and cheeks are thin and pale, the mouth is dry, and the tongue is red, swollen, and, at times, darkened (the so-called *black tongue*). Aphthous ulcers, fissuring, and angular cheilitis are also common.

When the diagnosis is suspected, measurement of the urinary excretion of N<sub>1</sub>-methylnicotinamide and/or pyridone (metabolites of

niacin) is helpful. Treatment of pellagra consists of a high-protein diet and nicotinic acid or nicotinamide in dosages of 100 to 400 mg/day supplemented by vitamin B complex. If a good diet can be maintained, complete recovery is the rule. The disease tends to be progressive and if untreated, may eventuate in death within several years.

## The Porphyrias

The porphyrias comprise a group of disorders of porphyrin, the chemical precursor for hemoglobin synthesis<sup>26,193-196</sup> (Table 19-6). Porphyrins, the only well-established photosensitizers made by the human body, are excited by visible light at the wavelengths 400 to 410 nm (Soret band) and emit a red fluorescence. When exposed to this wavelength in the presence of oxygen, porphyrins release energy that reacts with the oxygen to generate free radicals and singlet oxygen that causes damage to cells and tissues. β-Carotene quenches free radicals and singlet oxygen and thus may lessen the damage.

Two phenotypic patterns of phototoxicity are seen in patients with porphyria: the immediate effects characterized by pain, edema, erythema, and purpura; and the delayed effects, consisting of blistering and scarring. There are three main categories of porphyric disease in humans: erythropoietic, hepatic, and mixed, with mutations recognized in genes encoding ten enzymes of the heme biosynthetic pathway (Table 19-7). The erythropoietic porphyrias are divided into erythropoietic porphyria (autosomal recessive) and erythropoietic protoporphyrinia (EPP; autosomal dominant and less often autosomal recessive or X-linked dominant); the hepatic porphyrias include acute intermittent porphyria (AIP), porphyria cutanea tarda (PCT), hereditary coproporphyria, and variegate porphyria. Hepatoerythropoietic porphyria is a mixed form. Cutaneous findings are not a feature of δ-aminolevulinate dehydratase deficiency porphyria or AIP.<sup>26</sup> A distinctive, transient purpuric eruption, limited to areas exposed to blue light, has been described in transfused neonates with hyperbilirubinemia;<sup>197</sup> elevated levels of protoporphyrins and coproporphyrins were detected in plasma (Fig. 19-20). The American Porphyria Foundation offers patients information and support ([www.porphyriafoundation.com](http://www.porphyriafoundation.com)).

**Table 19-6** Pathway of Porphyrin Heme Biosynthesis, Enzyme Defects, and Disease

Metabolites	Enzyme	Type of Porphyria
Glycine + succinyl-CoA ↓	δ-Aminolevulinic acid synthase (ALA synthase) 1 and 2	X-linked (ALAS2, erythroid-specific)
δ-Aminolevulinic acid ↓	ALA dehydratase	ALA dehydratase
Porphobilinogen (PBG) ↓	PBG deaminase	Acute intermittent
Hydroxymethylbilane ↓	Uroporphyrinogen III synthase	Congenital erythropoietic
Uroporphyrinogen III ↓	Uroporphyrinogen decarboxylase	Porphyria cutanea tarda/ hepatocerebral
Coproporphyrinogen III ↓	Coproporphyrinogen oxidase	Hereditary coproporphyria
Protoporphyrinogen IX ↓	Protoporphyrinogen oxidase	Variegate
Protoporphyrin IX ↓	Ferrochelatase	Erythropoietic protoporphyrinia
Heme ↓		
Cytochromes, hemoglobin, and myoglobin		

**Table 19-7** Types of Porphyria

Type of Porphyria	Inheritance	Enzyme Deficiency	Photosensitivity	Scarring	Hypertrichosis	Other
<b>ERYTHROPOIETIC</b>						
Erythropoietic porphyria (EP)	AR XLR	Uroporphyrinogen III synthase (UROS); GATA binding factor 1 (GATA1)	+++	+++	+	Erythrodontia, splenomegaly, hemolysis, bone fragility
Erythropoietic protoporphyrinia (EPP)	AD/AR XLD	Ferrochelatase; δ-Aminolevulinic acid synthase, erythroid-specific (ALAS2)	++	+	±	Cholelithiasis, anemia, liver failure, marked skin burning or stinging
<b>HEPATIC OR COMBINED</b>						
Acute intermittent porphyria (AIP)	AD	Porphyrinogen deaminase	-	-	-	Acute abdomen and neuropsychiatric
Porphyria cutanea tarda (PCT)	AD	Uroporphyrinogen decarboxylase	++	++	+++	Milia
Hereditary coproporphyria (HCP)	AD	Coproporphyrinogen oxidase	+	+	+	Jaundice and anemia in the newborn (harderoporphyria); Acute abdomen and neuropathy
Variegate porphyria (VP)	AD	Protoporphyrinogen oxidase	+++	++	+	Acute abdomen
δ-Aminolevulinic acid dehydratase porphyria (ALAD porphyria)	AR	δ-Aminolevulinic acid dehydratase	-	-	-	Acute abdomen and neuropsychiatric
Hepatoerythropoietic porphyria (HEP)	AR	Uroporphyrinogen decarboxylase	+++	++	+	Erythrodontia, splenomegaly, anemia

AD, Autosomal dominant; AR, autosomal recessive; XLD, X-linked dominant; XLR, X-linked recessive.

**Figure 19-20** Purpuric phototherapy-induced eruption. Dramatic purpuric eruption at the areas of maximal blue light exposure in a baby with elevated plasma levels of protoporphyrins and coproporphyrins. The baby had been transfused for Rh incompatibility and treated for hyperbilirubinemia. Note the sparing at the site of lead placement.

### Congenital Erythropoietic Porphyria

Erythropoietic porphyria (congenital erythropoietic porphyria [CEP], Günther disease) is very rare.<sup>198</sup> It is characterized by the appearance of red urine during infancy (Fig. 19-21), severe photosensitivity that occurs in the first 2 or 3 years of life, splenomegaly, and hemolytic

**Figure 19-21** Congenital erythropoietic porphyria. The diaper of an affected baby demonstrates the red color of urine.

anemia.<sup>199</sup> Hemolysis *in utero* may present as hydrops fetalis, but 76% show manifestations by 5 years of age and 41% have at least one manifestation at birth.<sup>198</sup>

Photosensitivity is commonly absent in the neonatal period but generally becomes apparent during the first years of life as exposure to the sun increases. Phototherapy during the neonatal period for hyperbilirubinemia may lead to generalized blistering.<sup>200</sup> Rarely, the disorder is first manifested later in childhood or even adulthood.<sup>201</sup> Recurrent

**Figure 19-22** Congenital erythropoietic porphyria. Vesicles, bullae, and crusts on sun-exposed areas.

**Figure 19-23** Congenital erythropoietic porphyria. Brownish teeth that fluoresce under Wood lamp examination.

eruption of vesicles and bullae on sun-exposed areas of the skin (Fig. 19-22), filled with fluid that fluoresces pink, eventually results in mutilating ulceration, scarring, and loss of acral tissues, such as the ears, tip of the nose, eyelids, distal phalanges, and nails. Other common clinical features include hypertrichosis of the face and extremities and hyperpigmentation. The legendary werewolves of the Middle Ages, with fluorescent teeth and nails, mutilated and deformed ears, nose, and eyelids, and nocturnal habits due to their sensitivity to light, may have been persons afflicted with CEP. Asymptomatic pink hamartomatous papules of the perioral and perinasal area have been noted in several patients.<sup>198</sup>

The teeth are a pink to brown color (Fig. 19-23) and fluoresce under Wood lamp examination, because porphyrins bind to dental calcium phosphate. True erythrodontia of porphyria should not be confused with the pseudoerythrodontia of children with poor dental hygiene, which relates to overgrowth of fluorescent bacteria and can be removed. Microstomia, gingival recession, caries, and overcrowding of teeth are other features. Patients show a variety of ocular abnormalities that may lead to blindness, including photophobia, corneal scarring, ulceration, keratoconjunctivitis, and cataracts. The majority of patients have hemolytic anemia with associated splenomegaly. Neonatal jaundice, abnormal hepatic transaminases and hepatomegaly are sometimes reported, and pancytopenia has been described. Bone fragility results from the expansion of the bone marrow, although porphyrins may also be directly toxic to bone. The color of the urine of patients may vary from faint pink to burgundy or port wine, depending on the concentration of uroporphyrin.

The biochemical disturbance is a deficiency of the enzyme uroporphyrinogen III synthetase (UROS), resulting in marked overproduction of uroporphyrin I and coproporphyrin I in circulating erythrocytes, bone marrow cells, plasma, urine, and feces. The severity of the CEP is greater in patients who have heterozygous mutations

in ALAS2 (erythroid-specific mitochondrial 5-aminolevulinate synthase; see *Erythropoietic Protoporphyria* section).<sup>202</sup> Although most patients have biallelic mutations in UROS, mutation in the gene encoding GATA binding factor 1 (GATA1) can also cause CEP as an X-linked recessive disorder.<sup>203</sup> GATA1 is transcription factor that regulates the expression of UROS in developing erythrocytes but also is critical for normal erythropoiesis, globin gene expression, and megakaryocyte development. Affected children show thrombocytopenia, anemia that more closely resembles thalassemia, and dramatic increases in fetal hemoglobin (HbF). Wood light examination in patients with CEP may reveal reddish-orange porphyrin fluorescence in urine or aqueous suspensions of feces and thin smears of peripheral erythrocytes glow red under a fluorescent microscope. Patients (with UROS mutations) have normochromic anemia with elevated reticulocyte levels, circulating normoblasts, and normoblastic hyperplasia of the bone marrow.

The prognosis of CEP is poor in severe cases unless treated successfully by transplantation, with few patients surviving into the fourth or fifth decade of life.<sup>204,205</sup> Death, when it occurs, is often associated with hemolytic anemia. Bone marrow and allogeneic stem-cell transplantation may correct all disease manifestations except the erythrodontia.<sup>206</sup> Avoidance of light at wavelengths less than 510 nm markedly diminishes the cutaneous manifestations, anemia, and splenomegaly. This includes protection from light through window glass (including blinds and window filters that decrease the relevant visible spectrum), wearing protective clothing, and use of opaque sunscreens that block a broader spectrum. DHA, a component of sunless tanning agents, can block the visible light.<sup>207</sup> Ophthalmologic intervention with eye lubricants and topical antibiotics, dental management, and administration of supplemental vitamin D and bisphosphonates as needed for osteoporosis is important. Splenectomy for the hemolysis and chronic transfusion regimens to suppress bone marrow activity are variably successful. Surgical reconstruction has decreased the progressive disfigurement from ectropion, microstomia, and nasal deformity.<sup>205,208</sup> Prenatal diagnosis is possible by analysis of amniotic fluid and cells, and *in vitro* gene therapy for patients without a suitable transplant donor has been performed. Mild cases can be managed by avoiding sun exposure and trauma, as well as transfusions to suppress porphyrin overproduction.

### Erythropoietic Protoporphyria

Erythropoietic protoporphyrin (EPP), the most common form of porphyria in children, results from the combination of loss-of-function mutations of *FECH*, the gene encoding mitochondrial ferrochelatase, and on the other allele a polymorphism carried by 10% of Western Europeans in the noncoding region (IVS3-48T>C) of *FECH*.<sup>209–211</sup> Levels of ferrochelatase, which accelerates the incorporation of iron into protoporphyrin, are only 15% to 25% of normal levels in EPP. Although the disorder is autosomal dominant, parent-to-child transmission of overt disease is uncommon. Having polymorphisms on both alleles does not cause disease; however, true autosomal recessive disease with loss-of-function mutations on both alleles of *FECH* occurs in about 3% to 5% of affected individuals and may be associated with EPP.

X-linked (dominant) protoporphyrin (XLP) is a phenocopy of EPP and results from gain-of-function mutations in the X-linked erythroid-specific 5-aminolevulinate synthase (ALAS2) gene, which is essential for hemoglobin formation.<sup>212</sup> The incidence of XLP is 10% of that of EPP from *FECH* mutations in North America and even less in Western Europe.<sup>213</sup> Males with XLP have twofold higher erythrocyte protoporphyrin levels than patients with EPP, increasing their risk of photosensitivity and liver disease.

The common subtlety of clinical signs and symptoms and the absence of increased levels of protoporphyrin in urine (because of the relative insolubility of this porphyrin in water) may lead to failure of recognition of EPP. Nevertheless, the disease usually becomes symptomatic between 1 and 6 years of age because of photosensitivity.<sup>214</sup> The condition may be detected during infancy because the baby cries after brief exposure to sunlight. It manifests acutely from early spring to late summer as burning, stinging, or itching of the exposed skin after 5 to 30 minutes of sunlight exposure.<sup>215</sup> This burning sensation may be followed by pruritic reddened edematous plaques that

**Figure 19-24** Erythropoietic protoporphyrin (EPP). Vesicular lesions are only occasionally seen in patients with EPP.

**Figure 19-25** Erythropoietic protoporphyrin. Papular thickening of the skin after blistering is particularly common on the nose and overlying the knuckles.

return to normal within 1 to 2 days. Occasionally, papulovesicular (Fig. 19-24) and petechial eruptions occur and may persist for longer periods. Chronic changes include hypopigmentation, hyperpigmentation, and a papular thickening that gives a cobblestone appearance to the skin (Fig. 19-25). Despite the severely painful acute symptoms, chronic skin manifestations are often mild, ranging from grossly undetectable lesions to shallow linear or elliptical pits on the face, linear furrows around the lips, thickened hyperkeratotic skin, and a weather-beaten, leathery, or pebbly appearance, particularly over the nose or knuckles. Nails may be shed (photoonycholysis). Seasonal palmar keratoderma has been described as a sign of autosomal recessive EPP.<sup>216</sup>

Anemia has been reported in up to one-third of patients. Rarely, hypersplenism (which responds favorably to splenectomy) is associated with the anemia. Cholecystitis and cholelithiasis have been reported in up to 12% of patients, with gallstones consisting of almost pure protoporphyrin IX. Overall 20% to 30% of patients have manifestations of hepatic abnormalities, most commonly a mild increase in hepatic aminotransferases. Progressive hepatic failure occurs in 2% to 4% of patients, usually after 30 years of age, from retention of protoporphyrins, cholestasis, and eventual cirrhosis. However, cholestatic liver disease has even been described in affected infants.<sup>217</sup> The severity of the disease correlates with the amount of circulating protoporphyrins. Liver function testing should be performed annually, and alcohol and drugs with potential hepatotoxicity or cholestatic effects should be avoided. Carriage of null allele mutations, autosomal recessive EPP, and XLP have a higher risk of hepatic complications.<sup>212,218</sup>

Free protoporphyrin levels are high in circulating erythrocytes, plasma, bone marrow, liver, feces, and skin, but not in urine, so the best test is the free erythrocyte protoporphyrin level. Zinc-bound

erythrocyte protoporphyrins are high in XLP but not in EPP, because ferrochelatase is needed to synthesize both iron protoporphyrin (heme) and zinc protoporphyrin. Although total protoporphyrins (which are primarily free erythrocyte protoporphyrin) are usually measured if the more easily obtained “zinc-protoporphyrin level” is ordered, ensuring that the test measures the free erythrocyte protoporphyrins is important. Fluorescence of the erythrocytes can be demonstrated by Wood light or fluorescence microscopy.<sup>219</sup> In contrast to erythropoietic porphyria, fluorescence of teeth and nails is not present and there is no increase in fecal or urinary levels of uroporphyrins, although fecal protoporphyrins and coproporphyrins are increased. Ferrochelatase levels are 10% to 50% of normal in patient erythrocytes.

The management of EPP depends on limiting exposure to sunlight and use of sun-protective clothing and opaque sunscreens that block the wavelength range 400 to 410 nm. Some patients have had decreased photosensitivity after administration of β-carotene (Lumitene), which maximally absorbs in the visible spectrum at 450 to 475 nm and quenches free radicals in the skin. The usual dosage for children younger than 14 years of age is 30 to 150 mg and for adolescents is 120 to 180 mg (4 to 6 capsules a day). Skin yellowing, orange-colored stools, and occasional gastrointestinal upset may occur. Nevertheless, a recent systematic review did not confirm efficacy of β-carotene, vitamin C or N-acetylcysteine.<sup>220</sup> Narrowband UVB light using a PMLE protocol to harden skin (starting with 50% to 70% MED and increasing gradually) led to improvement in the majority of treated patients.<sup>221</sup> Subcutaneous implantation of 16 mg afamelanotide, an α-melanocyte-stimulating hormone analog to induce tanning, has markedly improved the quality of life in patients with EPP who have been treated chronically for up to 8 years.<sup>222</sup>

Transfusion may be required in patients with significant hemolytic anemia. Other therapeutic approaches that may be useful are oral administration of cimetidine, which reduces erythrocyte levels of protoporphyrin and photosensitivity; cholestyramine, which helps prevent reabsorption of protoporphyrin excreted into the intestinal lumen; and chenodeoxycholic or ursodeoxycholic acid. For patients with progressively deteriorating liver function, liver transplantation can be life saving,<sup>223,224</sup> but the risk of biliary complications is high; disease recurrence may be delayed by administration intravenously of hemin (an iron-containing porphyrin) and plasmapheresis.

### Porphyria Cutanea Tarda

Porphyria cutanea tarda (PCT) is the most common form of porphyria in adults and the second most common form of porphyria in children. Estimated to have an incidence of 1 in 25,000, it usually presents during the third and fourth decades of life. Autosomal dominant cases result from a mutation in uroporphyrinogen decarboxylase (*UROD*; decreases enzyme activity by 50%) and still need other genetic and environmental factors to manifest; to manifest clinical signs, *UROD* activity must be less than or equal to 20% of normal. In the familial form, the decreased *UROD* activity affects the liver, erythrocytes, and other tissues. Mutations in both *UROD* alleles usually lead to hepatocutaneous porphyria but may cause mild cutaneous disease.<sup>225</sup> About 80% of patients have the sporadic (type I) form in which the activity of *UROD* deficiency is inhibited specifically in the liver.

Skin lesions in PCT are vesicles or bullae on light-exposed cutaneous surfaces, especially the dorsal aspect of the hands, forearms, and face.<sup>226</sup> The blisters vary markedly in size from 1 mm to 3 cm across, with small blisters often being overlooked. They are most commonly filled by clear or slightly turbid liquid, but soon rupture, turn into erosions, and often become infected. On healing, the blister sites may scar or evolve into milia. These features may require differentiation from immunobullous disorders, especially epidermolysis bullosa acquisita (see Chapter 13). Other features include increased fragility of the skin, with erosions and ulcerations as a result of relatively minor trauma, hypertrichosis, and mottled hypopigmentation and hyperpigmentation of the face at sites of sun exposure. Sclerodermoid plaques (especially on the chest or temples) and dystrophic calcifications are rare in affected children.

PCT can be precipitated by iron overload, hepatitis C, human immunodeficiency virus (HIV), alcoholic cirrhosis, hemodialysis, or

administration of estrogens, hydantoins, griseofulvin, or chemotherapy drugs.<sup>227</sup> Accidental ingestion of the fungicide hexachlorobenzene was responsible for an epidemic of PCT in Turkey.<sup>228</sup> Mutations in *HFE*, associated with hemochromatosis; certain polymorphisms in cytochromes<sup>229</sup>; and the transferrin receptor gene (*TFRC*) also increase the risk.<sup>194</sup> Diabetes mellitus is present in 25% of patients with PCT, and patients not uncommonly show hepatomegaly and abnormal hepatic transaminase levels. The development of cirrhosis is a precursor of the hepatocellular carcinoma, which eventually develops in about 3% of patients.

Confirmation of the clinical diagnosis of PCT can be made by increased levels of urinary and fecal uroporphyrins, slightly elevated fecal coproporphyrin and protoporphyrin levels, and positive fluorescence of the urine with a Wood light. As with other forms of porphyria, skin biopsy specimens of vesicular lesions show subepidermal bullae with dermal papillae arising irregularly from the floor of the bulla into its cavity ("festooning"). Periodic acid-Schiff (PAS)-positive material is deposited around blood vessels and sometimes at the dermal-epidermal junction, sites where immunofluorescent studies show deposition of IgG and complement. Familial and sporadic cases can be distinguished by erythrocyte uroporphyrinogen-decarboxylase activity and uroporphyrinogen-decarboxylase genotyping.

Treatment is dependent on the elimination of triggering factors (e.g., alcohol, estrogen, iron ingestion). Treatment with low doses of hydroxychloroquine (3 mg/kg twice weekly) leads to drug-uroporphyrin complexes that are excreted. Clinical remission ensues in about 3 months, and biochemical remission is achieved in about a year. If antimalarial treatment is ineffective, phlebotomy is used to remove iron stores and porphyrins. Once biochemical remission is achieved, treatment is stopped and the patient is monitored for relapse, which generally occurs within 3 years until spontaneous remission. Spontaneous remission has been reported, but 5% to 16% of adults with long-standing untreated disease and chronic hepatitis develop hepatocellular carcinoma.

### Hepatoerythropoietic Porphyria

Hepatoerythropoietic porphyria, an extremely rare disorder, is considered to be a homozygous or heterozygous form of PCT. The disease is usually manifest before 2 years of age.<sup>230,231</sup> Dark urine is the most commonly observed sign. Skin lesions appear in childhood, and the activity of UROD in all organs is usually decreased to less than 10% of normal. The disorder is characterized by excessive porphyrin production in the liver and bone marrow, increased erythrocyte porphyrin levels, and severe photosensitivity with vesicles, bullae, crusts, and erosions. Skin fragility, hypertrichosis (that begins in infancy and early childhood), mutilating scarring deformities similar to those of CEP, and scleroderma-like changes of sun-exposed skin also occur. The face and dorsal aspect of the hands are the most severely affected areas. Malar hypertrichosis may be striking, and patients have erythrodontia (reddish brown teeth) that fluoresces when exposed to a Wood lamp. In addition to clinical features similar to those of erythropoietic porphyria, hepatoerythropoietic porphyria has biochemical abnormalities suggestive of PCT and EPP. The diagnosis is confirmed by finding huge elevations of erythrocyte protoporphyrin, urinary uroporphyrin, and fecal coproporphyrin. Sun avoidance is critical; plasma iron concentrations are normal, and phlebotomy is ineffective.

### Hereditary Coproporphyria

Hereditary coproporphyria has almost always been described in adults. The few cases that have been documented in children were initially mistaken for HV.<sup>232</sup> Rare homozygous cases have been reported in neonates with hepatosplenomegaly, hemolytic anemia, jaundice, and photosensitivity (harderoporphyria)<sup>233</sup>; feces show marked elevations of coproporphyrins. Some 20% to 30% of patients are photosensitive, and the skin lesions resemble those of PCT, chronic and usually appearing many days after sun exposure. Most patients have acute attacks of abdominal pain identical to those seen in AIP and variegate porphyria. Acute peripheral neuropathy has also been described. This condition, inherited as an autosomal dominant trait, is associated with a defect of coproporphyrinogen oxidase, resulting in accumulation of coproporphyrinogen III and its oxidized form, coproporphyrin III. Cutaneous eruptions occur concurrently with attacks of abdomi-

nal pain and psychiatric symptoms. The diagnosis is made by demonstration of elevated levels of coproporphyrin III in both urine and feces, and treatment is similar to that of patients with variegate porphyria, in addition to pain therapy for the acute abdominal attacks.

### Variegate Porphyria

Variegate porphyria (congenital cutaneous hepatic porphyria, South African porphyria) is an autosomal dominant disorder that results from heterozygous mutations in *PPOX* and decreased activity of protoporphyrinogen oxidase. This disease has its onset after puberty and generally appears in the fourth to fifth decades of life; only a few cases in childhood have been described.<sup>234</sup> It has a high incidence in the Afrikaners of South Africa.<sup>235</sup> Individuals with homozygous or compound heterozygous mutations can show severe photosensitivity with blistering and scarring beginning in infancy.<sup>236</sup> Other features are developmental delay, mental retardation, nystagmus, seizures, and short stature.<sup>237</sup>

The features of variegate porphyria resemble those of PCT but tend to be milder and less easily provoked. Clinical manifestations include sun sensitivity with vesicles or blisters on light-exposed surfaces, hyperpigmentation, a weather-beaten or waxy complexion with excessive furrowing of the forehead, cutis rhomboidalis frontalis, scars on the back of the neck and frontal hair margin, milia, and scleroderma-like plaques. The urinary findings overlap with those of both AIP and PCT, so that diagnosis is based on the plasma porphyrin fluorescence (6.26 nM) and a more than two-fold increase in excretion of fecal protoporphyrin. Treatment consists of avoidance of hepatotoxic agents and sun exposure, repeated phlebotomies, low-dose hydroxychloroquine therapy, and, in some patients, the administration of β-carotene.

### Acute Intermittent Porphyria and δ-Aminolevulinic Acid Dehydratase Porphyria

Acute intermittent porphyria (AIP) and δ-aminolevulinic acid dehydratase (ALAD) porphyria are rare disorders that share clinical features of episodes of acute abdominal pain associated with vomiting; constipation; peripheral paresis or paralysis; and psychological manifestations or psychoneuroses provoked by drugs that affect the liver, including barbiturates, sulfonamides, dapsone, griseofulvin, anticonvulsive agents, sulfonylurea compounds, and estrogens. Neither disorder tends to manifest before puberty or shows cutaneous features. AIP is an autosomal dominant disorder characterized by overproduction of porphyrin precursors (δ-aminolevulinic acid and porphobilinogen), which are excreted into the urine. ALAD porphyria, in contrast, is an even rarer autosomal recessive disorder with markedly deficient ALAD activity that results in overproduction of δ-aminolevulinic acid, but not porphobilinogen, in the urine.<sup>238</sup> False-positive urine porphyrin tests can be seen in children with heavy metal poisoning, including lead and mercury.<sup>239</sup>

The hypersensitivity syndromes are a group of disorders mediated by immunologic or hypersensitivity reactions to foreign proteins such as food or drugs, or to infectious agents, immunizations, and malignancies. Although diagnosis of these disorders is often relatively easy, difficulties commonly arise in determining the underlying cause. The most common hypersensitivity reactions are drug reactions,<sup>1</sup> and the skin is a common target. The overall incidence of drug reactions in hospitalized children is 9.5%,<sup>2</sup> and in outpatient children it is 2.5%, with reactivity to antibiotics occurring most often.<sup>3</sup> Urticarial and exanthematous reactions are seen most often.<sup>4</sup> If fever, lymphadenopathy, or facial edema accompanies an exanthematous drug reaction, the possible diagnosis of a systemic hypersensitivity disorder (drug reaction with eosinophilia and systemic symptoms [DRESS]) must be considered. The various types of drug reactions are summarized in **Table 20-1**. These include Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), lichenoid drug eruptions (**Fig. 20-1**) (see Chapter 4), fixed drug eruptions, pustular eruptions (acute generalized exanthematous pustulosis [AGEP]), acneiform eruptions (see Chapter 8), pseudoporphyrria (see Chapter 19), drug-induced vasculitis (see Chapter 21), and drug-induced lupus (Chapter 22). Some children experience multiple antibiotic sensitivity, most commonly to penicillins, sulfonamides, cephalosporins, and macrolides.<sup>5</sup> In these children, the manifestations of drug sensitivity can be different; for example a child may show an exanthematous response to amoxicillin, DRESS after phenytoin, and erythroderma after ingestion of sulfamethoxazole within a period of a few months.<sup>6</sup> The general approach to a child with suspected drug reaction is outlined in **Box 20-1**.

## Allergic Reactions

Allergy may be defined as a specific acquired alteration in the capacity of an individual to react to an antigen. Mediated by circulating or cellular antibodies, allergic reactions may be classified as immunoglobulin (Ig) E-mediated hypersensitivity (type I), cytotoxic (type II), Arthus-type toxic immune complex reactions (type III), and delayed-type hypersensitivity (type IV). Type II/anaphylactic reactions include local and systemic manifestations of the interaction between antigen and tissue cells previously sensitized with skin-sensitizing reaginic antibody, usually IgE. This interaction of antigen and antibody results in the release of pharmacologically active substances that produce urticaria, angioedema, anaphylaxis, hay fever, and asthma. Type II/cytotoxic reactions include those reactions initiated by antibody interacting with an antigenic component of the cell surface. The antigen may be a natural component of the cell or an unrelated antigen that has become associated with the cell. Examples include pemphigus (see Chapter 13), hemolytic disease of the newborn, transfusion reactions, hemolytic anemia, leukopenia, or thrombocytopenia caused by the reaction of antibody with drugs attached to blood-cell surfaces. Type III/toxic immune complex reactions (Arthus-type reactions) are associated with the deposition of immune microprecipitates in or around blood vessels, which results in tissue damage through activation of complement or toxic products from leukocytes attracted to the areas. Examples include serum sickness, vasculitis, glomerulonephritis, and local Arthus reactions after injection of antigens into the skin, subcutaneous tissue, or muscle. Type IV/delayed-type hypersensitivity is the result of the interaction between antigen and specifically sensitized lymphocytic cells, which results in a mononuclear cell infiltration and the elaboration of toxic lymphoid cell products. Examples include tuberculin and other skin test reactions, allergic contact dermatitis (see Chapter 3), lichenoid drug eruptions (see **Fig. 20-1** and Chapter 4), fixed drug eruptions, TEN, and graft-versus-host-type

reactions (see Chapter 25). Patch testing may be useful in determining the cause of allergic contact dermatitis (see Chapter 3).

## Urticaria

Urticaria, a systemic disease with cutaneous manifestations, occurs at some time in the life of about 15% to 20% of all persons. It is characterized by the appearance of transient well-circumscribed skin lesions that present as erythematous, intensely pruritic elevated swellings (wheals) of the skin or mucous membranes. More than 80% of cases of new-onset urticaria resolve in 2 weeks and more than 95% of new-onset cases within 3 months.<sup>7</sup>

Urticaria usually represents a type I (or immediate) hypersensitivity reaction in which the protein or its metabolite binds to IgE on the surface of cutaneous mast cells, leading to activation, degranulation, and release of vasoactive mediators such as histamine, leukotrienes, and prostaglandins. Examples of immunologically mediated urticaria are reactions to latex and reactions to peanuts (see below). Urticaria may also result from nonimmunologic triggering of mast cell release, such as from radiocontrast media, aspirin, many types of nonsteroidal anti-inflammatory drugs (NSAIDs), or opiates.

Typical lesions of urticaria have an edematous center with a halo of erythema (**Fig. 20-2**). They vary from pinpoint-sized papules to large lesions several centimeters in diameter. Central clearing, peripheral extension, and coalescence of individual lesions result in a clinical picture of oval, annular, or sometimes bizarre serpiginous configurations (**Figs. 20-3** and **20-4**). When annular or serpiginous patterns of urticaria occur, they can be confused with erythema multiforme (EM) or serum sickness reactions (**Fig. 20-5**), and the designation *urticaria multiforme* has been proposed.<sup>8-10</sup> Other mimics of urticaria include urticarial vasculitis, Henoch-Schönlein purpura, acute hemorrhagic edema of infancy (see Chapter 21), systemic onset juvenile idiopathic arthritis (see Chapter 22), and cryopyrin-associated periodic syndromes (see Chapter 25).<sup>11</sup>

Urticaria may be localized to one small area or may become generalized (**Fig. 20-6**). Subcutaneous extension may result in giant wheals. In infants and young children, swelling of the distal extremities with acrocyanosis may be a prominent feature of the urticarial reaction. Occasionally, particularly in infants and young children, bullae may form in the center of the wheal, usually on the legs and buttocks. Individual wheals rarely persist longer than 12 to 24 hours. Parents can draw a circle around a few lesions to verify clearance of each individual lesion by approximately 24 hours or less. Those lasting longer than 24 to 36 hours are probably not true urticaria and may represent another vascular pattern such as urticarial vasculitis (see Chapter 21) or EM.

Urticaria of less than 6 weeks' duration is considered acute. In 80% of children, acute urticaria is the result of infection, often viral, whereas in adolescents food and drugs play a more significant role. Among foods, dairy products play a more common role in younger children, in contrast to nuts, seafood, berries, and grains in older children. Streptococcal infection, mycoplasma, histoplasmosis, and coccidiomycosis in endemic areas are also well-known triggers, although almost every infectious agent has been associated with urticaria. Overall, up to 10% of episodes of urticaria are related to drugs, and these are usually acute in nature. The penicillins are the most common drugs to trigger urticaria, but only 10% to 20% of individuals who report allergy to penicillin are really allergic when skin prick testing to penicilloyl-poly-lysine and then oral drug challenge (if negative) is performed.<sup>12</sup> Other drugs most likely to induce an urticarial drug reaction are cephalosporins, sulfonamides, tetracyclines

**Table 20-1** Drug Eruptions in Pediatric Patients

Eruption	Key Drugs	Lesional Pattern	Mucosal Changes
Urticaria	Penicillins, cephalosporins, sulfonamides, tetracyclines, aspirin/NSAIDs, radiocontrast media	Pruritic erythematous wheals	None
Angioedema	Aspirin/NSAIDs, ACE inhibitors	Swelling of subcutaneous and deep dermal tissues	May be present
Serum sickness-like reaction	Cephalosporins, penicillins, minocycline, sulfonamides, macrolides, rifampin, ciprofloxacin, griseofulvin, itraconazole, bupropion, fluoxetine, rituximab, H1N1 vaccine	Urticular or erythema multiforme-like	None
Exanthematous	Penicillins, sulfonamides, cephalosporins, antiepileptics	Erythematous macules and/or papules	None
Drug hypersensitivity syndrome	Phenytoin, phenobarbital, carbamazepine, lamotrigine, allopurinol, sulfonamides, dapsone, minocycline, aspirin, vancomycin, azithromycin, abacavir, nevirapine, Chinese medicine	Edema (especially periorbital); erythematous macules and/or papules; sometimes vesicles or bullae	May be present
Lichenoid*	Captopril, enalapril, labetalol, nifedipine, propranolol, gold salts, hydrochlorothiazide, furosemide, spironolactone, hydroxychloroquine, ketoconazole, penicillamine, griseofulvin, tetracycline, carbamazepine, phenytoin, NSAIDs, hydroxyurea, imatinib, dapsone, sulfasalazine, allopurinol, iodides and radiocontrast media, IFN- $\gamma$ , omeprazole, penicillamine, TNF inhibitors, sildenafil	Discrete flat-topped reddish-purple papules and plaques	May be present
Fixed drug	Sulfonamides, ibuprofen, acetaminophen, salicylates, tetracyclines, pseudoephedrine, loratadine, teicoplanin, metronidazole, macrolides, barbiturates, lamotrigine, potassium iodide, quinine, phenolphthalein, foods and food flavorings (especially tartrazine)	Solitary to few erythematous, hyperpigmented plaques	Unusual
Pustular (AGEP)	$\beta$ -Lactam antibiotics, macrolides, clindamycin, terbinafine	Generalized small pustules and papules	None
Acneiform <sup>†</sup>	Corticosteroids, androgens, lithium, iodides, phenytoin, isoniazid	Follicular-based inflammatory papules and pustules predominate	None
Pseudoporphyria <sup>‡</sup>	NSAIDs, COX-2 inhibitors, tetracyclines, furosemide	Photodistributed blistering and skin fragility	None
Vasculitis <sup>§</sup>	Penicillins, NSAIDs, sulfonamides, cephalosporins	Purpuric papules, especially on the lower extremities; urticaria, hemorrhagic bullae, digital necrosis, pustules, ulcers	Rarely
Stevens–Johnson syndrome/toxic epidermal necrolysis	Sulfonamides, antiepileptics, NSAIDs, acetaminophen, allopurinol, dapsone	Target lesions, bullae, epidermal necrosis with detachment	Present
Drug-induced lupus <sup>  </sup>	Minocycline, procainamide, hydralazine, isoniazid, penicillamine	Urticular, vasculitic, erythematous	Rare

ACE, Angiotensin-converting enzyme; AGEP, acute generalized exanthematous pustulosis; COX-2, cyclooxygenase-2; IFN, interferon; NSAID, nonsteroidal anti-inflammatory drug; TNF, tumor necrosis factor.

<sup>§</sup>See Chapter 21.

<sup>||</sup>See Chapter 22.

(especially minocycline), antiepileptics, and monoclonal antibodies, including omalizumab. Although cross-intolerant reactions are more common than IgE-mediated reactions with NSAIDs,<sup>13</sup> selective immediate reactions to NSAIDs are becoming increasingly recognized with the widespread use of these medications in children (especially ibuprofen).<sup>14</sup> *In vitro* testing (immunoassays and basophil activation testing) can detect specific IgE antibodies for a limited number of drugs and complement prick testing but should be performed within 1 year after the occurrence of a reaction.<sup>15</sup> Anaphylactoid reactions (anaphylaxis without identifiable specific IgE antibodies) most commonly result from ingestion of acetylsalicylic acid. Non-immunologically mediated urticaria may result from radiocontrast media and NSAIDs. Psychologic stress may exacerbate (but not cause) urticaria.

Urticaria that recurs often and lasts longer than 6 weeks is termed *chronic*. Chronic urticaria is much more common in adults than in

children<sup>16</sup>; it may be present continuously or nearly every day (“chronic continuous urticaria”) or as attacks separated by symptom-free periods of up to several weeks (“chronic recurrent or intermittent urticaria”).<sup>17</sup> Diagnosis and treatment of a patient with chronic urticaria demands a complete history and physical examination, appropriate laboratory evaluation, and an awareness of possible underlying disease.

If the trigger is not clear, a child may have idiopathic urticaria. However, 30% to 47% of children with chronic urticaria are now recognized to have autoimmune (also called *auto-reactive*) urticaria.<sup>18–22</sup> Autoimmune urticaria is caused by IgG antibodies recognizing the high-affinity IgE receptor (Fc $\epsilon$ RI $\alpha$ ) or less commonly, IgE itself.<sup>23</sup> Patients may have autoimmune thyroid disease and less commonly, celiac disease, type 1 diabetes, juvenile idiopathic arthritis, and systemic lupus erythematosus (Fig. 20-7).<sup>24</sup> Reactions from food or food

**Figure 20-2** Urticaria. Transient well-circumscribed erythematous wheals occurred in this girl as a reaction to administration of cefixime. Note the edematous center and halo of erythema. Circling a lesion and noting whether it is clear 24 hours later facilitates diagnosis.

**Figure 20-3** Urticaria. Transient round and annular erythematous macules and slightly edematous plaques represent a reaction to cefdinir in this infant.

### Box 20-1 Approach to the Patient with Suspected Drug Reaction

#### Historical features

- Drugs taken, date of initiation, and duration
- Date of onset of eruption
- Response to removal and rechallenge

#### Clinical features

- Lesional morphology
- Number of lesions and distribution
- Involvement of mucous membranes
- Associated features: pruritus, fever, lymphadenopathy, visceral involvement

#### Laboratory testing

- Eosinophilia
- Specific IgE levels

#### Prick and intradermal tests for late phase reactions ( $\beta$ -lactam allergy)

#### Provocation testing

IgE, Immunoglobulin E.

additives have been described in 9%. However, the urticaria from food additives, artificial flavoring, or preservatives is not IgE-mediated but rather is a pseudoallergic reaction that is often delayed (4 to 12 hours after ingestion).<sup>25</sup> Among less common possible triggers of chronic urticaria are physical causes, foods and food additives, drugs (especially aspirin and NSAIDs), immunizations, insect bites, inhalant or contact allergens, and infections (parasites, *Helicobacter pylori*, *Chlamydia*, dental abscesses, sinus infections, low-grade urinary tract infection, and otitis). Chronic urticarial lesions with high fevers may also suggest cryopyrin-mediated auto-inflammatory disease (see Chapter 25). Urticarial vasculitis may be confused with chronic urticaria, but lesions persist beyond 24 hours (see Chapter 21).

In pediatric studies, remission rates at 1, 3, and 5 years after the onset of chronic urticaria range from 16% to 18%, 39% to 54%, and 50% to 68%, respectively, regardless of whether the chronic urticaria is autoimmune,<sup>20,22</sup> although being female and older than 10 years of age are poorer prognostic signs.

Further investigation should be based on the known underlying causes, history, and examination and could include complete blood count, erythrocyte sedimentation rate, antinuclear antibody, CH50,

free-T4, thyroid stimulating hormone, antithyroglobulin and antimicrosomal antibodies, skin prick tests for foods, food challenges, and stool examination for parasites. Food avoidance correlates better with a positive history of food reactivity than with positive prick testing.<sup>21</sup> The autologous serum skin test (ASST) through intradermal injection of the patient's own serum is used to confirm autoreactivity<sup>26</sup> and is more sensitive than the *in vitro* histamine-release urticaria test. However, new enzyme-linked immunosorbent assay (ELISA) and immunodot tests have recently been developed to measure anti-Fc $\epsilon$ RI $\alpha$  antibodies directly.<sup>27</sup>

Effective treatment of urticaria depends on identification of the etiologic factor and its elimination whenever possible.<sup>28</sup> First-line treatment in children is administration of a nonsedating histamine (H1) blocker such as cetirizine, loratadine, desloratadine, fexofenadine, or levocetirizine.<sup>29–32</sup> Dose escalation may then be required up to twofold to fourfold those used for management of allergic rhinitis.<sup>33,34</sup> Addition of hydroxyzine, diphenhydramine, or another sedating H1 blocker at night may be considered but should not replace nonsedating antihistamines. Sedating antihistamines are best administered about 1 hour before bedtime to minimize daytime drowsiness. Paradoxical hyperactivity and irritability, which requires discontinuation of the medication, has occasionally been described in some infants and children with the administration of H1 blockers, especially diphenhydramine. Doxepin, a tricyclic antidepressant with H1- and

**Figure 20-4** Urticaria. These annular and serpiginous wheals developed within minutes of eating shrimp.

**Figure 20-6** Urticaria. Wheals may coalesce and cover large areas of the body.

**Figure 20-5** Urticaria. Annular patterns of urticaria can be confused with erythema multiforme, and the term *urticaria multiforme* has been proposed.

**Figure 20-7** Urticaria. Chronic urticaria in this teenager in association with autoimmune diseases type 1 diabetes and hypothyroidism. He failed to respond to treatment with antihistamines and required systemic corticosteroids and methotrexate for control.

H<sub>2</sub>-antagonistic effects, has also been utilized for the treatment of chronic urticaria but may lead to intolerable sleepiness. Approximately 80% of patients respond to antihistamines. Concomitant administration of an H<sub>2</sub> blocker (such as ranitidine or cimetidine) tends to be of limited value, but a leukotriene receptor antagonist (e.g., montelukast) can be considered if antihistamines are insufficient. Antihistamine administration should be continued for a few weeks after clearance of the urticaria with gradual tapering of the dosage in order to determine whether they are still needed for control. Avoidance of aspirin and NSAIDs may be helpful, because these medications may exacerbate chronic urticaria. Monthly administration of subcutaneous omalizumab (150 to 300 mg for adolescents and adults) or cyclosporine may be required for chronic urticaria.<sup>32,35-38</sup> Dapsone, methotrexate, mycophenolate mofetil, cyclophosphamide, hydroxychloroquine, sulfasalazine, intravenous immunoglobulin (IVIG), and plasmapheresis have all been used for resistant chronic urticaria but have less evidence than omalizumab and cyclosporine.<sup>30,32,39-42</sup> The subcutaneous administration of 0.1 to 0.5 mL of epinephrine 1:1000 is often effective for patients with angioedema and severe urticaria. Although often effective in patients with severe or persistent urticaria,

administration of systemic corticosteroids should be reserved for acute reactivity in recalcitrant patients and should be limited to 10 days<sup>32</sup> because of the many potential side effects.

## Contact Urticaria

Urticaria may also occur from skin exposure to antigen<sup>43</sup> rather than through ingestion or inhalation (Fig. 20-8). In this case, the lesions tend to be localized to the site of contact, although rarely satellite lesions or even more generalized involvement has occurred. Exposure to certain jellyfish, corals, caterpillars,<sup>44</sup> moths, and chemicals can lead to contact urticaria through pharmacologic means. Immunologic reactions can also result in contact urticaria, as often occurs with exposure to fish or latex. Localized small wheals have also been described after contact with the spines of pet hedgehogs.<sup>45</sup> Aquagenic urticaria is a variant of contact urticaria in which small urticarial papules arise at follicles after exposure to water.

**Figure 20-8** Contact urticaria. Milk dripped on the thigh of this infant, leading to the rapid development of small wheals.

**Figure 20-10** Cholinergic urticaria. Discrete micropapular wheals are surrounded by a wide area of erythema and are induced by heat, exertion, or emotional stress.

**Figure 20-9** Dermographism. Sharply localized edematous reaction with a surrounding zone of erythema that occurs precisely at the site and within seconds of firm stroking of the skin.

Cholinergic urticaria (micropapular urticaria), which occurs in 5% to 7% of individuals with urticaria, is a very distinctive type.<sup>49</sup> It usually starts in adolescence and is associated with heat, exertion, or emotional stress. Cholinergic urticaria is characterized by a generalized eruption, especially on the trunk and arms, which consists of discrete, papular wheals, 1 to 3 mm in diameter, with or without a surrounding area of erythema (Fig. 20-10). The wheals first appear within minutes after sweating begins and occasionally are accompanied by exercise-induced bronchospasm, headache, gastrointestinal discomfort, and faintness. The duration of the eruption varies from 30 minutes to several hours; after an episode, a refractory period of about 24 hours ensues. A subset of patients with cholinergic urticaria have hypohidrosis or anhidrosis.<sup>50</sup>

Acetylcholine is thought to participate in the pathomechanism of wheal formation, but immediate type skin responses to one's own sweat, and less commonly, positive ASSTs have been described. Patients who react to their own sweat usually show nonfollicular wheals with satellites, whereas those individuals with cholinergic urticaria and positive ASST testing show a follicular-based process without satellite wheals. Once cholinergic urticaria occurs, the condition may recur for periods of months to years and then tends toward spontaneous improvement and resolution. Treatment consists of systemic antihistamines, particularly cyproheptadine, hydroxyzine, and nonsedating antihistamines such as cetirizine; awareness of potential precipitating factors; and avoidance of heat, excessive exertion, and excitement whenever possible. Another option is the use of oral anticholinergic medications to decrease sweating.<sup>51</sup>

Aquagenic urticaria, a disorder that resembles cholinergic urticaria, occurs most often in adolescence and is characterized by small, intensely pruritic, perifollicular papular wheals with surrounding erythema (Fig. 20-11). The palms and soles are spared. The disorder is precipitated by contact with water or perspiration (irrespective of temperature). Exercise and other cholinergic factors do not precipitate this disorder. Patients can drink water without adverse reaction. Antihistamines often improve reactivity, but do not totally suppress it.

Cold urticaria accounts for approximately 3% of chronic urticaria and has been documented in infants as young as 6 months. It is characterized by localized or generalized urticaria, sometimes with angioedema or anaphylaxis, that develops within a few minutes or hours after exposure to cold air or water, often upon rewarming. The urticaria may be confined to the area of skin in contact with cold (in milder cases) but may be generalized. In highly sensitive individuals, it may be associated with respiratory or cardiovascular compromise, especially with water immersion. The result is hypotension and on occasion, syncope, loss of consciousness, and drowning.<sup>52</sup> Respiratory signs such as nasal stuffiness, cough, and dyspnea, and oral or gastrointestinal symptoms such as swelling of the lips, swelling of the oral mucous membranes, dysphagia, and abdominal cramps may occur. Patients who experience oropharyngeal reactions to cool liquids or

## Physical Urticarias

The physical urticarias are a group of disorders in which wheals occur in response to various physical stimuli.<sup>46</sup> These include dermatographism and pressure, cholinergic, aquagenic, solar (see Chapter 19), and cold urticaria. Dermographism and cholinergic urticaria are quite common; cold urticaria is less common; and other patterns of physical urticaria are relatively rare.

Dermographism (dermatographism) is manifested by a sharply localized edematous or wheal reaction with a surrounding zone of erythema that occurs precisely at the site and within seconds of firm stroking of the skin (Fig. 20-9). The wheal tends to be maximal in size and intensity at about 6 minutes after onset and persists for approximately 15 minutes. This common phenomenon, known as the *triple response of Lewis*, is often seen in infants, occurs in about 50% of children, and is noted in only about 1% of adolescents or adults.

Pressure urticaria is a variant of dermatographism characterized by the development of hives or a deeper swelling simulating angioedema after local pressure such as from clothing or jewelry, or weight bearing.<sup>47</sup> The reaction is often painful rather than pruritic and may occur immediately after the pressure or more commonly, after a 4- to 6-hour delay ("delayed pressure urticaria").<sup>47</sup> Because of this delay in appearance, patients often fail to appreciate the cause of the disorder. The palms and soles are most commonly involved. Patients respond poorly to antihistamine therapy; some patients have responded to the leukotriene antagonist, montelukast.<sup>48</sup>

**Figure 20-11** Aquagenic urticaria. Small, intensely pruritic, perifollicular papular wheals with surrounding erythema that occur after contact with water or perspiration, regardless of temperature.

foods (especially lip swelling) are at increased risk for the development of systemic reactions.

Cold urticaria in children and adolescents is usually acquired, occurs more often in girls, and often appears suddenly. Anaphylaxis has been described in up to 30% at presentation.<sup>53</sup> Once symptoms develop, they are generally short-lived and recurrences usually disappear after a few months or years. Secondary forms of cold urticaria may also be associated with cold hemolysin and cold agglutinin syndromes. These forms, generally seen in adults, cause Raynaud phenomenon, acrocyanosis, and cutaneous ulcers. Some cases of cold urticaria manifested by itching, erythema, purpura, atypical Raynaud phenomenon, and ulceration are the result of cryoglobulins (see Chapter 21).

Cold urticaria can rarely be a manifestation of familial cold autoinflammatory syndrome (FCAS), an autosomal dominant disorder resulting from mutations in *CIAS1/NLRP3* (see Chapter 25). It is characterized by an urticarial or papular eruption, fever, chills, arthralgia, and sometimes headache, malaise, muscle tenderness, and significant leukocytosis. Patients more commonly complain of burning or stinging than of pruritus. Although the tendency to familial cold urticaria generally persists for life, the severity may decrease with advancing age. It generally develops after a latent period of several hours, and once it develops, it may persist for up to 48 hours. Familial atypical cold urticaria (FACU) is an autosomal dominant disorder with onset during childhood in which the urticaria and/or angioedema develop shortly after cold exposure (not delayed). Cold-stimulation testing is negative (no wheal), and in contrast with FCAS, patients do not have fever, chills or joint complaints.<sup>54</sup> Phospholipase C, gamma 2 (PLCG2)-associated antibody deficiency and immune dysregulation (PLAID) is a newly characterized autosomal dominant immunodeficiency syndrome associated with evaporative cold urticaria.<sup>55,56</sup> The cold urticaria presents within the first year in all patients and is characterized as pruritic blotchy macules but not true wheals; ice cube testing is negative. Patients may develop ulcerative lesions of the nasal tip, and occasionally fingers and toes, during the neonatal period that heals by infancy. They have a tendency to develop granulomatous dermatitis, which may be widespread.<sup>56</sup> Recurrent sinopulmonary infections, common variable immunodeficiency (CVID), and autoantibodies (especially antinuclear and anti-thyroid antibodies) are commonly associated.

The diagnosis of cold urticaria requires a careful history and investigation for other possible etiologic factors. The diagnosis may be confirmed by reproducing signs through local application of an ice cube for periods of 2 to 10 minutes with observation after removal for at least 10 minutes. The best areas for this testing are the face, neck, and particularly the arms (Fig. 20-12). Some patients fail to respond to ice but do respond to cold water or generalized cooling of the body. Critical temperature threshold testing shows an inverse relationship with disease severity and activity, which can be helpful for assessing both the severity and the impact of therapy.<sup>57</sup> Cold urticaria should be distinguished from cold-induced cholinergic urticaria, in which

**Figure 20-12** Cold urticaria. Application of an ice pack to an extremity for 2 to 10 minutes can induce a wheal.

cholinergic urticaria occurs while exercising in the cold and is not induced by ice cube testing. Immediate ice cube tests also tend to be negative with FCAS, FACU, and PLAID syndromes.

Underlying disorders are rare in children. Cryoglobulinemia, cryofibrinogenemia, and cold agglutinins have all been reported, particularly in adults, and can reflect an underlying diagnosis of essential mixed cryoglobulinemia, hepatitis, autoimmune disease, or lymphoma. Cold urticaria can also be associated with infectious disorders (toxoplasmosis, Epstein–Barr virus [EBV], *H. pylori*, hepatitis C, and human immunodeficiency virus [HIV]) and autoimmune disease (particularly lupus erythematosus or celiac disease).

Patients with cold urticaria, and particularly with severe or widespread urticarial reactions, should carry epinephrine and be forewarned of the risk of drowning after loss of consciousness when swimming or bathing in cold water. The treatment of cold urticaria is aided by oral administration of antihistamines, particularly nonsedating H1 blockers, although the sedating antihistamine cyproheptadine is also particularly helpful for cold urticaria, and leukotriene receptor antagonists have been used adjunctively. Increases in doses of nonsedating antihistamine to four times the standard dosages have shown additional benefit (vs. standard dosing) without increased adverse events.<sup>58</sup> For those patients who are unresponsive to systemic antihistamines and have increased levels of IgE, treatment with omalizumab may be helpful.<sup>59</sup> Desensitization to cold is an alternative that is now rarely performed; an extremity is gradually cooled in cold water for 5 to 10 minutes per day with a gradual increase in the time of exposure and decrease of the temperature over a period of weeks or months. This treatment is not regularly effective and must be done cautiously in an effort to minimize the risk of systemic reaction. Patients with cold urticaria as a manifestation of an autoinflammatory syndrome often require interleukin (IL)-1 blockers (e.g., anakinra) for response.<sup>60,61</sup>

## Anaphylaxis

Anaphylaxis is a life-threatening, immediate hypersensitivity reaction to the administration of an antigen that has previously produced a specific sensitization. It is characterized within minutes to 1 hour after injection or ingestion of antigen by pruritus of the palms, soles, and scalp, urticaria, and/or angioedema with systemic signs (weakness, dyspnea, hypotension, and circulatory collapse). Mucosal involvement of the airway leads to acute respiratory distress, and swelling of the gastrointestinal mucosa can result in abdominal pain, vomiting, or diarrhea. The incidence in children and adolescents is 10.5 episodes per 100,000 person-years, and most children have a personal history of atopy. Anaphylaxis can occur during infancy,<sup>62</sup> although the risk peaks during early childhood and decreases thereafter.<sup>63</sup> A biphasic reaction may occur, with recurrence usually within 8 hours of the initial episode. Anaphylactic reactions most often occur after ingestion of foods,<sup>64</sup> especially peanuts, cow's milk, and hen's eggs in children

(vs. wheat and shellfish in adults), or in response to drugs or insect venom.<sup>55,66</sup> Anaphylactic reactions to latex and peanuts are particularly troublesome, because they are so ubiquitous in the environment. Having asthma as well as IgE-mediated food allergy increases the risk of developing food-induced anaphylaxis. Exercise-induced anaphylaxis may also occur and is commonly food-dependent. Two subtypes have been described: nonspecific food-dependent exercise-induced anaphylaxis, in which filling the stomach before exercise is responsible, regardless of the kind of food ingested, and specific food-dependent exercise-induced anaphylaxis, an IgE-mediated food allergy in which anaphylaxis only occurs in combination with exercise. Several types of foods have been described to trigger exercise-induced anaphylaxis, but wheat appears to be most common.<sup>67</sup>

## LATEX ALLERGY

Latex allergy is a reaction to a peptide in natural rubber and occurs most commonly in children with spina bifida, presumably owing to the frequent exposure to catheters and latex gloves.<sup>68</sup> The use of latex-free or latex-safe equipment has markedly lowered the risk to children with spina bifida.<sup>69</sup> Atopic children also show an increased risk of latex allergy,<sup>70</sup> with up to 4% showing prick test reactivity.<sup>71</sup> Type I hypersensitivity reactions to latex may range from contact urticaria to life-threatening anaphylaxis. Severe anaphylactic shock without cutaneous erythema or urticaria has been described.<sup>72</sup> Type I reactions to latex differ from the type IV contact dermatitis reaction to antigens in rubber products (see Chapter 3). Children with type I hypersensitivity reactions often experience lip swelling after sucking on a pacifier or blowing up a balloon (Table 20-2). Aerosolized powder from latex gloves and inhalation may lead to runny nose, sneezing, itchy, swollen eyes, and wheezing in susceptible individuals. Approximately half of persons who react to latex show reactivity to certain foods, resulting in oral mucosal pruritus, urticaria, and wheezing; bananas, kiwis, avocados, and chestnuts contain proteins that cross-react with latex and are most commonly associated.<sup>73</sup>

Skin prick testing is most likely to yield positive responses to either latex or cross-reacting foods. Serum latex-specific IgE by Immuno CAP can also be used to detect type I reactivity to latex, but the high rate of false positives should be taken into account when making a diagnosis of latex allergy in patients with pollen allergy (30%), especially in those sensitized to more than one pollen species.<sup>74</sup> Avoidance of latex and related triggers is critical, and nonlatex substitutes such as Mylar balloons and vinyl or neoprene gloves are generally available. Desensitization is the only effective way to resolve latex allergy; percutaneous and sublingual approaches appear to be safer than subcutaneous administration.<sup>75</sup>

## NUT ALLERGY

Nut-induced anaphylaxis is a risk in the 1.1% of individuals who are allergic to peanuts and tree nuts<sup>76,77</sup> and has resulted in 50 to 100 deaths annually in the United States. Screening tests such as prick tests and radioallergosorbent tests (RASTs) are suggestive, but only food challenge confirms reactivity. Avoidance of peanuts is extremely difficult, and there has been no means to protect against accidental ingestion, which often occurs despite reassurance from servers.<sup>78</sup> Allergic reactions through kissing are well documented, particularly in adolescents.<sup>79</sup> In one study, 13% of subjects still had detectable levels of peanut 1 hour after ingestion of two tablespoons of peanut butter on a sandwich.<sup>80</sup> Although prenatal and postnatal avoidance of peanuts has been encouraged for at-risk individuals in the past, new data suggests that exposure to small amounts can lead to tolerance.<sup>81,82</sup> In a landmark trial of 500 infants at risk for peanut allergy, infants who avoided peanuts had a much higher risk of developing allergy than those who were given small numbers of peanuts regularly, regardless of whether they were sensitized to peanuts at baseline.<sup>82</sup> These data have led to the suggestion that 4- to 8-month-old infants at risk for peanut allergy with negative prick testing for peanuts or mildly positive prick testing and a nonreactive peanut challenge should be administered 2 g peanut protein three times weekly for at least 3 years.<sup>83</sup>

Omalizumab substantially increases the threshold of sensitivity to peanuts and may protect against unintended ingestion.<sup>84</sup> Oral immunotherapy with gradual increases in exposure to peanuts can decrease basophil activation, titrated skin prick tests, and peanut-specific IgE levels within 6 months.<sup>85</sup>

The treatment of anaphylaxis consists of the intravenous administration of antihistamines such as diphenhydramine (1.25 mg/kg), subcutaneous epinephrine (the adult dose AutoInjector contains 0.3 mg of epinephrine as 0.3 mL of epinephrine 1:1000, and the pediatric dose AutoInjector contains 0.15 mg of epinephrine as 0.3 mL of epinephrine 1:2000) for grade 2 anaphylaxis or higher,<sup>86</sup> and sometimes intravenous corticosteroid.<sup>87,88</sup> Epinephrine is the only medication shown to be life-saving when administered promptly, but it is underutilized.<sup>89</sup> Patients should have easy access to at least 2 doses of an epinephrine AutoInjector, with thorough training regarding correct use of a given device and an emergency action plan. In addition to EpiPen, Auvi-Q is a new AutoInjector available for children (and adults) that provides audio and visual cues regarding patient use and was found favorable to the traditional AutoInjector for method of instruction, preference to carry, and device size.<sup>90</sup>

Because of the delay before onset of effectiveness, oral medications are not indicated. If hypotension is present, intravenous fluids should be initiated to permit the rapid administration of plasma volume expanders, fluids, and electrolytes. Once shock is overcome and oral fluids are well tolerated, oral corticosteroids may be initiated. Anyone at risk for anaphylaxis should wear a medic alert bracelet and carry epinephrine in case of emergency. Management of anaphylaxis in schools has recently received attention, especially because of its distinct challenges and the need to be able to urgently administer epinephrine.

## Angioedema

The term *angioedema* (also called *giant urticaria* or *Quincke edema*) describes swelling of the eyelids, hands, feet, genitalia, the lips, tongue, airway, and gastrointestinal tract.<sup>91</sup> When it occurs in association with wheals, angioedema is a feature of urticaria. Fifty percent of patients with angioedema also show urticaria, and 10% of infants and children with urticaria show at least mild angioedema. Angioedema may be a component of anaphylactic reactions.

Angioedema without wheals has been recently classified by the European Academy of Allergy and Clinical Immunology into four acquired and three hereditary forms.<sup>92</sup> Angioedema is defined as hereditary when: (1) there is family history of angioedema in a first- or second-degree relative; (2) there is a mutation in *SERPING1* (encoding C1 inhibitor [C1-INH]) or *FXII* (encoding factor XII, a coagulation factor); and (3) there is a familial deficiency of C1-INH. Although

factor XII deficiency is more uncommon than C1-INH-hereditary angioneurotic edema (HAE), the clinical features of deficiency of C1-INH and deficiency of factor XII are similar,<sup>93</sup> and laboratory testing is required to distinguish these autosomal dominant disorders. Two of the three acquired forms (induced by angiotensin-converting enzyme inhibitors and a nongenetic form of C1-INH deficiency) usually occur in adults. Most cases of idiopathic acquired angioedema are histamine-responsive (histaminergic; termed *idiopathic histaminergic acquired angioedema [IHA-AAE]*), and medications (especially aspirin and NSAIDs), allergens, and physical agents have been implicated.

## C1 Inhibitor-Hereditary Angioneurotic Edema

Hereditary angioneurotic edema (HAE; hereditary angioedema) is characterized by recurrent episodes of edema of the subcutaneous tissue, particularly the hands, feet, and face, and of the gastrointestinal and/or upper respiratory tracts. Occurring in approximately 1 in 50,000 to 1 in 10,000 persons,<sup>94</sup> the defect results from a deficiency (85% of patients; type I) or dysfunction (15% of patients, type II) of the inhibitor of the first component of complement [C1-INH]. Deficiency or dysfunction of C1-INH leads to transient episodes of increased vascular permeability with increased cleavage of C4 by C1, depleting C4 levels. The major factor responsible for edema formation is now known to be bradykinin, which can induce leakage of postcapillary venules. Bradykinin is produced when high molecular-weight kininogen is cleaved by plasma kallikrein, the activity of which is controlled by C1-INH. HAE without urticaria and with no dysfunction or deficiency of C1-INH has been described.<sup>95</sup>

The earliest symptoms of HAE often begin in infancy or early childhood, with 50% of cases manifesting before the age of 10 years. The frequency and severity of attacks are typically exacerbated during adolescence and subside in the fifth decade. Onset during the first decade is associated with greater severity.<sup>96</sup> Based on survey data, prodromes have been described in 82.5% to 95.7% of patients surveyed, most commonly involving the skin or gastrointestinal tract and hours to days before the onset of angioedema; fewer than 10% reported were rarely or never able to predict an attack.<sup>97</sup> Affected individuals are prone to sudden attacks of circumscribed subcutaneous edema (angioedema) without associated urticaria. It usually affects the face or an extremity and may be severe enough to cause remarkable disfigurement of the affected parts. Areas of swelling may migrate, but the condition generally subsides within 24 to 72 hours. Several weeks of remission generally follow attacks. The skin and mucosal lesions may appear spontaneously or may be precipitated by minor trauma, especially dental work or surgery,<sup>98</sup> strenuous exercise, infection (especially of the airway), menses, pregnancy, administration of oral contraceptives or angiotensin-converting enzyme inhibitors, extremes of temperature, or emotional disturbances. There is no pitting, discoloration, redness, pain, or itching associated with the edema. However, many affected children show a nonpruritic serpiginous rash that resembles erythema marginatum.<sup>99</sup>

Gastrointestinal involvement is the presenting sign in 40% to 80% of affected children.<sup>100</sup> The recurrent colic and severe abdominal pain can simulate the acute abdominal pain of appendicitis. Nausea, vomiting, and diarrhea are additional complaints. Abdominal ultrasound may demonstrate edematous swelling of the intestinal wall and free peritoneal fluid. Involvement of the mucous membranes of the hypopharynx and larynx, although seen less often, may be particularly devastating; up to 25% of patients experience asphyxia, which is the leading cause of death and usually occurs during the third decade of life.

Diagnosis of HAE can be confirmed by the finding (at least twice and separated by 1 to 3 months) of reduced levels of C4 or C1-INH (quantitative and/or functional), or both. For those with C1-INH deficiency, levels tend to be 10% to 40% of normal, reflecting the haploinsufficiency. Of note, C4 and C1-INH levels do not tend to reach adult levels until about 3 years of age, necessitating genetic testing in infants. If levels of C4 are reduced in the presence of normal levels of C1-INH

protein, confirmation must rely on demonstration of a functional lack of C1-INH by chromogenic or immunoenzymatic assay.

Antihistamines and corticosteroids have not been effective in the management of patients. Epinephrine is beneficial in the control of swelling in only a very few patients. Tracheostomy commonly is life-saving in patients with laryngeal obstruction, but plasma-derived human C1-INH concentrate is available for treatment of acute episodes.<sup>101–103</sup> The median time to onset of relief in one pediatric study was 25 minutes and to complete resolution was 8 hours.<sup>103</sup> The US Hereditary Angioedema Association and others have proposed recommendations for comprehensive care of patients with HAE.<sup>104,105</sup> Recombinant C1-INH from transgenic rabbits has recently been approved for use in acute attacks.<sup>106</sup> Ecallantide,<sup>107</sup> a specific inhibitor of plasma kallikrein, and icatibant,<sup>108</sup> an inhibitor of the bradykinin receptor B2, are both used for acute attacks, but they have short half-lives and are not appropriate for prophylaxis.

In general, attacks tend to be less frequent and less severe in children, and most will not require long-term prophylaxis. However, prophylactic C1-INH administration with dosage escalation may be considered for children with more than two attacks per month, the need for acute treatment more than once annually, or more than one episode of severe abdominal pain in a year.<sup>109,110</sup> When used prophylactically, the concentrate reduced the median monthly attack rate by almost eightfold.<sup>101</sup> Antifibrinolytics (ε-aminocaproic acid and tranexamic acid) are less efficacious than other approaches and are now rarely used for prophylaxis. Attenuated androgens such as danazol are only appropriate for short-term prophylactic therapy, such as before dental procedures, because of their potential side effects.

As prevention, children and adolescents with HAE should not participate in contact sports, and toddlers should not attend daycare before kindergarten to minimize the risk of infection that could trigger attacks. Even the eruption of teeth and minor mechanical trauma can induce edema formation. If menstruation worsens HAE symptoms, long-term prophylactic doses can be increased, but oral contraceptives are triggers of the angioedema and should be avoided. Although use of angiotensin-converting enzyme inhibitor is unusual in children, these medications can exacerbate the signs of angioedema in affected individuals and should be avoided.<sup>111</sup>

## Scombroid and Ciguatera Fish Poisoning

Scombroid fish poisoning (scombrotoxicism) is a clinical syndrome that results from the ingestion of spoiled fish of the Scombroidea family (tuna, mackerel, and bonito) and fish such as bluefish, mahi-mahi, amberjack, herring, sardines, and anchovies.<sup>112,113</sup> The disorder, thought to be related to high levels of histamine and sarcine produced when these fish are improperly refrigerated, is characterized by pruritus, a diffuse erythema of the face and upper body,<sup>114</sup> somewhat resembling a sunburn and at times, giant hive-like lesions that develop within minutes to hours after ingestion of the toxic fish. Bacteria in the fish express a decarboxylase that converts histidine to histamine, which resists cooking and freezing. Symptoms resemble a histamine reaction and commonly include a hot, burning sensation rather than pruritus. The conjunctivae are often markedly injected, and many patients have a severe throbbing headache, tachycardia, palpitations, nausea, vomiting, abdominal cramps, diarrhea, dryness and a burning sensation or peppery taste in the mouth, urticaria, angioneurotic edema, oral blistering, hypotension, blurred vision, and asthma-like symptoms. Although superficially resembling an allergic reaction, patients with scombroid fish poisoning can be reassured that they do not have fish allergy and that scombroidosis will not occur when fish are handled properly. Symptoms are generally self-limiting and even if untreated tend to resolve within 8 to 10 hours. Treatment is supportive, and most patients treated with oral antihistamines become asymptomatic within 2 or 3 hours.

In contrast to scombroid fish poisoning, ciguatera fish poisoning is a common disorder endemic throughout the Caribbean and Indo-Pacific islands but has been reported in the United States. It is caused by the ingestion of ciguatoxin,<sup>115</sup> which originates from a dinoflagellate (*Gambierdiscus toxicus*). Present in certain fish such as the red snapper, amberjack, and sturgeon, ingestion of affected fish (whether

cooked, raw, or frozen) may result in this disorder. Clinical symptoms, which usually appear within 12 hours but sometimes within minutes after ingestion of ciguatoxin, include abdominal pain, cramping, diarrhea, nausea, vomiting, paresthesias, pain or burning when cold water is touched, arthralgia, myalgia, and in severe cases, hypotension, shock, respiratory depression, paralysis, coma, and death. The duration of illness averages 8.5 days but may be prolonged. Treatment consists of supportive measures, and intravenous mannitol has been found to be extremely effective, lessening the neurologic and muscular dysfunction of affected patients within minutes of administration.<sup>115</sup>

## Serum Sickness and Serum Sickness-Like Reactions

Serum sickness is an allergic reaction characterized by a cutaneous eruption (morbilliform, urticarial, or purpuric),<sup>116,117</sup> malaise, fever, lymphadenopathy, splenomegaly, proteinuria, and arthralgias.<sup>118</sup> The syndrome, originally noted and most commonly seen after the administration of antiserum of horse or rabbit origin, is now rarely encountered. However, serum sickness-like reactions (SSLRs) occasionally occur in children, especially 1 to 3 weeks after exposure to cefaclor, which has been described in approximately 0.2% of treated children.<sup>119,120</sup> Penicillins (especially amoxicillin),<sup>121</sup> tetracyclines,<sup>122</sup> cefprozil, sulfonamides, macrolides,<sup>123</sup> ciprofloxacin, rifampin,<sup>124</sup> griseofulvin,<sup>125</sup> itraconazole, fluoxetine, bupropion,<sup>126</sup> rituximab,<sup>127,128</sup> and the H1N1 influenza vaccine<sup>129</sup> have also been implicated as triggers of SSLR.<sup>3</sup> SSLR more closely resembles urticaria (or urticaria multiforme) than true serum sickness (Figs. 20-13 and 20-14), and lesions commonly show large areas of lilac or violaceous discoloration, especially centrally (Fig. 20-15). This classic observation has led to use of the term *purple urticaria* to describe the skin lesions seen in SSLR. Noncutaneous features most commonly include fever, malaise, lymphadenopathy, and arthralgias with periarticular swelling, particularly symmetrically involving the knees and metacarpophalangeal joints (Fig. 20-16). True arthritis is uncommon and seen significantly less often than in patients with true serum sickness. Affected children may also demonstrate facial edema, eosinophilia, headache, myalgia, and gastrointestinal symptoms, but renal and neurologic disease is rarely associated. Histologic evaluation of biopsy section may reveal vasculitis associated with cutaneous deposition of immune complexes, but hypocomplementemia and circulating immune complexes, as seen in true serum sickness, are absent.

SSLR generally is a self-limiting disease that subsides within 2 to 3 weeks after discontinuation of the causative agent. In the case of cefaclor, biotransformation of the parent drug, genetic defects in metabolism of reactive intermediates, and increased *in vitro* lymphocyte cytotoxicity have been thought to participate.<sup>130</sup> SSLR has been described as well in association with other drugs,<sup>118</sup> infection with

**Figure 20-13** Serum sickness-like reaction. Urticarial wheals occurred 2 weeks after exposure to cefaclor.

**Figure 20-14** Serum sickness-like reaction. Serpiginous and annular lesions that persisted more than 24 hours in a reaction to amoxicillin.

**Figure 20-15** Serum sickness-like reaction (SSLR). Note the central lilac discoloration, similar to that of erythema multiforme and typical of SSLR. This girl developed the reaction after 10 days of amoxicillin.

**Figure 20-16** Serum sickness-like reaction (SSLR). Note the swollen hand and large urticarial wheals in this girl with SSLR and arthralgias.

hepatitis B or C, and immunization against hepatitis B, rabies, and tetanus toxoid. Treatment with antihistamines, NSAIDs, and if severe, a short course of systemic corticosteroids helps to alleviate symptoms. In general, the risk of cross-reaction among  $\beta$ -lactam antibiotics is low, and patients who have reacted to cefaclor or cefprozil will usually tolerate other cephalosporins.

## Exanthematous Eruptions

The most common drug eruptions are morbilliform or exanthematous eruptions, characterized by erythematous macules and/or papules (Figs. 20-17 and 20-18). The risk of this type of eruption is increased by viral infection, such as the near 100% incidence of an exanthematous reaction in patients taking penicillin who have EBV infection, or the increased risk of drug reactions in patients taking sulfonamides who have human immunodeficiency virus (HIV) infection.

Most commonly, an exanthematous eruption begins 7 to 14 days after initiation of a new medication and sometimes after drug discontinuation. If an individual is rechallenged after an initial course of taking a medication, the reaction may develop within a few days. Most commonly, the eruption is symmetric and begins initially on the trunk before becoming generalized. Mucous membranes are usually spared, but palms and soles are often involved. Patients may experience varying degrees of associated pruritus and some have low-grade fever. Not uncommonly the eruption turns more of a brownish-red color in 7 to 14 days and may desquamate.

Penicillins, sulfonamides, cephalosporins, and antiepileptics are the most likely categories of drugs to cause exanthematous reactions. Viral exanthems tend to be indistinguishable from exanthematous drug eruptions and more commonly occur in pediatric patients. Eosinophilia favors a diagnosis of drug reaction; biopsy is generally not helpful. More severe drug reactions may be heralded by facial edema or marked eosinophilia, as in systemic hypersensitivity syndrome, or by mucous membrane lesions and dusky skin, as in SJS or toxic epidermal necrolysis.

Treatment is largely supportive. The decision to discontinue a drug must be made based on the need for continuing the medication. Many patients will show clearance of the eruption despite continuation of medication (for example, when an infant with otitis is treated with amoxicillin). However, patients may show progression to erythroderma. Desensitization has been used for reactions to sulfonamides in patients with HIV infection.

## Drug Reaction with Eosinophilia and Systemic Symptoms

This reaction, which is also called *drug hypersensitivity syndrome* (DHS), presents as an exanthematous drug reaction in association

**Figure 20-17** Exanthematous drug reaction. (A) and (B) Erythematous papules in an infant administered amoxicillin for otitis media. Given the distribution, a viral exanthema (Gianotti-Crosti) would also be considered.

with fever, facial swelling, conjunctivitis, and often internal organ involvement that leads to mortality in 10% of patients.<sup>131,132</sup> The clinical manifestations of DRESS syndrome typically begin 1 to 6 weeks after initiation of a responsible medication.

Fever and malaise often appear first and may be seen in association with cervical lymphadenopathy and pharyngitis. The cutaneous eruption occurs in approximately 75% of patients. It often starts on the face with edema, especially periorbital, then erythema and pruritus (Fig. 20-19). The erythema then spreads caudally. The exanthematous eruption raises concern about SJS or TEN; the lack of mucosal involvement in DRESS can be a useful distinguishing feature.

Of visceral sites of involvement, the liver is most common (about 50%), and the hepatitis may be fulminant, leading to death. Lymphadenopathy is often seen, and patients may complain of joint pain. Inflammation of the kidney, central nervous system, heart, and lungs has often been described. Thyroiditis occurs in a subset of patients and may not be noted until 2 to 3 months after onset. Atypical lymphocytosis and eosinophilia are seen in most affected individuals early in the course.

DRESS is most commonly caused by trimethoprim-sulfamethoxazole and the aromatic anticonvulsant agents, although viral infection has also been linked to DRESS. Sulfonamides are metabolized by acetylation to a nontoxic metabolite for renal excretion; slow acetylation has been associated with an increased risk of developing DRESS. Only aromatic amine forms of sulfonamides require this

**Figure 20-18** Exanthematous drug reaction. Confluence of erythematous macules from administration of cefdinir.

**Figure 20-19** Drug reaction with eosinophilia and systemic symptoms (DRESS). Three weeks after initiation of carbamazepine, this boy developed facial edema with dusky erythematous papules. The pruritic eruption subsequently spread caudally. Hepatic transaminase levels were noted to be significantly increased.

mechanism (e.g., these reactions do not occur with sulfonylureas and furosemide). Aromatic antiepileptics are metabolized by the cytochrome P450 system, and hereditary alterations in metabolism may lead to the accumulation of toxic arene oxide metabolites. Because these medications cross-react, affected individuals should avoid phenobarbital, phenytoin, carbamazepine, oxcarbazepine and lamotrigine.<sup>133</sup> Alternative antiepileptics include valproic acid, benzodiazepines, gabapentin, zonisamide, topiramate, levetiracetam, and vigabatrin. Other drugs that less commonly cause this syndrome are minocycline, amoxicillin, dapson, vancomycin,<sup>134</sup> abacavir, nevirapine,<sup>135</sup> aspirin,<sup>136</sup> allopurinol, azithromycin,<sup>137</sup> and traditional Chinese medicine.<sup>138</sup> Reactions to doxycycline have not been described in

patients who develop DRESS in response to minocycline. Clinical signs may vary dependent on causative drug. For example, lamotrigine rarely causes eosinophilia, abacavir leads to primarily respiratory and gastrointestinal manifestations without eosinophilia or hepatitis, and allopurinol reactions often involve the kidney.<sup>6,139</sup>

The eruption of DRESS syndrome persists for weeks to months after medication withdrawal. After an initial period of improvement, the cutaneous and visceral manifestations of DRESS may flare 3 to 4 weeks after onset. Lymphocyte transformation tests may be useful in confirming the triggering medication but should be performed 5 to 8 weeks after onset in patients with DRESS.<sup>140</sup> Challenge with the offending drug after initial reaction leads to reactivation of the fever and erythroderma within hours after initiation.

A role for concurrent herpes family viral infections has been emphasized in adult DRESS, particularly with reactivation of EBV and human herpesvirus (HHV) 6.<sup>141,142</sup> A recent pediatric study found concomitant evidence of HHV6 infection in 50% of the children, and in association with greater pulmonary involvement (50%) and longer duration of fever and hospital stay.<sup>132</sup>

Patients with suspected DRESS should have a variety of laboratory tests to consider visceral involvement. These include complete blood count, hepatic transaminases, serum creatinine level, urinalysis, and thyroid testing (which should be repeated after 2 to 3 months). Although topical corticosteroids and antihistamines may quell the pruritus in mild cases, patients with visceral involvement (especially for hepatitis, myocarditis, and interstitial pneumonitis) should be treated with systemic corticosteroids (1 to 2 mg/kg per day) for a few weeks, with gradual taper thereafter. Systemic corticosteroid treatment tends to shorten the hospital stay and reduce febrile days.<sup>132</sup> Anecdotal cases of successful treatment of DRESS with IVIG have been described.<sup>143</sup> Counseling of family members is important, because first-degree relatives of individuals with DRESS have a higher risk of developing these drug reactions.

## Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are now considered to be variants of the same hypersensitivity disorder.<sup>144,145</sup> The incidence of these conditions is 1 to 3 per million persons per year, although in patients with HIV infection the incidence is 1 per 1000 persons per year.<sup>146</sup> In a study of 708 patients, approximately 18% were children.<sup>147</sup> Classification has been based on the degree of epidermal detachment. Epidermal detachment of less than 10% of the total body surface area is considered SJS; more than 30%, TEN; and between 10% and 30%, a transitional SJS-TEN overlap condition. In children, SJS is seen more often than TEN or SJS-TEN overlap; in one study, 85% of pediatric cases had SJS, whereas 6% had SJS-TEN overlap and 9% had TEN.<sup>148</sup> Patients may appear to have SJS initially, but it evolves into typical TEN (Table 20-3). At one time, SJS was lumped with EM (see *Erythema Multiforme* section), which is now considered to be a distinct entity, primarily resulting from hypersensitivity to herpes simplex infection. Similarly, TEN was once confused with staphylococcal scalded skin syndrome (SSSS), a more superficial and crusted disorder in which the superficial blistering is caused by an exfoliatin produced by *Staphylococcus aureus* (see Chapter 14).

The underlying triggers of SJS and TEN are similar, although drugs cause the majority of cases overall and almost all cases of TEN (Box 20-2).<sup>149–154</sup> In children, SJS is much less commonly caused by medication than in an adult.<sup>155</sup> Most patients show evidence of SJS or TEN 7 to 21 days after the first drug exposure. Occurrence is almost always within the first 8 weeks of drug use and rarely within the first few days of drug administration. Children with an earlier onset (mean 2 to 3 days) have been previously exposed to the drug or a cross-reacting analogue. Although more than 200 medications have been implicated as potential triggers of SJS-TEN, sulfonamides, penicillins, phenobarbital, carbamazepine, and lamotrigine have been most strongly associated with SJS-TEN.<sup>154</sup> An algorithm for assessing drug causality in epidermal necrolysis (ALDEN) has been proposed and correlates well with case-control analysis results.<sup>156</sup> Patients carrying HLA-B\*15:02,

**Table 20-3** Classification of Stevens–Johnson Syndrome, Toxic Epidermal Necrolysis, and Stevens–Johnson Syndrome–Toxic Epidermal Necrolysis Overlap

	SJS	SJS-TEN	TEN
Lesional morphology	Targetoid lesions, dusky red macules, bullae	Targetoid lesions, dusky red macules, bullae	Targetoid lesions, dusky erythematous macules and plaques; detachment of epidermis
Localization of skin lesions	May be scattered and isolated; may be confluent, especially on the trunk and face	May be scattered and isolated; often confluent	Usually extensive involvement with widespread confluence
Involved skin	<10%	10% to 30%	>30%
Biopsy features	More interface dermatitis	Significant interface dermatitis + necrolysis	Predominantly necrolysis
Mucosal changes	Prominent	Prominent	May be less than in SJS
Systemic involvement	Often present	Always present	Always present

SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

NSAID, Nonsteroidal anti-inflammatory drug.

which is common in the Asian population, are at strongly increased risk for carbamazepine-induced SJS/TEN, and this population should have human leukocyte antigens (HLAs) screened before initiating antiepileptic drugs.<sup>157,158</sup> Other HLA antigens are being recognized in non-Asian populations.<sup>159</sup> Aromatic antiepileptics (phenobarbital, phenytoin, carbamazepine, lamotrigine) tend to cross-react and cannot be substituted for each other. Drugs with longer half-lives are associated with a higher incidence than those related but with shorter half-lives. NSAIDs, including ibuprofen, and acetaminophen<sup>154</sup> may also be triggers and possibly exacerbants with other drugs, and are best avoided during hospitalization for SJS-TEN.

Mycoplasma infection is the most likely infectious trigger of SJS in pediatric patients<sup>148,149,160</sup> and may be associated with less severe disease than drug-induced SJS.<sup>150</sup> Based on a recent literature review of more than 200 cases of mycoplasma-induced “SJS” and “EM” in children, an alternative diagnosis of “Mycoplasma pneumoniae-induced rash and mucositis” has been suggested for this disorder,<sup>161</sup> distinguished clinically by its prominent mucositis (oral, ocular, urogenital) and usually sparse cutaneous involvement. Other infections,<sup>151,152</sup> neoplasia, autoimmune disorders, and vaccination<sup>153</sup> have also been implicated, particularly herpes simplex virus, which is more typically linked to EM.

SJS and TEN are disorders of keratinocyte death (apoptosis), and granulysin is the main mediator.<sup>159</sup> Micro-ribonucleic acid (miR)-18a-5p, which targets an apoptosis gene (*BCL2L10*), has recently been identified as a serum biomarker that can distinguish early TEN from other drug eruptions.<sup>162</sup> Lymphocyte transformation tests have helped to identify the causative agents in some affected children, but in contrast to those for children with DRESS syndrome, need to be performed during the first week of the disorder.<sup>140</sup> The risk of developing SJS and TEN is significantly increased in patients with HIV infection and who have a decreased capacity to detoxify reactive intermediate drug metabolites (e.g., slow acetylators or individuals with defects in epoxide hydrolase-mediated detoxification).

Older children and adults are most likely to develop this spectrum of disorders, but the condition has been described in young infants

**Figure 20-20** Stevens–Johnson syndrome. Note the bullae on the sole in this girl who reacted to lamotrigine.

and neonates.<sup>163</sup> High fever, pronounced constitutional symptoms, and varying degrees of generalized targetoid lesions, bullae, epidermal detachment, and mucosal erosions (of at least two sites) are characteristic (see Table 20-3).<sup>164–166</sup> Patients not uncommonly show a 1- to 14-day prodromal period before the abrupt eruption of the typical features. During this prodromal period, affected children may show fever, malaise, headache, cough, coryza, sore throat, vomiting, diarrhea, chest pain, myalgia, and arthralgias.

Cutaneous involvement most often appears initially on the face and upper trunk. Palms and soles are commonly involved (Figs. 20-20 and 20-21). Erythematous and purpuric macules may develop flaccid gray discoloration or bullae (Figs. 20-22 and 20-23), become confluent, and sometimes detach, leaving a raw, denuded base (Figs. 20-24 and 20-25). Some of the macular lesions may show a dusky center, which gives a target-like (targetoid) appearance; however, the characteristic concentric rings of EM are absent. Some patients show limited targetoid lesions and little detachment (more typical of SJS), and others show extensive detachment (more typical of TEN). The early morbilliform eruption of TEN may be localized but more often is an extensive, painful erythroderma. After exerting light mechanical pressure with a finger to an area of erythema, the epidermis in patients with either SJS or TEN becomes wrinkled and peels off like wet tissue paper (see Fig. 20-25), the characteristic Nikolsky sign. The Nikolsky sign may be seen in patients without clinical evidence of epidermal detachment and can be a useful diagnostic tool. In addition to SJS and TEN, however, the Nikolsky sign may be seen in a variety of other bullous disorders (especially pemphigus, epidermolysis bullosa [see Chapter 13] and the SSSS [see Chapter 14]). Histopathologic examination of affected skin demonstrates necrosis of the lower epidermal cells with a sparse mononuclear cell infiltrate, and in the case of TEN, extensive

**Figure 20-21** Stevens–Johnson syndrome (SJS). Intensely erythematous macules are nearly confluent the palms of this boy with SJS from carbamazepine.

**Figure 20-22** Toxic epidermal necrolysis. Note the extensive small bullae that later coalesced and led to extensive denudation.

**Figure 20-23** Stevens–Johnson syndrome. Purpuric macules became bullous. Note the inflammation of the conjunctivae and lips.

necrosis with a subepidermal split. The epidermal necrosis correlates with the dusky blue coloration of lesions. The nails become dystrophic because of nailbed inflammation (Fig. 20-26).

Extensive mucosal involvement is more typical of SJS than TEN. The mucosal manifestations of SJS tend to occur 1 to 2 days before

**Figure 20-24** Toxic epidermal necrolysis. Note the discrete bullae on the scrotum sloughing of mucosae at the glans. The sloughed skin resembles wrinkled, wet, tissue paper.

**Figure 20-25** Toxic epidermal necrolysis (TEN). Note the sloughing of skin on the ear, which is exacerbated by gentle stroking of the area (positive Nikolsky sign). The mucosal involvement in this boy originally was typical of Stevens–Johnson syndrome, but he progressed to the extensive denudement of TEN.

cutaneous manifestations. The mucous membranes of the lips, tongue, buccal mucosae, eyes, nose, genitalia, and rectum may show extensive bullae with grayish white membranes, characteristic hemorrhagic crusts, and painful superficial erosions and ulcerations (Figs. 20-27 and 20-28). Uncommonly, the esophageal and respiratory epithelial mucosae are affected. By definition, two or more mucosal surfaces are involved. The oral mucosa is always affected, resulting in inability to drink or eat and leading to a risk of dehydration. Genital area lesions lead to painful micturition and defecation. Although lesions of the oral mucosae tend to heal without scarring, strictures or stenosis of esophageal, vaginal, urethral, and anal mucosae have been described as sequelae.

Severe purulent conjunctivitis with photophobia is the typical ocular manifestation (see Fig. 20-28).<sup>167</sup> Corneal ulcerations, keratitis, uveitis, and panophthalmitis may also occur. Sequelae occur in 40% of patients<sup>168</sup> and may be grave, with a possibility of keratoconjunctivitis sicca, corneal ulceration or neovascularization, trichiasis, symblepharon, and partial or even complete blindness.<sup>169</sup> The severity of

### Box 20-3 Features of Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis

Constitutional	
Fever	
Dehydration	
Mucocutaneous	
Stomatitis with hemorrhagic crusts	
Oral and genital erosions	
Dysphagia	
Purulent conjunctivitis with photophobia	
Occasionally esophageal and pulmonary mucosal sloughing	
Dusky erythematous macules, targetoid lesions, bullae, and skin sloughing	
Visceral	
Lymphadenopathy	
Hepatosplenomegaly with hepatitis	
Uncommonly: pneumonitis, arthritis, myocarditis, and nephritis	
Laboratory abnormalities	
Increased erythrocyte sedimentation rate (100%)	
Leukocytosis (60%)	
Eosinophilia (20%)	
Anemia (15%)	
Elevated hepatic transaminase levels (15%)	
Leukopenia (10%)	
Proteinuria, microscopic hematuria (5%)	

**Figure 20-27** Stevens–Johnson syndrome. Mucous membrane involvement with severe swelling and hemorrhagic crusting of the lips.

**Figure 20-28** Stevens–Johnson syndrome. This boy shows early ophthalmic involvement with conjunctival injection, eyelid edema, erythema, and exudative crusting.

the acute ophthalmologic manifestations does not correlate with long-term complications. Pulmonary involvement may occur as an extension from the oropharynx and tracheobronchial tree or may be the result of pneumonitis associated with an initiating viral infection or secondary infection. In extreme cases, renal involvement with hematuria, nephritis, and in some cases, progressive renal failure may result. Esophageal or tracheal ulceration, pyoderma, lymphadenopathy, hepatosplenomegaly with elevated transaminase levels, myocarditis, arthritis and arthralgias, and/or septicemia may also complicate the disorder (Box 20-3).

SJS is most often confused with Kawasaki disease. However, the conjunctivitis of Kawasaki disease lacks exudation, and the mucosal erythema and dryness is not associated with hemorrhagic crust and mucosal denudation<sup>170</sup> (see Chapter 21). The targetoid cutaneous lesions of SJS may resemble the target lesions of EM (see **Erythema Multiforme** section), a disorder usually attributed to herpes simplex infection in children; EM may also show blistering of the lip and oral mucosae that resembles SJS, although the blisters of EM are usually fewer and less symptomatic.<sup>171,172</sup> The cutaneous lesions of EM are more often found on the extremities and/or face, whereas the atypical target or purpuric lesions of SJS are more commonly located on the trunk.<sup>172</sup> Children with the rare immunobullous disorder, paraneoplastic pemphigus, may exhibit the mucocutaneous manifestations of SJS or TEN; the presence of epidermal acantholysis in biopsy specimens and the demonstration of antibody deposition in indirect immunofluorescence testing or immunoblot evaluation of serum allows paraneoplastic pemphigus to be distinguished (see Chapter 13). Other immunobullous disorders may also be confused with TEN (see Chapter 13). TEN and SSSS are usually easily distinguished: the blisters of TEN lead to denudement with keratinocyte apoptosis, whereas the desquamation of SSSS is superficial. In SSSS, the staphylococcal exfoliatin targets desmoglein 1, a desmosome component; because desmoglein 3 in the lower epidermis is able to compensate for desmoglein 1, the blistering of SSSS is superficial rather than panepidermal. SSSS also shows a different distribution with periorificial predominance and not mucosal involvement. Features of TEN occur as a severe manifestation of acute graft-versus-host disease, which is otherwise distinguished by history, other clinical findings, and histologic findings (see Chapter 25).

Although mild cases of SJS may show significant improvement within 5 to 15 days, the course of SJS or TEN is often protracted and may last more than a month. Epidermal detachment may be extensive, leading to massive fluid loss similar to that of a patient with burns. Bacterial superinfection with sepsis, impairment of temperature regulation, severe dehydration, electrolyte imbalance, excessive energy expenditure, and alteration in immunologic function are the usual complications. End-organ failure can be severe despite adequate supportive therapy. In adults, the mortality rate of SJS is 5%, transitional SJS-TEN 10% to 15%, and TEN 30% to 35%. Rates in children have been lower. A composite score (SCORTEN) has been used in adults to predict mortality<sup>173</sup> and has recently been shown to be predictive in pediatric patients of mortality, length of hospital stay, and infectious complications, especially when scored on admission.<sup>174</sup>

SJS and TEN are life-threatening disorders, and patients should be hospitalized. If damage to the epidermis is extensive, patients should

be admitted to an intensive care unit or burn unit to allow special attention to fluid requirements, electrolyte balance, intravenous caloric replacement, and avoidance of secondary infection. If possible, all drugs administered within 2 months before onset of the eruption should be discontinued,<sup>175</sup> and infectious causes should be sought and treated. Severe oropharyngeal involvement often necessitates frequent mouthwashes and local application of a topical anesthetic. When ocular involvement is present, ophthalmologic consultation should be obtained. Most recently, short-term use of potent topical corticosteroids and application of amniotic membrane to the entire ocular surface has been advocated to preserve visual acuity and an intact ocular surface.<sup>176–178</sup> Patients should receive intravenous fluids and either a liquid diet, if tolerated, or parenteral nutrition; the measured resting energy requirement in pediatric SJS/TEN is increased by 30%.<sup>179</sup> A mouthwash containing Maalox, elixir of diphenhydramine, and viscous lidocaine (mixed 1:1:1) can be soothing and decrease pain. Oral histamines such as hydroxyzine or diphenhydramine can be beneficial, and more vigorous pain control is often necessary. Of note, TEN has also been associated rarely with acetaminophen ingestion in children.<sup>180</sup>

Manipulation should be avoided, but if necessary, should be performed in a sterile fashion. Intact areas of skin should be kept dry. Open wounds should be cleansed daily. Detached areas should be covered with nonadherent, moist dressings (such as petrolatum-impregnated gauze) until reepithelialization occurs. Periorificial areas can be treated with antibiotic ointment (such as bacitracin or mupirocin). Biologic dressings or skin equivalents may be considered for patients with extensive denudation.<sup>181</sup>

The response to supportive care alone has been excellent in the majority of children.<sup>182</sup> The administration of systemic medications as treatment is controversial, and there is little evidence-based data to support its use, especially in pediatric patients. Short-term administration of intravenous systemic corticosteroids (4 mg/kg per day) or pulsed intravenous steroids is sometimes advocated if started within the first 2 to 3 days of a drug-induced reaction.<sup>183,184</sup> However, several anecdotal reports and open-label, noncomparative trials have not demonstrated efficacy.<sup>185</sup> Continuing use of systemic steroids may increase morbidity and mortality from secondary infection, prolonging wound healing, masking early signs of sepsis, and triggering gastrointestinal bleeding. IVIG has been promoted as treatment of SJS and particularly TEN. Although some children with SJS or TEN have had shorter duration of fever and decreased development of new blisters with early administration (within 24 to 48 hours) of 2.5 to 3 g/kg per day IVIG for 3 days,<sup>186–189</sup> other studies have shown no benefit to the use of IVIG,<sup>190</sup> including for pediatric disease.<sup>191,192</sup> Double-blind, randomized, controlled trials have not been performed. Cyclosporine, cyclophosphamide, and plasmapheresis<sup>193</sup> have also been used anecdotally with good results. Thalidomide administration has been linked to increased mortality in a randomized placebo-controlled trial.<sup>194</sup>

Long-term sequelae occur in 45% of affected children, including cutaneous dyschromia in 42%, which may persist for years.<sup>148</sup> Sun exposure should be avoided and sunscreens used liberally for at least a few months because of the potential for ultraviolet light-induced worsening of the residual dyspigmentation. Persistent nail dystrophy or onychia is also commonly reported (see Fig. 20-26).<sup>169</sup> Late ocular complications include dry eye syndrome (59%), subconjunctival fibrous scarring (33%), corneal erosions (29%), and in fewer than 25%, trichiasis, symblepharon, and visual loss.<sup>195</sup> Artificial tears and lubricants may be required for several years after diagnosis, if not lifelong, because ocular disease tends to progress after hospital discharge. A high rate of recurrence of SJS in children has recently been disclosed, with approximately 20% of children readmitted at least once for recurrent episodes. These episodes occurred between 2 months to 7 years after the index episode and were more often related to drug ingestion than mycoplasma infection.<sup>148,196</sup>

## Fixed Drug Eruption

*Fixed drug eruption* is a term used to describe a sharply localized, circumscribed round or oval dermatitis that characteristically recurs in

the same site or sites each time the offending drug is administered.<sup>197,198</sup> The persistent residual hyperpigmentation leads to the name of the eruption, although occasionally lesions do not become pigmented.<sup>199</sup> In one series, fixed drug eruption was second in incidence to exanthematous reactions to drugs and occurred in 22% of children with cutaneous reactions to drug ingestion.<sup>200</sup> Lesions first occur 1 to 2 weeks after initial ingestion of the drug, but within 30 minutes to 8 hours after subsequent exposures. Fixed drug eruptions are type IV immune reactions and have recently been shown to result from CD8+ memory T cells that persist intraepidermally at site of involvement and, upon stimulation by drug, release interferon (IFN)- $\gamma$ , leading to inflammation. Fas–Fas ligand interactions lead to the demonstrated basal keratinocyte apoptosis.

Lesions are solitary at first, but with repeated attacks, new lesions usually appear and existing lesions may tend to increase in size to more than 10 cm in diameter. Not uncommonly, lesions recur at the same site(s). The lesions tend to be erythematous, edematous, and dusky at their onset with well-defined borders. At times they may become bullous (Fig. 20-29), with subsequent desquamation or crusting and a residual hyperpigmentation that may persist for months (Fig. 20-30). Lesions can occur anywhere on the body but have a predilection for the perioral area, lips, hands, trunk, and genital region.<sup>201,202</sup> In a series of affected boys with genital involvement, the clinical presentation usually consisted of swelling and erythema of the penis and/or scrotum associated with pruritus or burning, restlessness, urinary retention, and painful micturition.<sup>202</sup>

By far the most common trigger of fixed drug eruptions in children is cotrimoxazole and other sulfa drugs. Acetaminophen, ibuprofen,<sup>203</sup>

**Figure 20-29** Fixed drug eruption. Well-defined, dusky erythematous plaques that may be bullous.

**Figure 20-30** Fixed drug eruption. The residual hyperpigmentation at the site of a fixed drug eruption may persist for months.

and less commonly, loratadine<sup>204</sup> and pseudoephedrine have also been causative, and a careful history of administration of over-the-counter products is of key importance. Although phenolphthalein was a common cause in the past, its elimination from over-the-counter laxatives has markedly diminished its culpability. Other causative preparations include phenytoin, ciprofloxacin, metronidazole, penicillin, tetracyclines, erythromycin, teicoplanin,<sup>205</sup> quinine and its derivatives, salicylates, potassium iodide, and metronidazole. Fixed food eruptions have been described after ingestion of various food substitutes and flavorings (especially tartrazine, as in artificially colored cheese crisps),<sup>206</sup> as well as licorice, cashews, lentils, and asparagus.

The diagnosis of fixed drug eruption is often missed, leading to repeated ingestion of the medication and recurrence. Lesions may be mistaken commonly for insect bites, urticaria, and, if more extensive, EM or in their stage of hyperpigmentation for erythema dyschromicum perstans. Biopsy can aid in the diagnosis of fixed drug eruption, especially in the early stage in which a lichenoid infiltrate with necrotic keratinocytes may be seen. Avoidance of the offending agent is key, but the associated pruritus can be controlled by application of medium-strength to potent topical corticosteroids. If necessary, challenge with the drug usually confirms the causative agent within 30 minutes to 8 hours, but theoretically can trigger a more severe reaction. Patch testing at the site of a previous lesion can lead to a positive result in up to 30% of patients.<sup>207</sup>

## Acute Generalized Exanthematous Pustulosis

Acute generalized exanthematous pustulosis (AGEP) is characterized by the acute onset of a generalized erythroderma topped with small, nonfollicular, sterile, pinpoint pustules, usually in association with fever (Figs. 20-31 and 20-32). The pathogenesis is poorly understood, but some cases have had variants in the gene encoding the IL-36 receptor antagonist (see Deficiency of IL-36 Receptor Antagonist [DITRA] section, Chapter 4).<sup>208</sup> The condition usually resolves spontaneously after 4 to 10 days with a characteristic pattern of desquamation. AGEP has been described in several children,<sup>209,210</sup> although it is much more common in adults. Medication has been the usual trigger in adults and can cause AGEP in children.<sup>211–213</sup> Among triggering agents have been antibiotics (amoxicillin-clavulanate, cephalosporins, macrolides, clindamycin, and terbinafine), paroxetine, and contrast agents. The majority of affected children, however, are administered no medication, suggesting that the condition is often triggered in response to viral infection or possibly vaccine administration.<sup>210</sup> Pustular psoriasis is the key differential diagnosis.

**Figure 20-31** Acute generalized exanthematous pustulosis. Affected individuals show large areas with erythroderma topped with nonfollicular, tiny, sterile pustules, usually in association with fever. Although often triggered by a virus or vaccination in children, this boy was taking an antiepileptic medication.

## Erythema Multiforme

Erythema multiforme (EM) is a specific self-limited hypersensitivity syndrome with a distinctive clinical pattern, the hallmark of which is the erythematous ring (the so-called *iris* or *target* lesion). The condition can occur at any age but is most commonly seen in young adults; 20% of cases occur in children. The majority of cases of EM in children are precipitated by herpes simplex virus (HSV) type 1 infection,<sup>214</sup> although HSV type 2 infection has been described in affected adolescents.<sup>215,216</sup> Approximately 50% of cases follow herpes labialis infection, usually by 3 to 14 days, although concurrent infection and EM have been noted. HSV deoxyribonucleic acid (DNA) has been detected in the early erythematous papules or the peripheral area of target lesions in 80% of patients with EM<sup>215</sup> despite the low recovery of herpes simplex in cultures of lesions.<sup>217</sup> When associated with HSV, the disorder has been termed *herpes-associated EM (HAEM)*. Other viral disorders, including varicella,<sup>218</sup> orf, and EBV infection, have been implicated, and histoplasmosis has been associated in endemic areas. EM in association with high fever can be a sign of Kawasaki disease, especially in infants<sup>219</sup> (see Chapter 21, Fig. 21-31).

The diagnosis of EM can generally be made by the clinical features and distribution of lesions (Box 20-4). The eruption is symmetric and may be noted on any part of the body, with a predilection for the palms and soles (Fig. 20-33), backs of the hands and feet, and extensor surfaces of the arms and legs. Lesions may be grouped, especially at the elbows and knees. As the disorder progresses over 72 hours (and occasionally as long as a week), lesions may extend to the trunk, face, and neck. Once present, lesions are fixed for at least 7 days.

The primary lesion of EM develops abruptly without a prodromal period (Figs. 20-34 and 20-35). The classic lesion is a “target” or “iris” lesion, in which there are three concentric zones: a central dusky cyanotic or violaceous region, a paler edematous zone, and a peripheral red ring, thus creating the multiformity of lesions. The central dusky clearing represents epidermal cell necrosis. Atypical papular lesions may have only two zones or poorly defined borders. Lesions may also become bullous (bullous EM) (Fig. 20-36), but in contrast to epidermal necrolytic disorders, less than 2% of the body surface area is generally involved. Careful inspection of the eruption in EM may disclose fine petechiae. Most lesions are asymptomatic, but itching or burning has been described. The isomorphic response

### Box 20-4 Clinical Features of Erythema Multiforme

- Acute, self-limited, recurrent course
- Duration of 1 to 4 weeks
- Symmetrically distributed, fixed lesions
- Concentric color changes in at least some lesions (“iris” or “target” lesions)
- If present, mucosal involvement limited to the mouth
- In children, most likely cause for recurrent disease is herpes simplex virus

**Figure 20-32** Acute generalized exanthematous pustulosis. Pinpoint sterile papulopustules overlying erythroderma. No medication was associated, and the condition was attributed to a virus.

**Figure 20-33** Erythema multiforme (EM). Round erythematous swollen plaques and target lesions on the palms. This girl developed in EM in association with her systemic lupus erythematosus.

**Figure 20-36** Erythema multiforme, bullous. If central epidermal necrosis is extensive, the center of the lesion may become bullous.

**Figure 20-34** Erythema multiforme. Classic target lesions and marginated wheals with central vesicles are characteristic.

**Figure 20-37** Erythema multiforme (EM). The trigger for erythema multiforme in children is commonly herpes simplex infection, which often precedes EM but may be detectable at the time when the EM is present.

**Figure 20-35** Erythema multiforme. Extensive target lesions on the thighs of a 12-year-old girl. The recurrent reaction was suppressed by administration of oral acyclovir.

(koebnerization) appears to participate in the development of lesions, with trauma and ultraviolet light injury as triggers.

Oral lesions are seen in 25% to 50% of children, usually in conjunction with cutaneous lesions. They initially appear as bullae that break soon after formation, accompanied by swelling and crusting of the lips

and erosions of the buccal mucosa and tongue. Gingival involvement is rare, which helps to distinguish EM from primary herpes simplex infection of the mouth (Fig. 20-37). Most children with mucosal involvement have a few lesions and are mildly symptomatic; however, patients with extensively crusted lips and large bullous target lesions that may mimic SJS have been described.<sup>171,172</sup> Systemic manifestations, when present, are mild and consist of low-grade fever, malaise, and in rare cases, myalgia or arthralgia.

Biopsy of skin lesions is usually not needed to make a diagnosis of EM. It should be performed only to consider other conditions such as lupus erythematosus or vasculitis.<sup>220</sup> Focal liquefaction degeneration of epidermal keratinocytes and exocytosis of mononuclear cells in the epidermis are seen.

Most episodes of EM heal within 2 to 3 weeks without sequelae. Recurrences a few times yearly, however, are common. Symptomatic treatment with oral antihistamines usually suffices. Given the association with HSV, however, prophylactic therapy with oral acyclovir (5 to 10 mg/kg per day) for 6 to 12 months should be considered for patients with recurrent disease.<sup>215</sup> Episodic therapy with acyclovir is not useful. Administration of immunosuppressive agents, such as oral corticosteroids, leads to longer and more frequent episodes.

### Annular Erythemas

The annular erythemas (erythema marginatum, erythema annulare centrifugum [EAC], erythema migrans, and annular erythema of

infancy) represent a group of reactive vascular dermatoses that are distinguished primarily by their oval, annular, arcuate, circinate, polycyclic, reticular, or serpiginous configurations with individual characteristics that allow differentiation into distinctive clinical categories.<sup>221</sup> They must be distinguished from other annular lesions seen in children, especially tinea, urticaria multiforme, EM and SSLR, annular pityriasis rosea, neonatal and subacute lupus erythematosus, granuloma annulare, and the annular lesions of erythrokeratoderma variabilis (see Chapter 5).

### ERYTHEMA MARGINATUM AND RHEUMATIC FEVER

Erythema marginatum is a distinctive form of annular erythema that occurs on the trunk (especially on the abdomen) and the proximal extremities of patients with active rheumatic fever.<sup>222,223</sup> It is seen more commonly in children than in adults with rheumatic fever but still only occurs in 6% of affected children.<sup>224</sup> The occurrence of erythema marginatum often follows the onset of migratory arthritis by a few days, but at times may also occur many months after the carditis.

Often easily overlooked, lesions are evanescent pink macules or papules that fade centrally in a few hours to several days, leaving a pale or sometimes pigmented center. They spread rapidly to form non-pruritic rings or segments of rings with elevated reticular, polycyclic, or serpiginous borders and may recur in crops in different areas. Lesions are commonly seen more easily in the afternoon, and coalescence of polycyclic lesions often results in a characteristic chicken wire-like appearance. Gentle warming of the skin tends to enhance visualization of pale or barely perceptible lesions. Although the eruption seldom lasts more than several weeks, occasionally it may recur at sporadic intervals for several months to years.

Erythema marginatum presents a clinical picture that characteristically resembles a variety of dermatoses, including urticaria, EM, and other transient figurate erythemas.<sup>225</sup> Unlike the characteristic rash of juvenile idiopathic arthritis (see Chapter 22), lesions of erythema marginatum are larger, spread centrifugally with central clearing, and are limited to the trunk and sometimes the proximal limbs. Histologic features of a neutrophilic perivascular infiltrate in the papillary dermis aid in diagnosis.

The most common associated features are carditis (76% to 93% of patients), fever (62%), congestive heart failure (44%), and arthritis (39% to 53% of patients). Sydenham chorea is rarely seen. Approximately 2% of patients show urticarial lesions without annular rings,<sup>226</sup> and up to 2% have subcutaneous nodules, usually a late manifestation. The nodules of rheumatic fever are smaller than those seen in juvenile idiopathic arthritis and usually clear within a month. They tend to occur in crops, are symmetrically distributed, are nontender, and are more readily felt than seen, requiring a careful search. Differentiation of subcutaneous nodules of rheumatic fever from rheumatoid nodules and granuloma annulare is not possible on clinical or histologic grounds alone and requires the presence of other features.

Currently accepted criteria for the diagnosis of rheumatic fever include two major or one minor manifestation and evidence of recent group A streptococcal disease. The major manifestations include erythema marginatum, carditis, polyarthritis, chorea, and subcutaneous nodules. The minor manifestations include fever, arthralgias, previous rheumatic fever or rheumatic heart disease, leukocytosis, elevated erythrocyte sedimentation rate or positive C-reactive protein, and prolonged PR interval. Typical erythema marginatum has also been described in a patient with psittacosis.<sup>227</sup>

### ERYTHEMA ANNULARE CENTRIFUGUM

Erythema annulare centrifugum (EAC) is an eruption characterized by persistent erythematous annular lesions, each with a clear center and a raised, thin, wall-like border that slowly enlarges centrifugally. Synonyms for EAC include *gyrate erythema* and *erythema perstans*.

Primary lesions of EAC tend to be single or multiple erythematous, edematous papules with a predilection for the trunk, buttocks, thighs, and legs (Figs. 20-38 and 20-39). They are asymptomatic except for occasional mild pruritus. The rings extend peripherally, usually slowly,

**Figure 20-38** Erythema annulare centrifugum (EAC). Slowly expanding annular lesions have dusky centers and palpable scaly erythematous borders. Although the annular rings showed no evidence of fungus, the EAC was thought to result from the patient's underlying tinea pedis.

**Figure 20-39** Erythema annulare centrifugum. No cause was found for the recurrent annular lesions in this infant.

1 to 3 mm/day, sometimes up to 4 cm in a week. New lesions may form within the original circle. The resulting overall shape may be irregular, oval, circinate, semiannular, target-like, or polycyclic. The borders may eventually reach a size of 10 cm or more in diameter. The duration of the disease is extremely variable and may go on for weeks or months and, with new lesions appearing in successive crops, often for years.

At times the palpable border of the expanding ring may be topped by microvesicles or may show a fine collarette of scale on its trailing edge, suggesting a diagnosis of tinea corporis. Fungal infections can be distinguished by their more pronounced epidermal changes, with vesication or scaling or both at the edge of the lesions, by microscopic examination of skin scrapings, and by fungal culture. When the diagnosis is uncertain, histopathologic examination of cutaneous lesions showing focal infiltration of lymphocytes around the blood

**Figure 20-40** Erythema annulare centrifugum. This 10-year-old boy has had chronic, transitory annular plaques on the face, trunk, and extremities since the first weeks of life. They only clear transiently with febrile episodes.

vessels and dermal appendages in a “coat sleeve” arrangement may help to establish the diagnosis.

The etiology of EAC is unknown. Although it often occurs without apparent cause, most cases appear to be related to hypersensitivity to drugs, fungi, viruses (*molluscum poxvirus*<sup>228,229</sup> and *herpes zoster*,<sup>230</sup> certain foods, blood dyscrasias, autoimmune endocrinopathies or hepatitis,<sup>231</sup> or neoplastic disease (lymphomas). A neonate with EAC in association with *pseudomonas* sepsis infection has been described.<sup>232</sup>

Because EAC represents a hypersensitivity reaction, treatment depends on the determination and removal of the underlying cause. Antihistamines produce variable and usually incomplete relief; topical corticosteroids tend to be ineffective. Although systemic corticosteroids may aid the temporary resolution of lesions, unless the underlying cause is removed, the disorder commonly recurs as soon as medication is discontinued. Empiric treatment with oral fluconazole is often dramatically effective (personal communication, AJM), suggesting that fungal disorders are a common trigger. Cases with onset during the neonatal period or early infancy and persistence into adulthood have been described (Fig. 20-40).<sup>233,234</sup> The eruption in these cases clears with febrile episodes or subcutaneous administration of IFN- $\alpha$ .

### Annular Erythema of Infancy

Annular erythema of infancy may be a subset of EAC or a distinct entity in which infants have cyclic eruptions of urticarial annular erythema without a demonstrable underlying cause.<sup>235</sup> Lesions of classic annular erythema of infancy last for only a few days, in contrast to the more persistent lesions of EAC. This benign disorder is asymptomatic. It may resolve spontaneously after 3 to 11 months.<sup>235</sup> Neonatal lupus (see Chapter 22) must be considered. Neutrophilic figurate erythema of infancy is considered a neutrophilic variant of annular erythema of infancy, although the recurrences of the annular erythema may continue beyond infancy.<sup>236</sup>

### ERYTHEMA MIGRANS

Erythema migrans (erythema chronicum migrans), the earliest sign of Lyme disease, is a cutaneous eruption that occurs after a tick bite and is characterized by single or multiple erythematous expanding lesions with advancing indurated borders and central clearing (see Chapter 14). Erythema migrans is caused by the tick-borne spirochete *Borrelia burgdorferi* (see Figs. 14-40 and 14-41).

### Panniculitis

**Panniculitis** is a term to describe a group of disorders in which the major focus of inflammation is in the subcutaneous fat (Box

### Box 20-5 Classification of the Subtypes of Panniculitis

H syndrome
CANDLE syndrome

CANDLE, Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature.

**20-5).**<sup>237-240</sup> The pathomechanism of most of these disorders is poorly understood. The most common subgroup is erythema nodosum, which is often associated with streptococcal infection in children but is considered a hypersensitivity disorder seen with several systemic disorders. Other forms of panniculitis are also commonly linked to systemic disorders, particularly collagen vascular disorders (see Chapter 22), Behcet syndrome (Chapter 25), lymphomas (see Chapter 10), diabetes (see Chapter 23), thyroid disease,  $\alpha_1$ -antitrypsin or pancreatic enzyme deficiency, and in association with generalized lipodystrophy. Disorders of the dermis, such as leukocytoclastic vasculitis and granuloma annulare, may show subcutaneous involvement but would not be considered primarily panniculitides. Infection may also lead to panniculitis, for example, especially with tuberculosis and erythema induratum of Bazin and less commonly with atypical mycobacterial infection<sup>241-244</sup> (see Chapter 14). Particularly in children who are immunocompromised, lobular panniculitis can be a feature of deep fungal infection (candidiasis, fusariosis,<sup>245</sup> aspergillosis, cryptococcosis, histoplasmosis, sporotrichosis, and chromomycosis) or bacterial infection (e.g., *Neisseria meningitidis*, *Streptococcus pyogenes*, *S. aureus*, *Klebsiella*, and *Pseudomonas* and *Nocardia* species).<sup>246</sup> Subcutaneous fat necrosis of the newborn and sclerema neonatorum are discussed in Chapter 2.

Classification of the panniculitides may be difficult, and several previous subtypes such as Weber–Christian disease and Rothman–Makai syndrome are no longer considered to be separate entities. Histopathologic evaluation of a biopsy large enough to include subcutaneous fat is often required to confirm the diagnosis of a specific form of panniculitis. Sections may show primarily septal involvement, as in erythema nodosum, or be lobular, as in the panniculitis associated with  $\alpha_1$ -antitrypsin disease. A largely lobular form with needle-shaped clefts within lipocytes is characteristic of subcutaneous fat necrosis of the newborn, sclerema neonatorum, and poststeroid panniculitis,<sup>247</sup> whereas necrosis is an early finding of the panniculitis induced by pancreatic enzymes.<sup>248,249</sup>

Cold panniculitis, which is most common in infants and children, is characterized by painful, poorly defined, erythematous plaques or subcutaneous nodules that develop in areas exposed to cold (Fig. 20-41).<sup>250</sup> Lesions appear several hours to 3 days after exposure and subside spontaneously, generally after a few weeks to a few months, leaving

**Figure 20-41** Popsicle panniculitis. This subtle erythematous macule resulted from cold panniculitis of the cheek after sucking on a popsicle. At times, the erythema is much more intense.

temporary residual pigmentation. The development of cold panniculitis in children appears to be related to the fact that subcutaneous fat solidifies more readily at lower temperatures in infants and young children than it does in adults. Cold panniculitis is often seen on the cheeks of toddlers and young children who suck popsicles ("popsicle panniculitis"),<sup>251</sup> at sites of contact with ice bags, cooling blankets before cardiac surgery or in treatment of arrhythmias,<sup>252</sup> and on the thighs and buttocks of young equestrians ("equestrian panniculitis"). Affected children are otherwise usually healthy, and no intervention is necessary.

The red or purple-red nodules of factitial panniculitis result from the injection of foreign substances into the subcutaneous tissue. Diagnosis requires a high index of suspicion but can be confirmed if foreign material is found in biopsy sections. For example, polarized light microscopic examination may show birefringent particles or, as in the case of injected silicone, oily substances with a characteristic Swiss cheese-like picture of oil cysts surrounded by fibrosis and inflammation. Milk, feces, mineral oil, and paraffin are among other substances that may be injected, leading to factitial panniculitis. In young children, these factitial lesions raise the possibility of Munchausen syndrome by proxy<sup>253</sup> (see Chapter 26).

Poststeroid panniculitis, a rare entity of childhood, is characterized by small, sometimes pruritic or painful subcutaneous nodules on the cheeks, arms, trunk, and buttocks of young children. These generally develop within 2 to 4 weeks after the sudden discontinuation of systemic corticosteroid therapy.<sup>254</sup> Lesions tend to regress spontaneously without scarring.

Panniculitis can be a feature of malignancy, particularly lymphoma. Subcutaneous panniculitis-like T-cell lymphoma more commonly occurs in adolescents but has been described in infants<sup>255–257</sup> (see Chapter 10).<sup>258,259</sup> Patients develop skin-colored to erythematous, often painful, subcutaneous nodules or hemorrhagic plaques. Fever, mucosal ulcerations, hepatosplenomegaly with hepatic failure, pancytopenia, and intravascular coagulopathy are associated features. Biopsy sections show often atypical lymphocytes surrounding adipocytes (lobular panniculitis). The minority of affected children have associated hemophagocytosis, which portends a poor prognosis. In children, in contrast with adults, the face is commonly affected and systemic involvement is more common. Molecular genetic analysis and immunophenotyping should be performed; most show clonal rearrangement. Suggested treatment includes initial administration of cyclosporine and prednisone for the inflammatory component, followed by combination chemotherapy for the lymphoma. Bexarotene has recently shown efficacy.<sup>260</sup>

**Figure 20-42** Traumatic fat necrosis. The panniculitis occurred after blunt trauma to the cheek and led to lipoatrophy.

Cytophagic histiocytic panniculitis is characterized by chronic panniculitis in association with fever, hepatosplenomegaly, and pancytopenia because of bone marrow hemocytophagocytosis. Histologically, the finding of cytophagic histiocytic panniculitis represents a reaction pattern that may be benign (in association with infection, especially EBV) or may prove to be associated with subcutaneous T-cell lymphoma. Panniculitis in association with vasculitis is a feature of hydroa-like lymphoma associated with EBV infection (see Chapter 19).

$\alpha$ 1-Antitrypsin is a protease inhibitor made by the liver. Most normal individuals carry the MM genotype (i.e., both alleles are M) and have normal levels of  $\alpha$ 1-antitrypsin. Heterozygotes with one S or Z allele have a moderate deficiency of the inhibitor; individuals who are homozygous for the Z allele have a severe  $\alpha$ 1-antitrypsin deficiency. The clinical manifestations of  $\alpha$ 1-antitrypsin deficiency in children or adults may be cirrhosis, emphysema, pulmonary effusions, pulmonary embolism, membranous proliferative glomerulonephritis, pancreatitis, arthritis, vasculitis, angioedema, and panniculitis.<sup>261</sup> The panniculitis is usually seen in homozygotes but has been described in heterozygotic pediatric patients, including the MS phenotype.<sup>262</sup> It is characterized by erythematous to purple tender nodules or plaques most commonly seen on the lower trunk, buttocks, and proximal extremities after trauma. Deep necrotic ulcerations may develop and discharge an oily material. Lesions are often persistent and resistant to therapy but eventually heal with scarring and atrophy. Replacement of  $\alpha$ 1-antitrypsin by intravenous infusion is the most effective therapy and can lead to rapid clearance of the panniculitis.

Patients with cutaneous polyarteritis nodosa (PAN), a form of deep dermal and subcutaneous vasculitis, typically show painful oval or linear nodules on the lower extremities surrounded by livedo reticularis and often stellate necrosis (see Chapter 21, Figs. 21-16 and 21-17).<sup>263</sup> Raynaud phenomenon is rarely described, but digital lesions may progress to gangrene.<sup>264</sup> Streptococcal pharyngitis may precede the eruption.<sup>265</sup> Although the cutaneous features may manifest as an isolated benign form, the multisystemic form of PAN should be considered in children with distal livedo reticularis and distal ischemic necrosis in association with weight loss, fever, abdominal pain, musculoskeletal signs, renal disease, and peripheral neuropathy.<sup>266–268</sup> Mutations in *CECR1*, encoding adenosine deaminase 2, have recently been described as causative in families with systemic PAN.<sup>269</sup>

Other forms of panniculitis include pancreatic panniculitis, a disorder that probably results from breakdown of subcutaneous fat caused by enzymes released into the circulation from a nodular or neoplastic pancreatic disease; erythema induratum, a deep-seated subcutaneous infiltration of the lower legs, especially the posterior calves, that often ulcerates before healing and results in atrophic scars (see Chapter 14); and traumatic panniculitis, a disorder consisting of hard, indurated, inflamed nodules that occur after injury (Fig. 20-42). Lobular panniculitis may also lead to lipoatrophy (Fig. 20-43).<sup>270–272</sup> Most often seen with systemic lupus erythematosus,<sup>273</sup> deep morphea and juvenile dermatomyositis<sup>274</sup> may also manifest with panniculitis that resolves with lipoatrophy (see Chapter 22). Residual lipoatrophy at the ankles in association with lobular panniculitis and lipophages has

**Figure 20-43** Panniculitis and lipodystrophy. This teenager had autoimmune hepatitis and acanthosis nigricans in association.

**Figure 20-45** Erythema nodosum. These inflamed nodules proved to be a hypersensitivity reaction to group A  $\beta$ -hemolytic streptococcal infection.

**Figure 20-44** Erythema nodosum. Tender, red, oval nodules on the extensor aspect of the legs. Note that several have darkened and resemble bruises.

been described with and without autoimmune disorders of other types, particularly thyroiditis and diabetes mellitus.<sup>275–277</sup> Panniculitis and lipoatrophy (particularly of the buttocks) are also features of *H syndrome*, an autosomal recessive disorder with panniculitis resulting from mutations in *SLC29A3*, a nucleoside transporter.<sup>278–281</sup> *H syndrome* is characterized by hyperpigmentation (often with induration) and hypertrichosis of the inner thigh that usually spreads to involve the middle and lower parts of the body with conspicuous sparing of the knees and buttocks. Patients also show hepatosplenomegaly, heart anomalies, and hypogonadism. Panniculitis with vasculitis and atypical cells is also a feature of chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE) syndrome (see Sweet Syndrome [Acute Febrile Neutrophilic Dermatosis] section).<sup>282</sup>

## Erythema Nodosum

Erythema nodosum is a hypersensitivity reaction characterized by red, tender, nodular lesions.<sup>283</sup> Occurrence peaks during adolescence and is rare in children younger than 2 years of age. During childhood, girls are affected slightly more than boys, in contrast to adults, in which women are affected three to four times more often than men. The disease has its greatest incidence in the spring and fall and is less common in summer.

Lesions are most often seen on the pretibial surfaces (Fig. 20-44) but occur more commonly in affected children on the thighs, arms, trunk, and face than in adults.<sup>284</sup> They are most often 1 to 5 cm in diameter and are symmetrically distributed. Lesions are occasionally located on the knees, ankles, thighs, extensor aspects of the arms, the face, and the neck. They are rarely found on the palms or soles (Fig. 20-45). Initially they appear as bright to deep red, warm, tender, oval, slightly elevated nodules. After a few days they develop a brownish red

### Box 20-6 Underlying Causes of Erythema Nodosum

Idiopathic (=50%)

Infections

$\beta$ -Hemolytic streptococcal infection, especially pharyngitis (most common detectable cause)

Mycoplasma, upper respiratory viruses (Epstein-Barr virus), mycobacteria (tuberculosis and atypical), coccidiomycosis in endemic areas

Uncommon: *Trichophyton mentagrophytes*, *Yersinia*, *Shigella*, hepatitis B, brucellosis, meningococcosis, Neisseria infection, cat-scratch disease, human immunodeficiency virus infection, *Chlamydia*, blastomycosis, histoplasmosis, sporotrichosis, syphilis, pertussis, *Escherichia coli*, leprosy

Inflammatory

Sarcoidosis

Inflammatory bowel disease

Behcet disease

Malignancy (especially leukemia)

Drugs

Oral contraceptives, sulfonamides, penicillins

Pregnancy

or purplish bruise-like appearance that is characteristic. Lesions do not ulcerate or leave scars.

Despite investigation, no underlying cause is found in most pediatric patients. Although possible etiologic causes are numerous (Box 20-6), the most common in the pediatric patient is  $\beta$ -hemolytic streptococcal infection. The list of other associated disorders is long, especially other infectious diseases (including tuberculosis, *Yersinia* infection, *Trichophyton mentagrophytes*<sup>285</sup> and infectious mononucleosis), administration of oral contraceptives, inflammatory bowel disease, celiac disease, and sarcoidosis.<sup>286–291</sup> In patients with coccidiomycosis, the presence of erythema nodosum suggests a positive prognostic sign and decreased risk of dissemination. Erythema nodosum leprosum shows panniculitis with leukocytoclastic vasculitis in biopsy sections.<sup>292</sup>

The eruption usually lasts 3 to 6 weeks but may recede earlier. Recrudescences may occur over a period of weeks to months, but attacks are seldom recurrent. Arthralgias may precede, coincide with, or follow the eruption in as many as 90% of cases. In the 10% of patients in whom the condition may present as a recurring disorder, recurrences are often associated with repeated streptococcal infection.

Erythema nodosum has a characteristic clinical picture, and diagnosis generally can be made on the basis of physical examination alone. Although diagnosis is usually not difficult, common bruises, cellulitis or erysipelas, deep fungal infections (such as Majocchi granuloma or sporotrichosis), insect bites, deep thrombophlebitis, angiitis, erythema induratum, and fat-destructive panniculitides can be confused with this disorder. Eccrine hidradenitis can resemble erythema nodosum on the palms or soles.<sup>293</sup> When the diagnosis is in doubt, bacterial and fungal cultures and histologic examination of skin biopsy specimens generally will help clarify the diagnosis.

The management of erythema nodosum is directed at identification and treatment of the underlying cause. Minimal evaluation usually involves obtaining a complete blood count (CBC), throat culture, an antistreptolysin O (ASO)/deoxyribonuclease (DNase) B titer, chest radiograph, and tuberculin testing. Bed rest with elevation of the patient's legs helps reduce pain and edema. When pain, inflammation, or arthralgia is prominent, NSAIDs can be prescribed. Salicylates, colchicine, potassium iodide and if severe, a short course of systemic corticosteroids are the most commonly used alternative therapies. In chronic or recurrent cases, detailed investigations must be performed to uncover the underlying cause. Intralesional corticosteroids commonly cause rapid involution of individual lesions, and in persistent or recurrent eruptions oral corticosteroids may be beneficial.

## Eccrine Hidradenitis

Idiopathic palmoplantar hidradenitis occurs suddenly in otherwise healthy children as erythematous painful nodules on the palms and soles.<sup>294</sup> The condition has been linked to vigorous physical activity, excessive sweating, and prolonged exposure to moisture. Some have suggested that this disorder may in some patients be synonymous with "Pseudomonas hot foot syndrome" (see Chapter 14). Lesional biopsies show neutrophilic perieccrine infiltrates, and the lesions are thought to result from mechanical rupture of the eccrine glands. Plantar surfaces are more commonly involved, leading to consideration of erythema nodosum, EM, bite reactions, chilblains, cellulitis, and embolic disease. In one affected infant, the eccrine hidradenitis delayed walking.<sup>295</sup> Although episodes recur in up to 50% of children, resolution typically occurs in 1 to 4 weeks, especially with rest. Therapy with topical and systemic corticosteroids is not clearly beneficial, although NSAIDs are often prescribed. Colchicine has also been used.<sup>296</sup>

Another form of eccrine hidradenitis is neutrophilic eccrine hidradenitis, a complication of cancer chemotherapy. Neutrophilic eccrine hidradenitis tends to develop 7 to 14 days after initiating chemotherapy, most commonly cytarabine. The disorder reflects the direct cytotoxicity of chemotherapy to the eccrine glands. Affected children are usually febrile, and the eruption is most commonly characterized by erythematous papules and plaques on the trunk, extremities, and face.<sup>297</sup>

## Cutaneous Reactions to Cold

A variety of conditions can occur when one is exposed to cold. Frostbite is caused by exposure to extreme cold. Trench foot and immersion foot are caused by a combination of cold and wetness. Perniosis (chilblains) represents an exaggerated response to cold and dampness in a predisposed individual. Individuals may also develop cutaneous changes after exposure to cold with dysproteinemia, such as with cryofibrinogenemia or cryoglobulinemia.

### FROSTBITE

Frostbite is a disorder caused by the actual freezing of tissue at temperatures of extreme cold ( $-19^{\circ}\text{C}$  to  $-23^{\circ}\text{C}$  [ $-2^{\circ}\text{F}$  to  $-10^{\circ}\text{F}$ ]).<sup>298,299</sup> The duration of exposure, wind velocity, dependency of an extremity, application of emollients, and factors such as fatigue, injury, immobility, and general health potentiate the effects of the cold.<sup>300</sup> Frostbite is caused by direct cold injury to the cell, vascular insufficiency (constriction and vasoocclusion), and damage from inflammatory mediators. The vasoconstriction that occurs is an effort to conserve core body temperature at the expense of the distal extremities. Frostbite generally affects exposed areas such as the toes, feet, fingers, nose, cheeks, and ears. Rarely, frostbite has resulted elsewhere from application of an ice pack<sup>301</sup> or from improper use of commercially available cryotherapy devices for wart removal.<sup>302</sup>

Four degrees of severity have been described. Frostnip, or first-degree frostbite, shows redness, edema, and transient discomfort. In mild cases, the affected area returns to normal within a period of a few hours with at most mild desquamation. Second-degree frostbite

presents with marked erythema and swelling; the numbness is replaced by burning pain, and within 24 to 48 hours, vesicles and bullae appear. Although healing occurs, patients may show continuing sensory neuropathy and cold sensitivity. In third-degree frostbite, hemorrhagic bullae or waxy, mummified skin is seen, consistent with extensive tissue loss. Full-thickness involvement of the skin, muscle, tendon, and bone occurs in fourth-degree frostbite; although recovery is possible, amputation (either surgical or autoamputation) results for most patients.<sup>303</sup>

The current goal of treatment is rapid rewarming to prevent further cold exposure and restore circulation.<sup>304</sup> The water bath temperature should be at least  $40^{\circ}\text{C}$  ( $104^{\circ}\text{F}$ ). Slow rewarming, use of dry heat, and rubbing with ice are all contraindicated. Pain during thawing and immediately after thawing should be treated with potent analgesics and sedatives. Core warming and fluid resuscitation are also important in patients with hypothermia. Other measures include wound care, administration of tetanus toxoid, avoidance of pressure and even light contact with the affected area, and vigorous treatment of infection when present. Thrombolytic therapy with intraarterial infusion of tissue plasminogen activator or iloprost (vasodilator) can improve perfusion.<sup>304–306</sup> If surgical measures are required, they should be delayed as long as possible. Because the prediction of tissue loss is difficult, amputation of necrotic tissue is best deferred for a period of at least 60 to 90 days to allow time for contracture, shrinkage, and the formation of a definitive line of demarcation between necrotic and viable tissue.

### TRENCH FOOT (IMMERSION FOOT)

Trench foot is a cold-induced nonfreezing injury of the extremities that occurs in individuals constantly exposed to a wet and cold environment. The disorder resembles a mild to moderate frostbite, has predominantly been noted in the homeless,<sup>307</sup> and is uncommon in children, although ice skaters and ice-hockey players are at risk.<sup>299</sup>

During exposure there is usually an initial uncomfortable feeling of coldness followed by virtually no discomfort and at times, a feeling of warmth as the nerves become sensitive. The limb becomes cold, numb, blue, swollen, and pulseless. The pain is aggravated by heat and relieved by cold. The ischemic tissue is prone to infection. In severe cases there is muscle weakness, joint stiffness, and gangrene that usually heals without tissue loss. A form of immersion foot has also been described in patients exposed to warm water for long periods of time. This disorder, characterized by a wrinkling, blanching, and maceration of the skin on the plantar and lateral aspects of the feet, has largely been reported in military personnel in tropical areas and in individuals who wear insulated boots for long periods of time. This form is generally reversible, leaving no residual disability.

Prevention is the best treatment. The skin should be rapidly dried should the condition occur. In the warm-water form of immersion foot, the application of silicone grease before water immersion may be helpful.

### PERNIOSIS

Perniosis (chilblains) is an exaggerated response to cold in predisposed individuals.<sup>308,309</sup> In pediatric patients, it largely is seen in teenagers but has been described in younger children.<sup>310</sup> It has been noted in several adolescents with anorexia nervosa<sup>311</sup> and may relate to impaired thermoregulation. Wet linings in shoe boots have also been blamed. Characterized by the occurrence of localized cyanosis, erythematous nodules, or ulcerations on exposed extremities in cold and damp weather, the disorder is most common in Northern Europe and the northern United States.

Perniotic lesions may also be seen in patients with lupus erythematosus (see Chapter 22), hemolytic anemia, and chronic myelomonocytic leukemia.<sup>312</sup> Painful chilblain-like lesions on the fingers, toes, and ears during early childhood is the pathognomonic features and usually the first manifestations of familial chilblain lupus, an autosomal dominant disorder that is caused by heterozygous mutations in *TREX1* (3' repair exonuclease 1) or in one family, *SAMHD1* (SAM domain and HD domain-containing protein 1).<sup>313,314</sup> Affected

individuals subsequently develop arthralgias, antinuclear antibodies (ANA), and sometimes cytopenias. These ulcerating chilblain-like lesions, often leading to digital ischemia, tend to occur during infancy in 40% of individuals with Aicardi–Goutières syndrome, an autosomal recessive disorder that results from biallelic mutations in *TREX1* and *SAMHD1*, as well as *RNASEH2A*, *RNASEH2B* (a later-onset form), and *RNASEH2C*.<sup>315–317</sup> The feet and hands are often cold, even without chilblain lesions. Affected children also have microcephaly, inflammatory encephalopathy and developmental delay, and arthritis. Biopsies may resemble lupus erythematosus,<sup>318</sup> and autoimmune antibodies may be present. Upregulation of IFN-stimulated genes has been demonstrated in patients with both familial chilblain lupus and Aicardi–Goutières syndrome.

Mild cases of perniosis are manifested by an initial blanching and then by ill-defined erythematous macules that become infiltrated and vary from a dark pink to a violaceous hue. In most cases the disorder is characterized by edematous patches of erythema or cyanosis that appear 12 to 24 hours after exposure to cold. Initially patients are usually unaware of the disorder. With time the areas become edematous and bluish red and eventually develop numbness, tingling, pruritus, burning, or pain.

Individual lesions tend to appear in a symmetrical distribution, principally on the dorsal aspect of the phalanges of the fingers (Fig. 20-46) and toes (Fig. 20-47) and on the heels, lower legs, thighs, nose, and

ears. The course is usually self-limiting and lasts 2 or 3 weeks. In young girls and adolescent women who wear skirts rather than slacks, the calves and shins are common sites of involvement. Chronic perniosis occurs repeatedly during cold weather and disappears during warm weather. Blistering and ulceration occasionally occur, and at times, lesions may heal with residual areas of pigmentation.

Children with more persistent or atypical lesions should have laboratory testing to eliminate possible underlying causes. These include CBC, ANA, and cryoglobulin, cryofibrinogen, and cold agglutinin levels. Serum protein electrophoresis levels are usually assessed in affected adults, but the incidence of patients with monoclonal gammopathy is much lower in children. Treatment consists of proper clothing to prevent undue exposure to cold, application of antipruritics, soothing lotions or ointments, and in severe cases, administration of nifedipine<sup>319,320</sup> or pentoxifylline.<sup>321</sup> Hydroxychloroquine has also been reported to improve pernio.<sup>322</sup>

### COLD-SENSITIVE DYSPROTEINEMIAS

The cold-insoluble proteins that precipitate at low temperatures include cryoglobulins, cryofibrinogens, and cold agglutinins. Cryoglobulins are composed of immunoglobulins (see Chapter 21), often in association with hepatitis C virus ribonucleic acid (RNA).<sup>323</sup> Cryofibrinogenemia involves increased circulating levels of fibrinogens (as well as fibrins and fibrin-split products) that gel in the cold.<sup>324,325</sup> In contrast to cryoglobulins, which may be found in serum samples, cryofibrinogens are consumed in clotting and thus are only present in plasma samples. Cold agglutinins are antibodies that promote aggregation of erythrocytes with cold exposure and are most commonly found in pediatric patients with mycoplasmal infection, although association with EBV has also been described.<sup>326</sup> Because cryoproteins may precipitate at a temperature as high as 35°C, the blood sample for testing must be maintained at 37°C until centrifugation. For testing, the sample is chilled to 4°C for 72 hours.

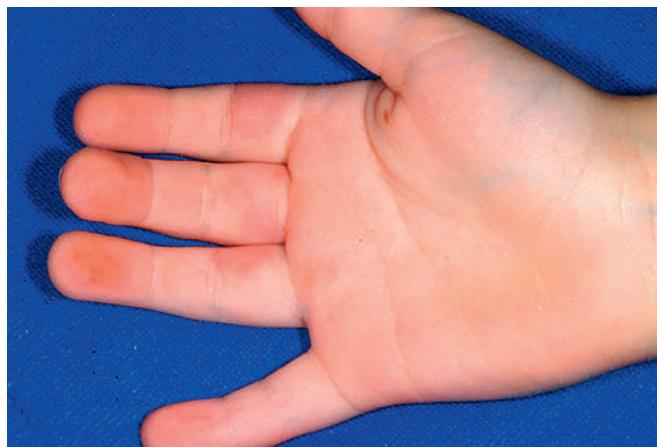

The most common manifestation of cold-induced dysproteinemia is palpable purpura that is often retiform (net-like) (see Chapter 21) and can progress to severe vasoocclusion (Fig. 20-48). Most individuals with cold-related occlusion syndromes have circulating cryoglobulins rather than cryofibrinogens or cold agglutinins. Other manifestations of increased levels of circulating cryoglobulins are urticaria, urticarial vasculitis, cold urticaria, livedo reticularis, pernio, Raynaud phenomenon, acral bullae, and digital ulcerations. In children, cryofibrinogenemia usually occurs as a secondary disorder related to infection,<sup>327</sup> but primary cryofibrinogenemia has been described and may respond to stanozolol.<sup>328</sup> The most common visceral manifestations of cryofibrinogenemia are arthralgias, weakness, neuropathy, and glomerulonephritis. A rare autosomal dominant form has been described in children and is characterized by painful purpura, slow healing of small ulcerations, and pedal edema during the winter season.<sup>329</sup> If cold agglutinins cause clinical problems, the typical manifestation is hemolysis; acrocyanosis, Raynaud phenomenon, livedo reticularis, and necrosis have rarely been described. Identification and treatment of the underlying disorder, as well as cold avoidance, are important.

### Cutaneous Reactions to Heat

Burns are the most common adverse reaction to heat (see Chapter 26). Erythema ab igne rarely occurs in the industrialized world with central heating.

### ERYTHEMA AB IGNE

Erythema ab igne is an acquired, persistent reticulated erythematous and pigmented condition of the skin produced by prolonged or repeated exposure to moderately intense, but not burning, heat. It most commonly occurs from use of heating pads but has been described after exposure to heat from fireplaces, hot water bottles, radiators, heating elements in cars,<sup>330</sup> heating blankets in the intensive care unit,<sup>331</sup> and exposure to laptop computers (on the thighs).<sup>332,333</sup>

**Figure 20-46** Perniosis (chilblains). Edematous red, painful nodules appeared on the fingers after exposure to cold.

**Figure 20-47** Perniosis (chilblains). Note the inflamed nodules on the toes of this adolescent girl. Although nodules resolved, painful nodules continued to develop on an annual basis beginning in January and lasting until April. She was otherwise healthy.

**A****B**

**Figure 20-48** Cryoglobulinemia. In this patient, palpable purpura and early vasoocclusion (**A**) progressed within 24 hours to severe vasoocclusion (**B**), requiring digital amputation.

**Figure 20-49** Erythema ab igne. Reticulated brown pigmentation on the lower back after prolonged exposure to a heating appliance.

The disorder is characterized by a mottled appearance of the skin exposed to the heat and eventually is manifested by a reticulated, annular, or gyrate erythema that progresses to a pale-pink to purplish dark-brown color with superficial venular telangiectasia and hyperpigmentation (Fig. 20-49). As in burn scars, squamous cell carcinomas have been reported in plaques of erythema ab igne. When present, these carcinomas tend to be aggressive, with metastases occurring in more than 30% of cases.

Treatment of erythema ab igne consists of protection from further exposure to the offending heat source. Once exposure to heat is

discontinued the erythema may fade, but the hyperpigmented changes are often permanent.

## Sweet Syndrome (Acute Febrile Neutrophilic Dermatosis)

Acute febrile neutrophilic dermatosis (Sweet syndrome) is characterized by raised painful papules, nodules, plaques, or bullae on the limbs, face, and neck, accompanied by fever and leukocytosis.<sup>334,335</sup> Many children have a history of upper respiratory tract illness 1 to 3 weeks before the onset of lesions. The disorder has been described in an infant as young as the first weeks of life,<sup>336</sup> but only 5% of cases are in children.<sup>337</sup> It is most common in women between 35 and 66 years of age.

Although commonly “idiopathic,” 58% of children with Sweet syndrome have an associated underlying disease, which is usually uncovered by complete history and physical examination, as well as a CBC with smear evaluation. Most of these are “parainflammatory” conditions with infection, although upper respiratory tract infection is most common, 1 to 3 weeks before the eruption, otitis media, viral meningitis, and human immunodeficiency virus.<sup>338</sup> Sweet syndrome has also been described with immunodeficiency<sup>339</sup> (T-cell deficiency,<sup>340</sup> CVID,<sup>341</sup> glycogen storage disease with neutropenia, and chronic granulomatous disease).<sup>342,343</sup> Other associated inflammatory disorders are inflammatory bowel disease,<sup>344</sup> systemic lupus erythematosus,<sup>345,346</sup> chronic multifocal osteomyelitis, vasculitis,<sup>334</sup> and Takayasu arteritis. Approximately 25% of children with Sweet syndrome have an underlying neoplastic or premalignant disorder (myelogenous leukemia, juvenile myelomonocytic leukemia,<sup>338</sup> myelodysplastic syndrome,<sup>347</sup> acute lymphoblastic leukemia, osteosarcoma, aplastic anemia, or Fanconi anemia<sup>348</sup>). Paraneoplastic Sweet syndrome more often presents on the face and oral mucosa. In such cases, the Sweet syndrome manifests simultaneously with the malignancy, suggesting that the possibility of malignancy must be investigated upon presentation but is unlikely to develop after the initial evaluation. Drugs have been linked to Sweet syndrome: granulocyte or granulocyte-macrophage colony-stimulating factor,<sup>349</sup> all-transretinoic acid,<sup>350</sup> trimethoprim-sulfamethoxazole, carbamazepine, imatinib, and minocycline, but in each case the patient had an underlying inflammatory or neoplastic disorder. A Sweet-like syndrome during the first 6 months of life has been associated with neonatal lupus and CANDLE syndrome, an auto-inflammatory disorder caused by mutations in the *PSMB8* gene.<sup>351,352</sup> The lesions of CANDLE syndrome tend to be annular and show a characteristic mixed infiltrate with atypical myeloid cells, which aids in the diagnosis.

Patients with acute febrile neutrophilic dermatosis usually have spiking fevers early in the course associated with raised, brightly erythematous, painful papules, plaques, or nodules asymmetrically distributed on the face, neck, and limbs (particularly the upper arms), with sparing of the areas between the upper chest and thighs. Lesions often occur in crops, and pathergy is common. Elevated plaques measure 1 cm or more in diameter, are distributed in an asymmetric pattern, and tend to develop partial clearing, resulting in an arcuate configuration as the border of the lesion advances (Fig. 20-50). They are indurated, red to plum-colored, and heal without scarring, often leaving a residual reddish brown color (Fig. 20-51). Larger plaques commonly have a mammillated surface from edema that simulates vesicles but is firm to palpation.

Leukocytosis ranging from 15,000 to 20,000 (with 80% to 90% polymorphonuclear leukocytes) is common, and myalgia, polyarthralgia, and polyarthritides of large joints have been reported in 15% to 25% of patients.<sup>353</sup> The fever precedes the cutaneous eruption by days to weeks in at least 50% of patients. Conjunctivitis and episcleritis may be present. Systemic inflammatory response syndrome with septic shock and multiorgan dysfunction has been associated in one child.<sup>354</sup> Rarely, postinflammatory slack skin with arterial laxity and aortic or mitral valve regurgitation has followed Sweet syndrome<sup>355,356</sup>; these children may develop potentially fatal coronary artery disease.<sup>357,358</sup>

Acute febrile neutrophilic dermatosis generally presents a fairly characteristic clinical picture that can be confirmed by cutaneous

**Figure 20-50** Sweet syndrome. Asymmetric indurated annular plaques.

**Figure 20-51** Sweet syndrome. Asymmetrically distributed indurated plum-colored plaques and nodules. (Courtesy of Dr Sarah Chamlin.)

biopsy. To establish the diagnosis, it has been suggested that patients must fulfill both major criteria and at least two of the minor criteria (Box 20-7). Biopsy specimens show a dense dermal perivascular infiltration of polymorphonuclear leukocytes, sometimes with nuclear dust, but without vasculitis. A similar histologic picture can be seen in patients with neutrophilic urticarial dermatosis, usually related to underlying systemic lupus erythematosus in pediatric patients<sup>359</sup> but distinguishable clinically from Sweet syndrome by urticarial macules or plaques without edema and lasting less than 24 hours.

If untreated, lesions of Sweet syndrome may extend and persist for up to a year, eventually resolving spontaneously without residual scarring. Patients generally respond to systemic corticosteroids (1 to 2 mg/kg per day) within a few days. Once the patient responds, the systemic corticosteroids should be tapered gradually over 2 to 3

#### Box 20-7 Major and Minor Criteria for Diagnosis of Sweet Syndrome

##### Major criteria

- Abrupt onset of tender or painful erythematous or violaceous plaques or nodules
- Predominantly neutrophilic infiltration of the dermis without leukocytoclastic vasculitis

##### Minor criteria

- Illness preceded by fever or infection
- Fever accompanied by arthralgia, conjunctivitis, or underlying malignancy
- Leukocytosis  $>10,000/\text{mm}^3$
- Good response to systemic corticosteroids and lack of response to antibiotics

months in an effort to prevent recurrences; some patients respond to corticosteroids but experience a flare with withdrawal. Potassium iodide, colchicine, dapsone, methotrexate, cyclosporine, and chlorambucil are treatment alternatives.

### Bowel-Associated Dermatosis-Arthritis Syndrome

Bowel-associated dermatosis-arthritis syndrome (intestinal bypass disease, bowel bypass syndrome) was originally described as a complication of jejunointestinal bypass surgery, which is only rarely performed in an adolescent for obesity.<sup>360</sup> However, the disorder has also been described in individuals with gastrointestinal disorders, including inflammatory bowel disease.<sup>361</sup> The disorder is characterized by a flu-like illness (chills, malaise, and myalgia), asymmetric polyarthritis, tenosynovitis, thrombophlebitis, retinal vasculitis, and crops of skin lesions. Lesions are most often seen on the arms and hands and less often on the shoulders and flanks. They are generally asymptomatic or mildly pruritic. Lesions begin as 3- to 10-mm erythematous macules, which develop into purpuric vesiculopustules that undergo central necrosis and resemble insect bites. Lesions over acral areas may be painful and often mimic the pustulovesicular lesions of gonococcemia; lesions on the shins or ankles, which are generally erythematous, tender nodules, may be mistaken for erythema nodosum.

The eruption usually lasts for 2 to 6 days and recurs at varying intervals for weeks to months. It is thought to result from bacterial overgrowth in blind intestinal loops and production of circulating immune complexes directed against the bacterial peptidoglycans. Biopsies of skin show a massive dermal infiltrate of neutrophils showing leukocytoclasia and occasionally a necrotizing vasculitis; some patients show lobular neutrophilic and septal panniculitis.

Short-term treatment of 1 mg/kg per day of prednisone markedly ameliorates the cutaneous and rheumatologic manifestations. Tetracycline, minocycline, metronidazole, clindamycin, sulfisoxazole, and dapsone have been suggested for both acute exacerbations and chronic prophylaxis. Surgical revision is curative.

### Hypereosinophilic Syndrome

Hypereosinophilic syndrome is a multisystemic disorder characterized by peripheral blood eosinophilia of at least 1500 eosinophils/ $\mu\text{l}$  without parasitic or allergic causes. Characteristically, the increase in eosinophils is present for 6 months or longer and is associated with infiltration of organs by eosinophils.<sup>362</sup> The condition is seen primarily in middle-aged men, but pediatric patients have been described.<sup>363,364</sup> The pathogenesis of the hypereosinophilic syndrome remains unknown, but many affected individuals have myeloproliferative disorders. The activated eosinophils are thought to cause the end-organ damage.

The manifestations can be variable, and almost any organ system can be involved. Approximately 50% of patients demonstrate cutaneous involvement. Pruritic erythematous or hyperpigmented macules,

**Figure 20-52** Hypereosinophilic syndrome. This patient shows purpuric areas on the palms, but a wide variety of cutaneous manifestations occur in 50% of patients, ranging from pruritic erythematous or hyperpigmented macules and papules to serpiginous lesions with vesicles to purpuric papules, petechiae, and livedo reticularis.

papules, serpiginous lesions with vesicles, purpuric papules (Fig. 20-52), splinter hemorrhages, nailfold infarcts, urticaria, Wells syndrome (see *Wells Syndrome*), erythema annulare, diffuse erythema, angioedema, livedo reticularis, and nodules, some of which are ulcerated, and mucosal ulcers have been described. These lesions may appear anywhere on the body but are generally present over the trunk and extremities.

Except for the blood and bone marrow involvement, cardiovascular disease is the major cause of morbidity and mortality. The heart often shows restrictive cardiomyopathy and subendocardial fibrosis; myocardial infarction may result.<sup>363</sup> Pulmonary complications (seen in 40% of patients) include interstitial infiltrates, a persistent nonproductive cough, and pleural effusion. Neurologic findings include hemiparesis, dysesthesias or paresthesias, slurred speech, confusion, and at times, coma. Affected individuals often show hepatosplenomegaly. Hepatic dysfunction, diarrhea with or without malabsorption, and renal involvement with persistent hematuria and hypouricemia have also been reported.

Hypereosinophilic syndrome is now classified based on underlying pathology as: (1) myeloproliferative, (2) lymphoproliferative, (3) idiopathic/undefined, (4) overlapping, (5) associated, and (6) familial.<sup>365</sup> Treatment is now specific to the underlying disease. However, systemic corticosteroids are the treatment of choice for most pediatric patients. Mepolizumab, which inhibits IL-5, is another option,<sup>366</sup> and imatinib has revolutionized the therapy for patients with the myeloproliferative form of the hypereosinophilic syndromes. Other treatment modalities are hydroxyurea, vincristine, IFN- $\alpha$ 2b, and fludarabine.<sup>367</sup>

## Wells Syndrome

Wells syndrome (eosinophilic cellulitis) occasionally occurs in pediatric patients, including in neonates and young children.<sup>368-371</sup> The condition starts with a prodromal burning sensation or itching and spreads rapidly for 2 or 3 days. Patients most commonly show sudden outbreaks of erythematous, often painful or pruritic, edematous urticarial or cellulitis-like plaques, often with sharp pink or violaceous borders. The morphology of lesions can vary. Although most children show plaque-type Wells lesions, annular granuloma-like lesions and papulovesicular, papulonodular, urticarial, bullous, and fixed drug-like lesions have been described. Lesions most commonly affect the lower limbs, followed in incidence by the upper limbs, trunk, face, scalp, and neck. The disorder gradually subsides over 2 to 8 weeks to be replaced by blue or slate-colored indurated patches that slowly fade. Recurrences are typical. The preceding history of insect bites,

### Box 20-8 Most Common Physiologic Changes of Pregnancy and the Postpartum Period

Skin	Striae Acrochordons
Vascular	Palmar erythema Hemorrhoids Varicosities Edema, nonpitting Spider angiomas Pyogenic granulomas
Pigment	Melasma Linea nigra Hyperpigmentation of the areolae
Hair	Hirsutism Postpartum alopecia Telogen effluvium Androgenetic alopecia Nail dystrophy

parvovirus B19 infection,<sup>372,373</sup> fungal infections, drug eruptions (particularly penicillin), reactions to vaccinations,<sup>374</sup> or underlying hematologic disease in some patients suggests that Wells syndrome represents a hypersensitivity reaction.

The clinical picture is striking, and the affected areas often resemble acute bacterial cellulitis, urticaria, insect bites, or a vesiculobullous contact dermatitis. Biopsy is usually necessary to confirm the diagnosis and shows diffuse infiltration of eosinophils throughout the dermis with "flame figures," which can be seen in a variety of disorders of eosinophil activation. Peripheral eosinophilia is common. Although the prognosis of Wells syndrome is generally excellent and most lesions tend to fade spontaneously, systemic corticosteroids hasten resolution. Dapsone, griseofulvin, minocycline, cyclosporine, and colchicine have sometimes been found to be effective.<sup>375</sup>

## Pregnancy and Pregnancy-Related Dermatoses

Pregnant adolescents may show a variety of physiologic changes during their pregnancy and postpartum periods (Box 20-8). In addition to these physiologic changes, a variety of pruritic dermatoses in association with pregnancy have been described. Although controversial, the specific dermatoses of pregnancy have recently been reclassified into pemphigoid gestationis (4.2%); pruritic urticarial papules and plaques of pregnancy (PUPPP) (21.6%); cholestasis of pregnancy (3%); a new category of atopic eruption of pregnancy, which includes eczema during pregnancy (49.7%), prurigo of pregnancy (0.8%), and pruritic folliculitis of pregnancy (0.2%); and miscellaneous dermatoses (20.6%) (Table 20-4).<sup>376-378</sup> Pustular psoriasis (see Chapter 4) may be triggered by pregnancy as well and presents during the third trimester with erythematous patches studded with subcorneal pustules. Pustular psoriasis of pregnancy (also called *impetigo herpetiformis*) may lead to stillbirth or neonatal death because of placental insufficiency. Apart from pemphigoid gestationis, an intensely pruritic immune-mediated blistering eruption (reviewed in Chapter 13), the cause of pregnancy-related dermatoses is unknown.

PUPPP, also called *polymorphic eruption of pregnancy (PEP)*, is the most common cutaneous disorder specifically related to pregnancy.<sup>379</sup> Intensely pruritic, the dermatitis occurs late in the third trimester or in the immediate postpartum period. It occurs in approximately 1 in 160 pregnancies and 75% of the time affects a primigravida.<sup>380</sup> The disorder has only once been described in the neonate of an affected mother (in contrast to pemphigoid gestationis).<sup>381</sup> This is a disorder of exclusion, and no diagnostic test is available.

**Table 20-4** Classification of Pruritic Dermatoses of Pregnancy

Name	Alternate Names	Risk to Fetus
Pemphigoid gestationis	Herpes gestationis, gestational pemphigoid	Increased risk of prematurity and small-for-gestational-age babies
Pruritic urticarial papules and plaques of pregnancy (PUPPP)	Toxic erythema of pregnancy, polymorphic eruption of pregnancy (PEP)	None
Atopic eruption of pregnancy, eczema in pregnancy, prurigo of pregnancy	Prurigo gestationis (of Besnier), papular dermatitis of pregnancy, early onset prurigo of pregnancy, pruritic folliculitis of pregnancy	None
Cholestasis of pregnancy	Obstetric cholestasis, intrahepatic cholestasis of pregnancy	Increased risk of premature labor, fetal distress, meconium staining, and fetal death

**Figure 20-53** Pruritic urticarial papules and plaques of pregnancy. Note the small erythematous papules and urticarial wheals on the distended abdomen of this pregnant adolescent.

The condition usually begins as 1- to 2-mm urticarial papules on the abdomen (Fig. 20-53), often within the abdominal striae. These papules soon coalesce to form large erythematous plaques and then spread to involve the abdomen, buttocks, thighs, and in some cases, the arms and legs. The upper chest, face, palms, soles, and mucous membranes tend to be spared. Although pruritus is commonly extreme, and patients are often unable to sleep, excoriations are rare. Topical application of corticosteroids usually provides symptomatic relief; if the condition is severe or unresponsive to topical medication, brief courses of systemic corticosteroids are often beneficial.

Intrahepatic cholestasis of pregnancy occurs in 1 in 1500 pregnancies (20% of cases of obstetrical jaundice) and is characterized by intense pruritus. The only skin lesions are excoriations. By definition, affected females have generalized pruritus without history of exposure to hepatitis or hepatotoxic drugs, with appearance usually during the last trimester of pregnancy and disappearance within 2 to 4 weeks after delivery. The condition tends to recur during subsequent pregnancies in 65% of affected women and has been associated with risks to the fetus (see Table 20-4). The risk with twin pregnancies is higher, and a positive family history is seen in 50% of affected individuals.

Pruritus tends to be worse at night and on the trunk, palms, and soles. No primary skin lesions are seen. Approximately half of affected patients show jaundice, dark urine, or stools light in color. More severely affected women may have malabsorption, including that of vitamin K. The diagnosis can be confirmed by finding increased serum bile acids without evidence of viral hepatitis or another explanation. Treatments include rest and a low-fat diet, cholestyramine, oral guar gum (a dietary fiber that lowers bile acid levels), and ursodeoxycholic acid (which can substitute for more toxic bile acids).

*Prurigo of pregnancy* is a term used to describe a heterogeneous group of disorders that occurs earlier than PUPPP, usually in mid-trimester, and is now included as part of atopic eruption of pregnancy

(see Table 20-4). Cholestasis as a cause of pruritus must be eliminated through finding normal liver function tests. Pruritic folliculitis of pregnancy, a subset of prurigo of pregnancy, presents between the fourth and ninth months of pregnancy as a pruritic follicular papular and pustular eruption and generally resolves within a few weeks after delivery. Eczema in pregnancy presents, most commonly during the second trimester, as eczematous patches and plaques that can be generalized. Topical application of corticosteroids or narrow-band ultraviolet B (UVB) light have been helpful in the management of this subset of patients.

## Autoimmune Progesterone Dermatitis

This rare disorder most commonly begins at menarche and is thought to represent an autoreactivity reaction to progesterone.<sup>382</sup> It thereafter occurs approximately 3 to 10 days before the onset of menstrual flow and ends approximately 2 days into menses. It may also be seen in individuals on anovulatory hormone therapy and in pregnant women during the first trimester of pregnancy. The condition is characterized by urticarial vesiculobullae, papules, pustules, EM, and dyshidrotic eczema-like eruptions on the extensor surfaces of the thighs, forearms, hands, and buttocks.<sup>383,384</sup> Rarely, the disorder may manifest with angioedema and laryngeal spasms requiring epinephrine administration.<sup>385</sup>

The diagnosis of autoimmune progesterone dermatitis can be confirmed by an urticarial wheal at the site of intradermal skin test to an aqueous progesterone suspension. Treatment consists of estrogens or tamoxifen. Oophorectomy can be considered for patients unresponsive to other modes of therapy.

The term *vasculitis* refers to inflammation of blood vessels, a finding that can be seen in association with a variety of clinical manifestations and as either a primary or secondary phenomenon. Along with vessel inflammation there is deposition of fibrinoid material in vessel walls and the presence of nuclear fragments (nuclear dust) resulting from disintegration of neutrophilic nuclei (karyorrhexis) within the vessel wall and surrounding tissues (hence the terminology *leukocytoclastic vasculitis*). The presence of vasculitis may result in tissue injury owing to vascular stenosis, occlusion, aneurysm, or rupture. The incidence of childhood vasculitis is approximately 50 cases per 100,000 children per year, with geographic differences noted throughout the world.<sup>1</sup>

The vasculitic disorders are a heterogeneous group of conditions, many of which present with (or eventually result in) cutaneous manifestations. Classification of the vasculitides is difficult and has most often been based on the gross and microscopic features of the disease process, primarily the vessel size involved (i.e., large, medium-sized, or small). Large-vessel vasculitides, which will not be discussed here, include giant-cell (temporal) arteritis and Takayasu arteritis. Medium-sized vasculitides involve predominantly visceral arteries and include two of the most common forms of pediatric vasculitis syndromes, polyarteritis nodosa (PAN) and Kawasaki disease (KD), both of which will be discussed. The other entities covered in this chapter all represent small-vessel disorders, which tend to involve primarily capillaries and venules. It should be remembered that this classification of vasculitis based on vessel size is imprecise, and overlap in the size of involved vessels is common. A summary classification of pediatric vasculitides is shown in Table 21-1. The original patient groups used to develop vasculitis classification criteria by the American College of Rheumatology (ACR) did not include children. Subsequently the vasculitis working group of the Pediatric Rheumatology European Society (PRES), in conjunction with the European League Against Rheumatism (EULAR) and the Pediatric Rheumatology International Trials Organization (PRINTO), more recently developed and validated criteria for some of the most common childhood vasculitides, a process that culminated at the 2008 Ankara Consensus Conference.<sup>2,3</sup> A summary of these criteria is shown in Table 21-2.

## Henoch–Schönlein (Anaphylactoid) Purpura

Henoch–Schönlein purpura (HSP), also known as *anaphylactoid purpura*, is a form of small-vessel vasculitis that occurs primarily in children (especially boys) between 2 and 11 years of age, most commonly occurring in children under the age of 5 years. It is the most common type of childhood systemic vasculitis. The classic presentation is a combination of nonthrombocytopenic palpable purpura in dependent areas, arthritis, abdominal pain, and glomerulonephritis. HSP is an inflammatory disorder that has been linked hypothetically to several potential etiologic agents including group A β-hemolytic streptococci (GABHS), other bacterial or viral organisms, immunizations, and drugs, although the exact etiology remains unclear.<sup>4</sup> There are reports of patients with coexisting HSP and acute rheumatic fever, highlighting the potential association between GABHS and HSP.<sup>5</sup> *Bartonella henselae* has also been suggested as a potential etiologic infectious agent.<sup>6</sup> Although the nature of the immunologic reaction in HSP is not completely clear, the common history of antecedent upper respiratory tract infection preceding the onset of symptoms suggests a hypersensitivity phenomenon resulting in localized or widespread

vascular damage. A fairly consistent immunologic observation is the deposition of immunoglobulin (Ig) A immune complexes in affected organs (i.e., skin, kidneys) when studied by immunofluorescence. IgA complexes, however, are not a necessary requirement for the development of HSP, and their absence should not exclude the diagnosis. Around one-third of patients have elevated serum IgA levels.<sup>7</sup> Several polymorphisms involving cytokines and cell-adhesion molecules that modulate inflammatory responses and endothelial cell activation have been observed and may correlate with disease susceptibility, extent of involvement, and/or severity of renal disease.<sup>8</sup> Mutations in the *MEFV* gene, which is classically associated with familial Mediterranean fever with homozygous or compound heterozygous mutation, have been described in some patients with HSP and may portend more common gastrointestinal and joint involvement and edema.<sup>9</sup>

The clinical picture of HSP is often, but not always, distinctive. Most patients with a rash present with an initial urticarial eruption of macules and papules (Fig. 21-1) that rapidly become purpuric and are distributed primarily on the lower extremities (Figs. 21-2 through 21-4) and buttocks (Fig. 21-5). Lesions may also occur on the upper extremities, trunk, and face, and in some instances skin lesions may develop in patterns at pressure sites. In some patients, petechiae (Fig. 21-6) or ecchymoses ("bruises") (Fig. 21-7) may predominate over palpable purpuric lesions. The cutaneous eruption is the presenting feature of HSP in 50% of cases.<sup>4</sup> Newer purpuric lesions develop and may result in a polymorphous appearance. Other skin lesion morphologies, including vesicular or bullous lesions, erosions or ulcers, necrosis, gangrene, and even erythema multiforme-like lesions, may occur.<sup>10,11</sup> Marked edema of the hands, feet, scalp, or face may also be seen, especially in younger patients.<sup>4,12</sup> The disease often consists of a single episode that may last for several days to weeks, but in some cases recurrent attacks may occur at intervals for weeks to months.

Individual lesions of HSP occur in crops, tend to fade after about 5 days, and eventually are replaced by areas of hyperpigmentation or ecchymoses. Although the differential diagnosis of the skin lesions may include drug reaction, erythema multiforme, or urticaria, the presence of palpable purpura (the hallmark of leukocytoclastic vasculitis) will usually clarify the true nature of the disorder. This characteristic finding, created by edema and extravasation of erythrocytes, gives individual lesions their diagnostic palpable and purpuric appearance as well as their nonblanching quality (i.e., individual lesions cannot be blanched when viewed through a glass slide exerting pressure over the surface, a technique called *diascopy*).

Occasionally the face, mucous membranes of the mouth and nose, and the anogenital regions may show petechiae. In males, vasculitis of the scrotal vessels may lead to acute scrotal swelling with or without erythema or purpura (Fig. 21-8). Pain may be severe, and this presentation may mimic that of testicular torsion or other causes of "acute scrotum," necessitating ultrasonography and/or radionuclide scans to help differentiate between these disorders.<sup>13</sup> In one study, roughly 20% of males with HSP had scrotal involvement, and these patients were noted to have an association with headache, edema, and elevated C3 levels.<sup>14</sup>

Systemic involvement in HSP, which is seen in up to 80% of cases, most commonly occurs in the kidneys, gastrointestinal tract, and joints. The degree of systemic involvement varies, with joint or gastrointestinal symptoms seen in as many as two-thirds of affected children. Renal disease occurs most often and is the most significant correlate of long-term prognosis.<sup>7</sup>

The clinical expression of HSP kidney involvement varies from transient microscopic hematuria to rapidly progressive glomerulonephritis. Glomerulonephritis is seen overall in 40% to 50% of children with

**Table 21-1** Classification of Pediatric Vasculitides

Predominant Vessel Size	Disorder
Large	Takayasu arteritis
Medium	Polyarteritis nodosa Kawasaki disease
Small	Hypersensitivity vasculitis (cutaneous leukocytoclastic vasculitis) Henoch-Schönlein purpura Acute hemorrhagic edema of infancy Hypocomplementemic urticarial vasculitis Cryoglobulinemic vasculitis Erythema elevatum diutinum (primarily adults) ANCA-associated: Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) Churg-Strauss syndrome Microscopic polyangiitis

ANCA, Antineutrophil cytoplasmic antibody.

**Figure 21-1** Henoch-Schönlein purpura. These early lesions are urticarial in nature. Note associated central erosion/crusting in some of the plaques.

**Table 21-2** Diagnostic Criteria for Some Childhood Vasculitides: Ankara Classification\*

Disorder	Diagnostic Criteria
Henoch-Schönlein purpura	Purpura or petechiae (mandatory) with lower limb predominance <sup>†</sup> and at least one of following 4 criteria: Abdominal pain Histopathology (LCV with IgA deposits or proliferative GN with IgA deposits) Arthritis or arthralgia Renal involvement
Childhood polyarteritis nodosa	Histopathology (necrotizing vasculitis in medium- or small-sized arteries) or angiographic abnormalities <sup>‡</sup> (mandatory) plus 1 of the following 5 criteria: Skin involvement <sup>§</sup> Myalgia/muscle tenderness Hypertension Peripheral neuropathy Renal involvement
Granulomatosis with polyangiitis <sup>  </sup>	At least 3 of the following 6 criteria: Histopathology (granulomatous inflammation within artery wall or perivascular area) Upper airway involvement <sup>¶</sup> Laryngotracheobronchial stenosis Pulmonary involvement** ANCA positivity Renal involvement

Modified from Ozen S, Pistorio A, Iusan SM, et al. EULAR/PRINTO/PRES criteria for Henoch-Schönlein purpura, childhood polyarteritis nodosa, childhood Wegener granulomatosis and childhood Takayasu arteritis: Ankara 2008. Part II. Final classification criteria. Ann Rheum Dis 2010;69:798–806.

ANCA, Antineutrophilic cytoplasmic antibody; GN, glomerulonephritis; Ig, immunoglobulin; LCV, leukocytoclastic vasculitis.

\*Also referred to as EULAR/PRINTO/PRES criteria.

<sup>†</sup>For purpura with atypical distribution, demonstration of IgA deposit in biopsy required.

<sup>‡</sup>Angiography: aneurysm, stenosis, or occlusion of medium- or small-sized artery.

<sup>§</sup>Livedo reticularis, nodules, infarctions.

<sup>||</sup>Formerly known as Wegener granulomatosis.

<sup>¶</sup>Purulent/bloody nasal discharge, recurrent epistaxis/crusts/granulomas, septal perforation or saddle nose deformity, sinusitis.

<sup>\*\*</sup>Nodules, cavities, or fixed infiltrates.

**Figure 21-2** Henoch-Schönlein purpura. Urticarial, purpuric papules and plaques on the lower extremity.

HSP and is usually transient and benign.<sup>15</sup> The renal lesion in HSP is indistinguishable histopathologically from that of IgA nephropathy (Berger disease), although the latter tends to occur more often in older patients.<sup>4</sup> The renal involvement may not become apparent for several weeks; hence the importance of long-term follow-up monitoring for development of this complication. Most often, however, if kidney involvement is going to be seen, it will be found within 3 months of disease onset.<sup>16</sup> Potential correlates of kidney disease in HSP include age over 4 years, persistent purpura, severe abdominal pain, and depressed coagulation factor XIII activity less than 80%.<sup>16</sup> Initial renal insufficiency appears to be the single best predictor of the further clinical course in children with HSP nephritis.<sup>17</sup>

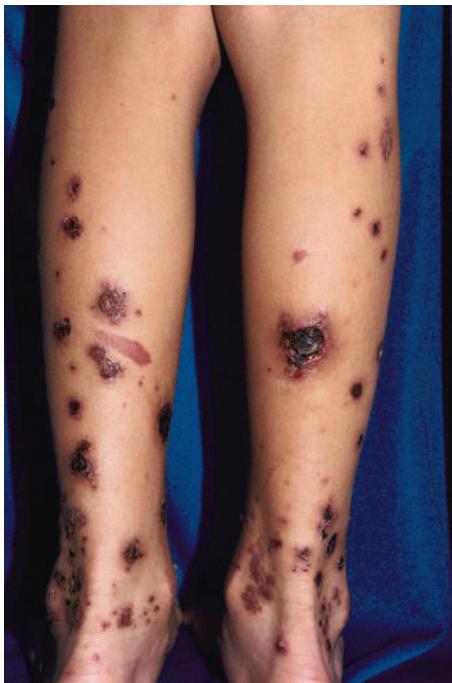

Gastrointestinal signs and symptoms result from edema and hemorrhage of the bowel wall as a result of vasculitis. They most often include colicky abdominal pain (that may be severe and associated with vomiting), hematochezia, and hematemesis. Visceral infarction or perforation, pancreatitis, cholecystitis, esophageal involvement, colitis, protein-losing enteropathy, intussusception, hemorrhage, or

**Figure 21-3** Henoch–Schönlein purpura. Palpable purpuric papules and plaques.

**Figure 21-5** Henoch–Schönlein purpura (HSP). Palpable purpura of the buttocks, a classic site of involvement in HSP.

**Figure 21-4** Henoch–Schönlein purpura. These purpuric plaques became bullous with subsequent necrosis.

**Figure 21-6** Henoch–Schönlein purpura. This patient had small petechial macules of the upper extremities with larger, more classic purpuric plaques of the buttocks and lower extremities.

shock may also be associated. Intussusception, seen in up to 2% of patients, is more common in boys. Because non-HSP-associated intussusception generally occurs in children younger than 2 years of age, when intussusception is diagnosed in older children HSP must be strongly considered. Chronic intestinal obstruction with ileal stricture has also been reported, occurring months after resolution of the acute illness.<sup>18</sup>

Joint involvement in HSP is characterized by tender and painful joints with primarily periarticular swelling. True arthritis is less common. Although the ankles and knees are most often affected, the elbows, hands, and feet may also be involved. HSP joint symptoms tend to be oligoarticular. Arthritic symptoms are usually transient and rarely result in permanent deformity.

In addition to the skin, genitourinary and gastrointestinal tracts, and joints, other organ involvement is occasionally seen in HSP. Central nervous system (CNS) involvement results most commonly in headache and occasionally behavioral alteration, hyperactivity, intracerebral bleeds, paresis, or seizures.<sup>4,19</sup> Status epilepticus has been

rarely reported.<sup>20</sup> Respiratory involvement may range from an asymptomatic pulmonary infiltrate to recurrent episodes of pulmonary hemorrhage. Bleeding diathesis may occasionally occur.

The diagnosis of HSP is seldom difficult when patients exhibit the classic “tetrad” of organ involvement (skin, kidneys, gastrointestinal tract, and joints). However, many patients show only some of these findings, and the differential diagnosis depends on which organ-specific symptoms predominate. The differential diagnosis of palpable purpura may include hypersensitivity vasculitis (HV) (usually caused by drug reaction; see Hypersensitivity Vasculitis section), hemorrhagic diathesis (i.e., factor deficiency), or sepsis. In addition, the more “ecchymotic” lesions of HSP may be mistaken for child abuse<sup>21</sup> and must be evaluated within the context of the overall clinical presentation. When the diagnosis remains in doubt, histopathologic examination of a skin biopsy specimen is useful in confirming the presence of vasculitis. Direct immunofluorescence revealing IgA immune complexes is highly suggestive of but not pathognomonic for HSP. Other laboratory investigations to be considered include serum chemistry profile, blood-cell counts, coagulation studies, abdominal radiographic studies, stool guaiac testing, urinalysis, and kidney biopsy.

The overall prognosis for most patients with HSP is excellent, and full recovery without permanent residua is the norm. The disease tends to run its course over 4 to 6 weeks. In younger children, the disease is generally milder and of shorter duration with fewer renal and gastrointestinal manifestations and few recurrences. Renal disease is the most important prognostic indicator, and end-stage renal disease may occur in up to 5% of patients with nephritis.

**Figure 21-7** Henoch-Schönlein purpura. Occasional patients have ecchymotic (bruise-like) lesions without classic purpura, as in this 9-year-old male.

**Figure 21-8** Henoch-Schönlein purpura (HSP). This patient with HSP developed an acute onset of scrotal pain with edema and purpuric changes.

Long-term follow-up care is indicated in patients with kidney involvement. Recurrent flares of HSP may occur in up to 3% of patients, and in one study had a lag period of 2 to 26 months after the initial presentation.<sup>22</sup>

Supportive care is sufficient for the majority of patients, and nonsteroidal anti-inflammatory agents are useful for significant joint pain. The goals of HSP therapy are to minimize symptoms, decrease short-term morbidities, and prevent chronic renal insufficiency.<sup>23</sup> Systemic corticosteroids have been advocated for patients with severe gastrointestinal, joint, or scrotal involvement, as well as for renal involvement. They are generally not recommended for rash, mild joint pain, or mild abdominal discomfort alone. Various regimens have been recommended for HSP nephritis, including oral methylprednisolone or prednisone, high-dose intravenous pulse methylprednisolone, urokinase, cyclophosphamide, mycophenolate mofetil, azathioprine, plasma exchange, dipyridamole, and heparin/warfarin.<sup>17,24–29</sup> The benefits of systemic steroid therapy for HSP remain somewhat controversial. A meta-analysis revealed that corticosteroids reduced the mean resolution time of abdominal pain, reduced the odds of

**Figure 21-9** Acute hemorrhagic edema of infancy. Medallion-like ("cockade") purpura in a newborn female with congenital onset of the disease.

**Figure 21-10** Acute hemorrhagic edema of infancy. Purpuric patches with scalloped borders in an infant male with the disorder.

developing persistent kidney disease, and reduced the odds of both surgical intervention and recurrence.<sup>23</sup> However, in a long-term study assessing outcomes 8 years after a randomized placebo-controlled prednisone study in a cohort of 171 HSP patients, there were no differences between prednisone and placebo groups with regard to hematuria, proteinuria, or hypertension.<sup>30</sup> A retrospective cohort study of hospitalized children with HSP revealed an association between decreased hazard ratios for abdominal surgery, endoscopy and abdominal imaging, and early corticosteroid exposure.<sup>31</sup> Taken together, these and other reports suggest the need for more controlled studies of the effect of corticosteroids on HSP outcomes.

## Acute Hemorrhagic Edema of Infancy

Acute hemorrhagic edema (AHE) of infancy (AHE of childhood, Finkelstein disease) is a form of leukocytoclastic vasculitis characterized by fever, large purpuric skin lesions, and tender edema and reported most often in infants and children between the ages of 4 months and 3 years. The cutaneous lesions often have a "cockade" (medallion-like) pattern, with scalloped borders and central clearing (Fig. 21-9). They begin as edematous papules with petechiae and expand centrifugally with coalescence to result in the characteristic clinical pattern (Figs. 21-10 and 21-11).<sup>32</sup> Facial edema is common. Although the cutaneous eruption may be impressive, patients are usually otherwise well, and involvement of the gastrointestinal tract, kidneys, and joints is uncommon. Intussusception has been rarely observed.<sup>33</sup> The etiology

**Figure 21-11** Acute hemorrhagic edema of infancy. Multiple purpuric papules and plaques in the same patient shown in [Figure 21-10](#).

**Figure 21-12** Hypersensitivity vasculitis (HV). Multiple purpuric papules in an adolescent female with a drug-induced HV.

is unclear, although an infectious trigger (i.e., upper respiratory infection, conjunctivitis, pharyngitis, otitis media, or pneumonia) is hypothesized. Prodromal symptoms most often are limited to those of respiratory tract illness or diarrhea.<sup>34</sup>

Skin biopsy in AHE reveals leukocytoclastic vasculitis similar to HSP. Direct immunofluorescence studies, however, do not consistently reveal IgA deposition and in up to three-quarters of patients are entirely negative.<sup>32–36</sup> Laboratory findings may include leukocytosis and an elevated erythrocyte sedimentation rate, but hematuria, proteinuria, and hematochezia are usually absent. The course of AHE is marked by a rapid onset with a short benign course followed by complete recovery, usually over 1 to 3 weeks.<sup>37</sup> No treatment is generally necessary, because AHE is typically a self-limited process. Although the disorder resembles HSP, controversy exists over whether it represents an infantile form of HSP or whether it is a distinct and unrelated clinical entity. Arguments in favor of the latter include the lack of internal organ involvement, the absence of IgA immune deposits in most patients, and the benign course without a propensity toward recurrences.

**Figure 21-13** Hypersensitivity vasculitis (HV). Petechial macules of the penile shaft, glans penis, and scrotum in a young male with HV.

## Hypersensitivity Vasculitis

*Hypersensitivity vasculitis (HV)* (cutaneous small-vessel vasculitis, cutaneous leukocytoclastic vasculitis, cutaneous leukocytoclastic angiitis) is a term used to denote a leukocytoclastic vasculitis involving primarily the skin and in most cases is secondary to a drug ingestion or infectious process. It is most common in adults and significantly less common in children, in whom HSP is the most common form of cutaneous vasculitis. Potential infectious etiologies of HV include Streptococci, hepatitis B and C, nontyphoidal *Salmonella*, and *Mycobacteria* (both tuberculous and nontuberculous).<sup>38,39</sup>

The diagnosis of HV is one of exclusion, and other causes of primary cutaneous vasculitis (i.e., HSP, cryoglobulinemic vasculitis [CV]) or secondary cutaneous vasculitis (i.e., urticarial vasculitis [UV], connective tissue disorders, malignancy, endocarditis, Behcet disease) must be ruled out. The lesions of HV tend to occur in “crops” (groups of lesions of similar age) because of simultaneous exposure to the inciting antigen.<sup>40</sup>

Patients with HV most often present with palpable purpura ([Fig. 21-12](#)) and less often with urticaria, vesicles, pustules, superficial ulcers, or necrotic lesions. The lesions may be smaller and petechial in appearance in some patients ([Fig. 21-13](#)). Skin involvement is most notable in dependent areas and in areas of trauma or tight-fitting clothing.<sup>41</sup> Symptoms are usually absent, although pain or burning may be present, and systemic involvement is uncommon.

The list of potential drug causes of HV is extensive and includes multiple classes of antibiotics, nonsteroidal anti-inflammatory agents, antiepileptic drugs, insulin, propylthiouracil, omeprazole, and oral contraceptives.<sup>41–46</sup> (For a more complete listing of potential drug

etiologies, see Chapter 20.) Identification and withdrawal of the offending agent is vital in patients with HV, and in those with skin-limited disease no other specific therapy is usually necessary. For patients with either severe cutaneous or systemic involvement, therapeutic options include corticosteroids, colchicine, dapsone, or other immunosuppressive agents. The lesions of HV usually resolve over weeks to months with resultant postinflammatory hyperpigmentation.

## Urticular Vasculitis

*Urticular vasculitis (UV)* refers to a type of cutaneous leukocytoclastic vasculitis that presents with urticarial features and is often associated with an underlying systemic disease. In contrast to common urticaria, the lesions of UV are distinct in that they last for longer than 24 to 48 hours, often have a dusky or purpuric appearance, are associated more often with burning than pruritus, and leave postinflammatory hyperpigmentation after resolution ([Fig. 21-14](#)).<sup>40,47</sup> Confirmation of the diagnosis of UV often requires skin biopsy given the potential overlap with other conditions, especially allergic urticaria.<sup>48</sup> Deposits of IgG, complement, or fibrin may be found around blood vessels in UV in up to 80% of patients.<sup>49</sup>

UV may be idiopathic or associated with other diseases including autoimmune disorders, infections, drug reactions, or paraneoplastic syndromes. Most patients can be characterized as having either normocomplementemic UV (in which case the majority represent

**Figure 21-14** Urticarial vasculitis. These urticarial plaques, which had been persistent and had a faint purpuric quality, revealed leukocytoclastic vasculitis on histologic evaluation. The patient was ultimately diagnosed with systemic lupus erythematosus.

idiopathic UV) or hypocomplementemic UV (see the following section). Patients with hypocomplementemic UV have a propensity toward more severe multiorgan involvement and systemic disease associations.<sup>40,47,48</sup> The most commonly associated autoimmune disorders are systemic lupus erythematosus (SLE) and Sjögren syndrome (see Chapter 22). Serum sickness-like reactions to drugs, cryoglobulinemia, and hepatitis C virus (HCV) infection are also associated in some patients with UV.

### HYPOCOMPLEMENTEMIC URTICARIAL VASCULITIS SYNDROME

*Hypocomplementemic urticarial vasculitis syndrome (HUVS)* is the terminology used to describe patients with UV in association with angioedema and systemic symptoms, most often obstructive pulmonary disease and ocular inflammation (conjunctivitis, iritis, episcleritis, uveitis). Glomerulonephritis and arthritis may also be present, and the condition is relatively rare in pediatric patients.<sup>50</sup> Decreased serum Clq levels are seen in most patients, and autoantibodies against this factor are detectable in the serum.<sup>47</sup> Although antibodies to Clq are also found in some patients with SLE, HUVS appears to be a unique entity.

The cutaneous lesions of UV are urticarial in nature, favor the trunk and proximal extremities, and often have a purpuric quality. The primary distinguishing features are the persistence of lesions longer than is typical for allergic urticaria (2 to 6 hours), pain or burning, and associated hyperpigmentation as the lesions resolve. If the diagnosis of UV is confirmed, a thorough physical examination and laboratory investigation to assess for associated conditions are indicated. If an underlying disease is identified, specific therapy for that disorder is indicated. There is otherwise no specific therapy for UV. Various therapeutic modalities including prednisone, hydroxychloroquine, indomethacin, azathioprine, colchicine, methotrexate, cyclophosphamide, cyclosporine, intravenous Ig and dapsone have been used but with an inconsistent response.<sup>41,47–49,51,52</sup>

### Cryoglobulinemic Vasculitis

Cryoglobulins are circulating IgGs that precipitate at temperatures below 37°C and may be associated with any of several infectious, autoimmune, or malignant disorders. When these immune complexes deposit in blood-vessel walls and activate complement, CV results. Cryoglobulins have been classified into three types based on the presence or absence of monoclonality and their association with rheumatoid factor. Type I (monoclonal cryoglobulinemia) is a monoclonal antibody and is usually associated with a hematologic malignancy, whereas types II and III are composed of a mixed antibody response and hence are termed *mixed cryoglobulinemia*. The terminology essen-

tial mixed cryoglobulinemia is used to describe mixed cryoglobulinemia in the absence of other identified infectious, immunoblastic, or neoplastic disorders.<sup>53</sup> The most common infectious disease to be associated with CV is HCV, which is associated with mixed cryoglobulins.<sup>54</sup> In one large series of adults with SLE, cryoglobulins were detected in the sera of 25% of the patients and were associated with an increased incidence of HCV infection.<sup>55</sup> Patients with CV may experience a variety of skin manifestations including purpura, papules, nodules, skin necrosis, urticaria, livedo reticularis, and bullous or ulcerated lesions.<sup>41</sup> The classic triad of CV is purpura, weakness, and arthralgias, along with possible multiorgan involvement.<sup>53</sup> Treatment for CV should be directed toward the underlying systemic disease when one is identified. The main goals of therapy for mixed cryoglobulinemia are to eradicate HCV infection, delete the underlying B-cell clonal expansions that occur, and deplete the cryoproteins. A variety of anti-inflammatory, antiviral, and immunosuppressive agents (including pegylated interferon- $\alpha$ , ribavirin, and rituximab) have been used to this end with variable success.<sup>56</sup>

### Necrotizing Vasculitis with Granulomas

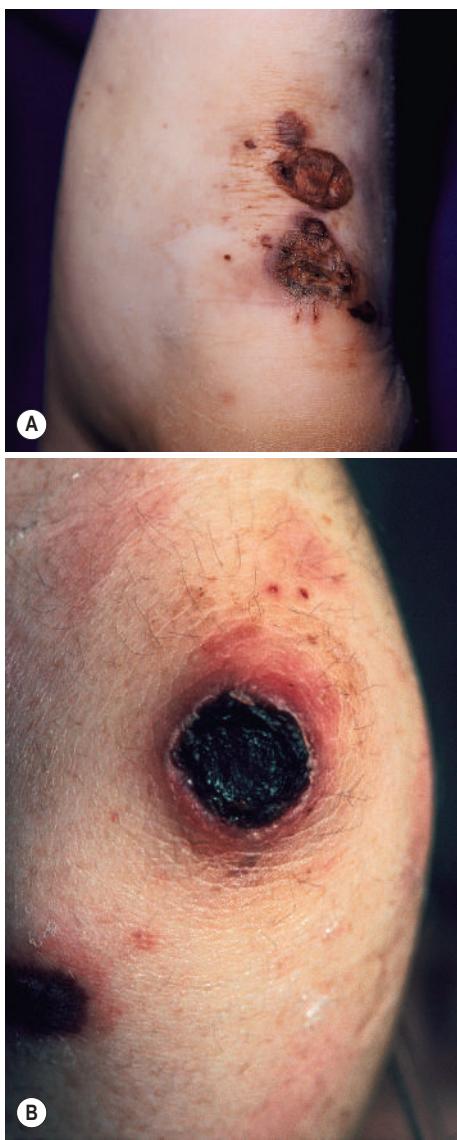

There are several systemic diseases in which necrotizing vasculitis is seen in association with granulomatous changes, including granulomatosis with polyangiitis (GPA), allergic granulomatosis (Churg-Strauss syndrome), and lymphomatoid granulomatosis. The first two will be discussed in this section. These disorders are primarily seen in adults but may occasionally occur in children. They are often associated with antineutrophil cytoplasmic antibodies (ANCA), which may play a pathogenic role and more importantly are useful in the diagnosis and management of (mainly small-vessel) vasculitides.<sup>7</sup> GPA and Churg-Strauss syndrome, along with the entity microscopic polyangiitis (MPA), have been collectively referred to as *ANCA-associated vasculitides*. MPA, which is not discussed in detail here, is characterized by a necrotizing small-vessel vasculitis without granuloma formation and with a similar presentation to GPA with less common involvement of the ear, nose, and throat, and occasional limitation to the kidneys.<sup>57</sup> Pulmonary capillaritis and necrotizing glomerulonephritis are seen, as are constitutional symptoms such as fever, malaise, arthralgias, myalgias, and weight loss.<sup>58</sup> Severe anemia may occasionally be the presenting symptom of MPA.<sup>59,60</sup>

### GRANULOMATOSIS WITH POLYANGIITIS

GPA (formerly known as *Wegener granulomatosis*) is a necrotizing granulomatous vasculitis of small- to medium-sized arteries involving the upper and lower respiratory tract in association with kidney involvement and variable degrees of vasculitis in other organ systems. Although it is quite rare, among the primary systemic vasculitides in children GPA is one of the most common and has an annual incidence of 0.03 to 3.2 per 100,000 children.<sup>61</sup> Classification criteria for GPA have been proposed by the ACR and the EULAR/PRES.<sup>61</sup> The latter diagnostic criteria have been demonstrated more sensitive in classifying pediatric GPA than the ACR criteria.<sup>62</sup>

GPA usually presents with constitutional symptoms (malaise, fatigue, fever, and weight loss), and symptoms referable to the upper and/or lower respiratory tracts include cough, rhinorrhea, nasal stuffiness, nasal mucosal erosions or ulcers, earache, or sinusitis. Hemoptysis or pleurisy may be present, and nodular cavitary lesions in the lungs are a characteristic finding on radiographic studies. The nose, nasal sinuses, nasopharynx, glottis, trachea, bronchi, and lungs may all be affected by the necrotizing vasculitis, and subglottic stenosis and nasal deformity may result, the former occurring more commonly in children.<sup>63</sup> Conjunctival injection may be present, as may arthralgias, myalgias, and glomerulonephritis, although pediatric disease may present without renal involvement. End-stage renal failure may occasionally result.

Skin involvement occurs in up to 53% of pediatric patients with GPA.<sup>63,64</sup> The manifestations are variable but most commonly consist of palpable purpura. Necrotic papules and plaques (Fig. 21-15), subcutaneous nodules, vesicles, pustules, and ulcers resembling pyoderma gangrenosum may occur. Papulonecrotic lesions may favor the

**Figure 21-15** Granulomatosis with polyangiitis (GPA; formerly known as Wegener granulomatosis). Painful, ulcerative, necrotic plaques on the ankle (**A**) and elbow (**B**) of a female with GPA.

extremities (especially the elbows) but may also occur on the face and scalp.<sup>41</sup> Purpura occurring on the lower extremities in conjunction with abdominal pain and hematuria may be the presenting feature of GPA, and this constellation may mimic HSP in the early stage.<sup>65</sup> Gingivitis can occur and presents as spongy, friable, and exuberant tissue with petechiae and preferential involvement of the interdental papillae. Ophthalmologic findings (which may occur in up to 50% of patients) include not only conjunctivitis, but also dacryocystitis, episcleritis, corneoscleral ulceration, retinal artery thrombosis, uveitis, proptosis, cavernous sinus thrombosis, and pseudotumor of the orbits. Pericarditis, endocarditis, and coronary vasculitis have been reported, and peripheral neuropathy and cerebral vasculitis, with or without subarachnoid or intracerebral hemorrhage, have been noted in up to 25% of patients.

The diagnosis of GPA is suggested by the clinical presentation and confirmed by tissue biopsy examination in conjunction with laboratory findings. Histologic evaluation of tissues (especially skin, lung, or kidney) reveals the characteristic necrotizing granulomatous vasculitis picture, which is highly suggestive of (but not pathognomonic for) GPA within the appropriate clinical context. Up to 80% of patients with GPA have positive cytoplasmic ANCAs (c-ANCA) and usually

negative perinuclear ANCAs (p-ANCA) on laboratory testing. In one series of pediatric patients with GPA, c-ANCA positivity correlated with kidney involvement.<sup>63</sup>

Before the advent of cytotoxic agents, GPA was nearly always a fatal disease with a mean survival of 5 months. The most commonly used treatment is a combination of immunosuppressive agents, most often glucocorticoids and cyclophosphamide and occasionally azathioprine.<sup>7,8,61</sup> Less commonly utilized therapies include plasmaapheresis, extracorporeal membrane oxygenation, intravenous immunoglobulin (IVIG), mycophenolate mofetil, and rituximab. Survival rates have improved with the addition of cytotoxic agents to the corticosteroids, but side effects and toxicities related to these drugs are a major source of morbidity. The use of methotrexate is advocated by some, and this agent has shown promise both in induction therapy in combination with glucocorticoids and in maintaining remission of the disease after induction with a cyclophosphamide and glucocorticoid regimen.<sup>66,67</sup> Cotrimoxazole is often used for treatment of GPA and may have benefit both in the prevention of opportunistic infection and in modifying disease activity.<sup>8,61</sup> Long-term morbidities related to GPA and its therapy may include infertility, skeletal complications (osteoporosis, avascular necrosis), renal failure, subglottic stenosis, hearing impairment, and nasal septal or upper airway deformities.<sup>68,69</sup>

### CHURG–STRAUSS SYNDROME

Churg–Strauss syndrome (CSS, allergic granulomatosis, eosinophilic GPA) is a rare condition characterized by atopic manifestations and a granulomatous vasculitis involving small- and medium-sized arteries. It occurs primarily in males between 30 and 40 years of age and only rarely in children. A distinguishing feature of CSS-associated asthma compared with typical allergic asthma is the late onset in the former, at a mean age of 35 years.

Patients with CSS often experience a prodromal phase during which time they have allergic rhinitis and asthma, and occasionally sinusitis and nasal polyps. After several years, they develop peripheral eosinophilia, eosinophilic tissue infiltration, worsening of their asthma, gastroenteritis, and diffuse pulmonary infiltrates (second phase). The third, or vasculitic, phase presents with fever, weight loss, and widespread vasculitis and inflammation. If left untreated, this phase may result in death. Clinical manifestations may include arthralgias, myositis, peripheral neuropathy, eosinophilic pneumonitis (Löffler syndrome), and occasional renal, cardiac, CNS, or ocular involvement. Cardiac involvement occurs in roughly half of the patients and may include pericarditis, myocarditis, and tamponade.<sup>70</sup> Skin involvement may occur in up to 70% of patients and includes palpable purpura, petechiae, subcutaneous nodules, urticaria, livedo reticularis, and papulonecrotic lesions similar to GPA.<sup>41,71</sup> Digital ischemic ulcers and Raynaud phenomenon have also been noted.<sup>72</sup>

The ACR criteria for the diagnosis of CSS support the diagnosis when four of the following six criteria are met: asthma, eosinophilia greater than 10%, mononeuropathy/polyneuropathy, nonfixed pulmonary infiltrates, paranasal sinus abnormality, and biopsy containing a blood vessel with extravascular eosinophils.<sup>73</sup> Laboratory studies may be useful, because approximately 70% of adult patients with CSS have a positive ANCA, usually perinuclear with antimyeloperoxidase specificity (MPO-ANCA).<sup>72</sup> However, in contrast to adult patients, pediatric patients with CSS may be negative for ANCA.<sup>70,74,75</sup> In adults, ANCA positivity appears to portend more common ear-nose-throat manifestations (rhinitis, sinusitis, polyps), peripheral nerve involvement, and renal disease, whereas ANCA negativity may predict more common cardiomyopathy.<sup>76</sup>

CSS is treated with glucocorticoids with or without the addition of other immunosuppressive agents (i.e., cyclophosphamide, azathioprine), and the prognosis has traditionally been fairly favorable with a lower mortality rate in comparison to other systemic vasculitides. Combination therapy with other agents including cyclophosphamide, azathioprine, infliximab, or methotrexate may be useful in some patients. Steroid-dependent asthma, however, is common and may persist even after the vasculitis is in remission.<sup>77</sup> In a large series of children with CSS, more common cardiopulmonary manifestations, less common peripheral neuropathy, and higher mortality were noted when compared with the clinical experience in adults.<sup>74</sup> However, in

another smaller series, mononeuritis multiplex was present in 60% of children with CSS.<sup>75</sup>

## Erythema Elevatum Diutinum

Erythema elevatum diutinum (EED) is an uncommon dermatosis seen most often in middle-aged adults and characterized by violaceous papules, plaques, and nodules that have a predilection for acral and extensor surfaces. Common locations for the lesions of EED include the elbows, knees, dorsum of the hands and feet, pretibial surfaces, buttocks, and skin overlying the Achilles tendon.<sup>78</sup> The trunk and mucous membranes are usually spared. Histologically the lesions reveal a leukocytoclastic vasculitis.

EED presents with papules and plaques ranging in size from a few millimeters to several centimeters. They may be yellow and simulate xanthomas, but more often they are violaceous to brown, and less commonly erythema, vesicles, or bullae may be present. The differential diagnosis may include Kaposi sarcoma or bacillary angiomatosis. Although the lesions are typically asymptomatic, they may be tender or painful and may be accompanied by systemic abnormalities such as arthralgias, fever, and malaise. A burning sensation within lesions has been reported by some patients and may worsen in the evening or after exposure to cold temperatures.<sup>79</sup> Spontaneous involution may occur after a period of years without scarring, but residual hypopigmentation or hyperpigmentation is common.

The pathogenesis of EED is unknown, although it is believed to be an immune complex-mediated vasculitis. It has been described in association with various conditions, including hematologic malignancies, infections, autoimmune disease, and inflammatory bowel disease.<sup>78,80</sup> Rheumatoid arthritis-associated EED may present with the skin lesions in conjunction with peripheral ulcerative keratitis.<sup>81</sup> In recent years, EED has emerged as a dermatosis associated with human immunodeficiency virus (HIV).<sup>82</sup> It has been reported in a young woman with juvenile idiopathic arthritis,<sup>83</sup> as well as in a school-aged boy with a history of recurrent streptococcal pharyngotonsillitis, in whom it abated after dapsone therapy and tonsillectomy.<sup>84</sup>

EED tends to run a chronic course and may be persistent or may occasionally spontaneously resolve. Although topical or intralesional corticosteroids may sometimes be useful, the response to these agents is generally unsatisfactory. Dapsone may be effective and to many is considered the treatment of choice, although the lesions often recur upon discontinuation. Other reported therapies include colchicine, tetracycline, and cyclophosphamide. Surgical excision of large nodules is another therapeutic option.

## Polyarteritis Nodosa

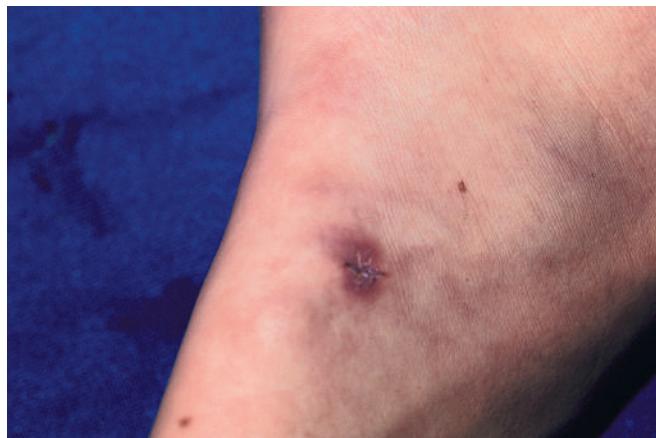

Polyarteritis nodosa (PAN), also known as *periarteritis nodosa*, is a relatively uncommon vasculitis in children that is characterized by inflammation of medium-sized (and in some cases, small-sized) arteries. Several subtypes of PAN have been identified, and the prognosis is variable and largely dependent upon the extent of associated (extra-cutaneous) organ involvement. The two variants discussed in this section are cutaneous PAN (cPAN) and systemic PAN. An infantile type of PAN may occur in children under 2 years of age but is now considered by most to represent a severe form of KD. The clinical features of pediatric PAN are briefly summarized in Table 21-3.

Patients with PAN often have constitutional symptoms including fever, malaise, and weight loss, as well as myalgias and arthralgias. Painful skin nodules, purpura, ulcerations, and livedo reticularis (Fig. 21-16) are the most common cutaneous findings. The nodules vary from 0.5 to 1 cm, are tender to palpation, and are usually red-purple (Fig. 21-17). They may follow the course of superficial arteries and are especially common around the knee, anterior lower leg, and dorsum of the foot.<sup>41</sup> Healing of the ulcerative skin lesions of PAN may result in atrophic, ivory-colored, stellate-shaped scars and hyperpigmentation.<sup>40</sup> Peripheral ischemia with infarction or gangrene may occur (Fig. 21-18). Other manifestations include abdominal pain, hematochezia, neuropathy, Raynaud phenomenon, and cardiac and

**Table 21-3** Clinical Features of Polyarteritis Nodosa in Childhood

	TYPE	
	Systemic PAN	cPAN
Presentation	Fever, CS	Fever, mild CS
Skin findings	Nodules, purpura, ulcers, livedo reticularis, infarction/gangrene, edema, Raynaud phenomenon	Nodules, purpura, ulcers, livedo reticularis, edema, gangrene
Extracutaneous involvement	Cardiac, renal, CNS/PNS, musculoskeletal, gastrointestinal, rarely pulmonary	Musculoskeletal, occasional PNS
Prognosis	Variable; relapse in around 35%	Good

Cutaneous polyarteritis nodosa in childhood: a case report and review of the literature. *Arthritis* 2010;2010:687547. CNS, Central nervous system; cPAN, cutaneous polyarteritis nodosa; CS, constitutional symptoms (fever, fatigue, weight loss); PAN, polyarteritis nodosa; PNS, peripheral nervous system.

**Figure 21-16** Polyarteritis nodosa. Reticulate mottling (livedo reticularis) on the medial foot of a patient with polyarteritis nodosa.

**Figure 21-17** Polyarteritis nodosa. These dusky red nodules were firm and tender to palpation.

**Figure 21-18** Polyarteritis nodosa. This child with polyarteritis nodosa developed dusky red changes of the toes, followed by necrosis, as a manifestation of peripheral ischemia.

renal involvement, which may lead to renovascular hypertension. Pericarditis and valvular heart disease may occur. The lungs are usually spared in patients with PAN, although pleural effusions and pneumonitis have been reported.<sup>85</sup> Death, when it occurs, is usually attributable to renal failure, intracranial or intraabdominal hemorrhage, hypertensive heart failure, disseminated infection, or myocardial involvement.

Although the cause of PAN is unknown, it is presumed to represent a hypersensitivity-type immune-complex vasculitis with deposits of IgM, C<sub>3</sub>, or both in affected vessel walls.<sup>86</sup> Hepatitis B virus infection is associated in some cases, and group A streptococcal infection has been suggested as another potential infectious etiology. Laboratory findings may reveal anemia, leukocytosis, thrombocytosis, and an elevation of acute-phase reactants.<sup>87</sup> Serologic markers may be useful, as patients may have a positive ANCA (usually p-ANCA, although c-ANCA has also been observed). However, serologic studies alone are of limited use in the diagnosis of PAN given their lack of specificity or sensitivity. Skin biopsy is diagnostically valuable and reveals fibrinoid necrosis and inflammation of arteries in the deep dermis and subcutaneous layer and in some cases, septal panniculitis. Direct immunofluorescence studies are variable, occasionally revealing IgM or C<sub>3</sub> deposition. Mutations in the gene for familial Mediterranean fever, *MEFV*, are found in some pediatric patients with PAN and may represent a susceptibility factor, especially in countries where familial Mediterranean fever and its carriers are more common.<sup>88</sup>

cPAN (also known as *benign cPAN*) is the terminology used to describe a clinical variant of PAN in which cutaneous lesions predominate and there is no (or very limited) extracutaneous involvement. It is the most common form of PAN in children and tends to have a chronic course notable for remissions and relapses. The typical skin findings in cPAN are painful red nodules, especially on the lower extremities and malleoli with ulcers, purpura, and livedo reticularis. Peripheral gangrene and autoamputation occur with greater incidence in pediatric patients who have onset of cPAN in the first decade of life.<sup>89</sup> Constitutional symptoms including fever, arthralgias, myalgias, and peripheral nervous system involvement (mononeuritis mul-

tiplex, peripheral neuropathy, cranial nerve palsy) may occur, but visceral involvement is absent. The most notable laboratory aberrations are leukocytosis and elevation of the erythrocyte sedimentation rate.<sup>90</sup> The definitive diagnosis of cPAN is established by histopathologic features in tissue-biopsy specimens. The overall outcome of cPAN is favorable, although there are rare reports of cPAN evolving into systemic disease.

The mainstay of management for PAN is systemic corticosteroids. Cyclophosphamide, dipyridamole, azathioprine, intravenous γ-globulin, methotrexate, and plasma exchange have also been used.<sup>87,91,92</sup> Refractory disease has been treated with tumor necrosis factor (TNF)-α blockade (infliximab, etanercept, adalimumab), and rituximab has also been reported as effective.<sup>93,94</sup> In patients with skin-limited disease, therapy with aspirin or nonsteroidal anti-inflammatory agents has also been advocated.<sup>58,90,95</sup>

## Kawasaki Disease

Kawasaki disease (KD; also acute febrile mucocutaneous lymph node syndrome) is an acute febrile disease of childhood that is one of the leading causes of acquired heart disease in the world. It was described initially in 1967 by Tomisaku Kawasaki. KD is most prevalent in Japan, and its incidence is much higher in Asian-American populations, possibly suggesting a unique genetic susceptibility. Pathologically, KD is a vasculitis involving the small and medium-sized muscular arteries with a predilection for involvement of the main coronary vessels.<sup>96</sup> As mentioned earlier in this chapter, many believe that the entity referred to in the past as infantile PAN represents in fact a severe phenotype of KD.

The majority of cases of KD occur in children younger than 5 years of age, with a peak incidence in those 2 years and younger. The disease tends to be more common in boys than girls, and the attack rate in siblings (1%) is 10-fold higher than in the general population.<sup>97</sup> The mean age of patients with KD is younger in Japan than in the United States. Regional epidemics of KD have been observed, and the disease may occur year round, although larger numbers occur during the winter and early spring. The incidence of KD in the United States is estimated at 19 to 21 per 100,000 children younger than 5 years.<sup>98,99</sup>

The diagnosis of KD may be challenging, and misdiagnosis is common. In fact, missed diagnosis of KD is among the most common malpractice verdicts against child health practitioners.<sup>100</sup> Increasingly, atypical or “incomplete” presentations of KD are being diagnosed and tend to be more common in the youngest patients, in whom an extremely high level of suspicion must be maintained.<sup>100</sup> The diagnosis of KD should be considered in any infant with prolonged, unexplained fever. Delays in diagnosis and initiation of therapy may also occur more often in older children, who overall have a lower prevalence of disease.<sup>101</sup> In a large prospective study of patients with KD, common associated symptoms noted within 10 days before the diagnosis included irritability, vomiting, anorexia, cough, diarrhea, rhinorrhea, weakness, abdominal pain and joint pain.<sup>102</sup>

The diagnostic criteria for KD are listed in Box 21-1. KD should be considered in the differential diagnosis of any infant or child with fever, rash, and red eyes.<sup>97</sup> The fevers in KD are usually of abrupt onset and are quite high (>39°C), and the response to antipyretics is usually minimal. The fever usually lasts 1 to 2 weeks in the absence of treatment but may last as long as 3 to 4 weeks.<sup>103</sup> Although the Centers for Disease Control and Prevention (CDC) case definition of KD specifies fever persisting for 5 or more days, the diagnosis of KD is in some instances established before this time when other supporting features are present. The conjunctival injection (Fig. 21-19) is distinctive, with involvement of the bulbar conjunctivae more often than the palpebral conjunctivae and the absence of exudate (which may help in the differentiation from adenoviral infection). Perilimbal sparing (presenting as a white halo around the iris, Fig. 21-20) is characteristic and may be useful in differentiating KD eye involvement from other infectious or allergic processes.<sup>97</sup> Irritability is common in children with KD and may relate to cerebral vasculitis or aseptic meningitis.<sup>104</sup>

Oropharyngeal changes in KD are most notable for dry, red, fissured, and crusted lips (Figs. 21-21 and 21-22). Hyperemia of the oral mucosa and a red strawberry tongue (Fig. 21-23) (similar to that seen

### Box 21-1 Diagnostic Criteria for Kawasaki Disease

#### Classic Kawasaki Disease (KD)

Fever for 5 days or more,\* plus at least 4 of the following 5 clinical signs:

- Bilateral nonexudative bulbar conjunctivitis
- Oral mucous membrane changes: erythema of the oropharyngeal mucosa, injected or fissured lips, strawberry tongue
- Peripheral extremity changes: erythema or edema of hands/feet (acute), periungual desquamation (convalescent)
- Polymorphous rash
- Cervical lymphadenopathy (at least 1.5 cm, often unilateral)

#### Incomplete KD

Fever for  $\geq 5$  days with 2 or 3 of the above clinical criteria

#### Atypical KD

Patients who fulfill KD criteria but who have a clinical feature that is not typically seen with KD

\*In the presence of fever and the other diagnostic criteria for KD, experienced physicians may make the diagnosis before the fifth day of fever. Rowley AH, Shulman ST. Kawasaki syndrome. *Pediatr Clin N Am* 1999;46(2):313–29.

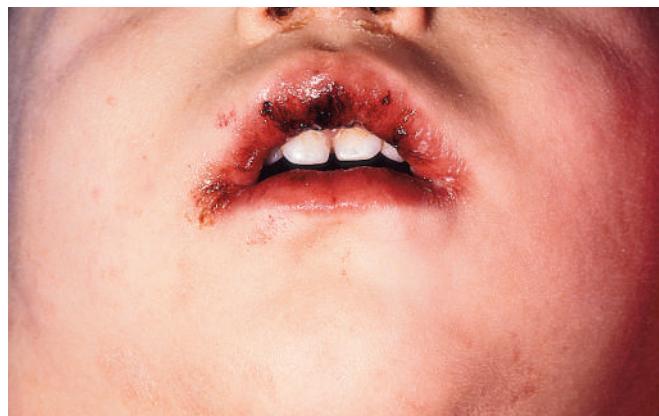

**Figure 21-19** Kawasaki disease. Nonexudative, bulbar conjunctival injection.

**Figure 21-20** Kawasaki disease. The conjunctivitis in this patient demonstrates the notable perlimbal sparing (halo of noninvolvement adjacent to the iris).

in streptococcal scarlet fever) are also seen. The peripheral extremity changes include nonpitting edema of the dorsal hands (Fig. 21-24) and feet (Fig. 21-25) and erythema of the palms and soles (Fig. 21-26). The edema is characterized by flesh-colored or red-violaceous brawny swelling, along with fusiform swelling of the digits and taut skin noted on the dorsal surfaces. Patients may complain of pain or

refuse to walk. Periungual desquamation (Fig. 21-27) is a later finding, generally seen in the subacute or convalescent stages of KD. It begins at the tips of the digits and over a period of days to weeks, gradually progresses to involve the fingers, toes, palms, and soles. Recurrent episodes of skin peeling after upper respiratory tract infection may occur in up to 11% of KD patients for several years after their recovery.<sup>105</sup> Transverse linear grooves in the nail plates (Beau lines; Fig. 21-28) may also be appreciated months into the course of disease.

Cervical lymphadenopathy is the least common feature seen in KD, occurring in approximately 50% to 75% of patients.<sup>103</sup> When present it is usually quite obvious on physical examination given the size of the involved node(s). The diagnostic criterion specifies a size of at least 1.5 cm. Some patients with KD present with solely fever and unilateral enlargement of cervical lymph nodes. Generalized lymphadenopathy is not a feature of KD.

The cutaneous eruption of KD is polymorphous, and the majority of patients will have skin manifestations at some point during their illness. The most common presentations are that of a nonspecific, diffuse macular and papular erythematous eruption (Fig. 21-29) or a diffuse urticarial process (Fig. 21-30). A scarlet-fever-like rash with "sandpaper" papules on a background of erythema and erythema-multiforme-like lesions (Fig. 21-31) may also occur. Small pustules superimposed on urticarial erythema have also been observed.<sup>106</sup> An important finding on skin examination is accentuation of the eruption in fold areas, especially the groin (Figs. 21-32 and 21-33), which is quite common and should increase the practitioner's suspicion for KD in the presence of other suggestive clinical features. This erythematous, desquamating perineal eruption was found to occur in 67% of patients with KD in one series.<sup>107</sup> Erythema, induration, and

**Figure 21-27** Kawasaki disease. Digital and periungual desquamation occurred late in the course of the disease in this boy who had coronary arterial aneurysms.

**Figure 21-25** Kawasaki disease. Mild edema of the feet accompanied by blanchable, erythematous macules and patches.

**Figure 21-28** Kawasaki disease. Transverse ridges (Beau lines) and nail-plate separation, which may occur several months after treatment for Kawasaki disease.

ulceration at the bacillus Calmette–Guérin (BCG) vaccination site have been described during the course of KD.<sup>108,109</sup> Rarely, severe peripheral ischemia with resultant gangrene may occur (Fig. 21-34).<sup>103</sup> Although the cutaneous eruption of KD is quite polymorphous, vesicles, bullae, and purpura are virtually never seen. The histopathologic features of skin biopsy material from patients with KD are nonspecific.

A psoriasis-like skin eruption, occasionally with a pustular psoriasis appearance, may also be seen in children during the acute or convalescent phases of KD.<sup>110,111</sup> In one series, two of nine patients had a family history of psoriasis, and in all of the patients, the psoriasis resolved with therapy for the KD and did not recur.<sup>110</sup> Whether this observation reflects activation of "latent" psoriasis in genetically

**Figure 21-29** Kawasaki disease. This young girl has hyperemic lips with crusting and a diffuse, confluent erythematous skin eruption.

**Figure 21-30** Kawasaki disease. Urticular patches are the prominent skin finding in this patient.

**Figure 21-31** Kawasaki disease. This child had a diffuse erythematous eruption with annular and targetoid (erythema multiforme-like) lesions.

predisposed individuals or a common etiologic agent for both KD and psoriasis is unclear.

The differential diagnosis of children with fever, rash, and red eyes is broad, and in addition to KD includes toxin-mediated bacterial infections (scarlet fever, toxic shock syndrome, staphylococcal scalded-skin syndrome), Rocky Mountain spotted fever, viral exanthematosus illnesses (i.e., adenovirus, measles, enterovirus), drug reactions (including Stevens–Johnson syndrome and toxic epidermal necroly-

**Figure 21-32** Kawasaki disease. The classic perineal eruption of Kawasaki disease is notable for accentuation in folds and desquamation.

**Figure 21-33** Kawasaki disease. This perineal and genital desquamation was preceded by pustules and occurred in a 5-year-old boy with high fevers, conjunctival injection, oropharyngeal changes, lymphadenopathy, and markedly elevated inflammatory markers.

**Figure 21-34** Kawasaki disease. Peripheral ischemia with gangrene of the distal digits.

sis), and a variety of other infectious, inflammatory, or connective tissue disorders. The differentiation of KD from acute adenoviral infection can be challenging. Although the presentations of these two processes can be very similar, two potentially distinguishing features of adenovirus infection are a purulent (vs. nonpurulent) conjunctivitis and the lack of a perineal accentuation of the rash.<sup>112</sup> A Kawasaki-like syndrome has also been observed in adults infected with HIV.<sup>113</sup> Because there exists no reliable diagnostic test to confirm KD, the

### Box 21-2 Clinical Clues to the Diagnosis of Kawasaki Disease

- Persistent fever for more than 5 days
- Fever unresponsive to antipyretics
- Extreme irritability, inconsolable nature of child
- Perilimbal sparing of conjunctival injection
- Perineal accentuation of erythematous/desquamating rash
- Erythema, induration or ulceration of BCG vaccination site
- Sterile pyuria
- Gall bladder hydrops
- Increasing ESR in light of clinical improvement/defervescence

BCG, Bacillus Calmette-Guérin; ESR, erythrocyte sedimentation rate.

**Table 21-4** Laboratory Findings in Kawasaki Disease

Finding	Comment
Leukocytosis	Often neutrophilic; toxic granulations may be present
Anemia	Normocytic, normochromic
Thrombocytopenia	Associated with severe coronary disease, myocardial infarction
Thrombocytosis	In subacute stage (usually ≥10–14 days after onset of illness)
Increased ESR	Normalizes over 6–10 weeks
Increased CRP	Normalizes in 2–5 days with treatment
Low albumin	
Abnormal lipids	Decreased HDL, total cholesterol; increased triglycerides, LDL
Increased transaminases, bilirubin	Secondary to gallbladder hydrops
Sterile pyuria	Mild proteinuria occasionally
CSF pleocytosis	Mononuclear
Increased NT-proBNP	Associated with cardiomyocyte stress; may be a marker for those developing coronary artery disease

CRP, C-reactive protein; CSF, cerebrospinal fluid; ESR, erythrocyte sedimentation rate; HDL, high-density lipoprotein; LDL, low-density lipoprotein; NT-proBNP, N-terminal probrain natriuretic peptide.

diagnosis continues to rest on clinical vigilance, and the overall picture of the patient. Box 21-2 lists some useful clues to the diagnosis of KD.

Recurrent toxin-mediated perineal erythema (RTPE) is a benign, self-limited mucocutaneous disorder that may mimic some aspects of KD. The reported patients had perineal erythema, occasional involvement of the axillary and inguinal folds, and occasional desquamation of the fingers and feet.<sup>114</sup> Patients may report a recurrent history of such eruptions and are generally otherwise well. RTPE is believed to be caused by a unique clinical response to toxins elaborated by streptococci and staphylococci. Some patients have had positive pharyngeal or perianal cultures for GABHS.<sup>114,115</sup>

Other clinical features of KD include cardiac manifestations, CNS and gastrointestinal involvement, extreme irritability, lethargy, urethritis with sterile pyuria, anterior uveitis, musculoskeletal complaints (arthritis and arthralgia), and peripheral gangrene. CNS involvement may include meningeal signs with cerebrospinal fluid (CSF) pleocytosis, cerebral infarction, sensorineural hearing loss, and cranial nerve palsies. Gastrointestinal manifestations include hepatomegaly, hepatitis, gallbladder hydrops, diarrhea, and jaundice. Laboratory findings of KD are listed in Table 21-4.

Cardiac sequelae represent the most serious complications of KD. Cardiac involvement may occur during the acute or later stages of the disease. Early manifestations include pericardial effusions and myocarditis, which may present with tachycardia and gallop rhythm.<sup>96</sup> Congestive heart failure, arrhythmias, and valvular regurgitation (especially mitral) may also occur. The most significant cardiac

complication, though, is the development of dilatation or aneurysms of the coronary arteries, which occur in up to 5% to 10% of patients despite the use of appropriate therapy (and in up to 20% of untreated children).<sup>100,116,117</sup> Changes in the coronary arteries may continue to evolve beyond the acute phase of the illness, but the development of aneurysms more than 8 weeks after the acute illness is quite unusual. Although death owing to coronary occlusion has occasionally been noted after apparent recovery from the illness, most deaths occur suddenly between 3 and 8 weeks after the onset of the disease. "KD shock syndrome" is a rare association, presenting during the acute phase with hypotension and a shock-like state.<sup>117</sup>

The etiology of KD remains a mystery. Hypothetical causes have included infectious agents (via conventional antigen), a toxin-mediated superantigen process, genetic predisposition, and immune activation. In support of an infectious etiology are the fact that KD presents in a similar fashion to some other self-limited exanthematosus diseases, the seasonal predilection, the rare occurrence in infants under the age of 6 months (possibly suggesting protective maternal immunity), and the rarity of recurrences.<sup>97</sup> Many agents have been implicated, but none proven definitively, including *Staphylococcus*, *Streptococcus* species, *Candida* species, *Rickettsia* species, herpesviruses, *Mycoplasma pneumoniae*, human adenoviruses and Gram-negative bacteria.<sup>96,118–120</sup> Superantigen-secreting bacteria such as staphylococci and streptococci, specifically those that stimulate a Vβ2 T-lymphocyte response, have been postulated to be involved in the pathogenesis of KD.<sup>121</sup> IgA plasma cells have been identified in coronary vessel walls, pancreas, kidney, and respiratory tract in patients who succumbed to KD, suggesting entry of the KD etiologic agent through the upper respiratory tract with systemic spread to other organs.<sup>122</sup> The genetic predisposition hypothesis is appealing, given the disproportionately high attack rate among children of Japanese, Chinese, and Korean ethnicity, but the exact association remains unclear. Polymorphisms in the genes for C-reactive protein and TNF-α may be associated with a predisposition toward KD, with single-nucleotide polymorphisms occurring with greater frequencies in KD as compared with control subjects.<sup>123</sup> Candidate genes identified for KD include *ITPKC*, *FCGR2A*, *CAMK2D*, *CSMD1*, *LNX1*, *NAALADL2*, and *TCP1*, among many others.<sup>124–128</sup> A remarkable seasonality of KD has been observed, which is shared among extra-tropical areas (those north of the Tropic of Cancer) in the Northern Hemisphere.<sup>129</sup> A time series analysis of three geographically distinct regions with a high KD incidence (Japan, San Diego, and Hawaii) suggests that tropospheric wind currents may influence the development of disease via fluctuations in wind circulation (and possibly wind-borne transmission of the KD trigger).<sup>130,131</sup> Research into the pathogenesis of KD has been extensive, but the etiology remains elusive.

Treatment of KD is predicated on the ability to recognize the condition and rapidly render a diagnosis, which in some patients remains a challenge. The ultimate goals of therapy are to reduce inflammation and thus the potential for damage to the arterial wall.<sup>97</sup> The mainstays of therapy for KD are IVIG and aspirin, which should be initiated within the first 10 days of illness whenever possible.<sup>101</sup> In the United States, IVIG is generally given in one intravenous infusion of 2 g/kg infused over 12 hours, which was shown to be more effective than the more traditional 4-day course.<sup>132</sup> Issues surrounding IVIG therapy in KD include the expense of the preparation and the potential transmission of blood-borne pathogens, such as hepatitis C. Such transmission of infectious diseases is extremely rare since the institution of the current purification and processing practices in 1994.<sup>100</sup> A subgroup of patients with KD are resistant to IVIG therapy and seem to be at greatest risk for the development of coronary artery aneurysms and long-term sequelae.<sup>96</sup>

Aspirin is also started concurrently with IVIG, initially at a dosage of 80 to 100 mg/kg per day (in 4 divided doses) until the fever subsides (child is afebrile for 48 to 72 hours). This high-dose regimen is useful for its anti-inflammatory effect. Low-dose aspirin therapy (3 to 5 mg/kg per day) is then recommended, primarily for its antiplatelet effect. Unless the echocardiogram detects coronary artery abnormalities, aspirin therapy is discontinued once the laboratory studies normalize, which is usually within 2 months of the onset of disease. Risks of aspirin therapy include hepatitis, hearing loss, and Reye syndrome, the latter of which is mainly of significance in the setting of acute

varicella or influenza. Lower doses of aspirin (i.e., 30 to 50 mg/kg per day) are used in Japan given concerns in that population about potential hepatotoxicity. The exact role of aspirin therapy, as well as the risk-to-benefit ratio of high-dose versus low-dose regimens in patients with KD remains controversial.

Whereas the majority of patients with KD have an excellent response to the above therapies, approximately 5% to 15% have a suboptimal response. In these patients, a second dose of IVIG is often effective.<sup>125</sup> Other therapies that have been evaluated for KD (and for which there is no current consensus) include corticosteroids, pentoxifylline, and anti-TNF agents. A randomized prospective study failed to show any significant advantages of the addition of intravenous methylprednisolone to conventional primary KD therapy.<sup>133</sup> Other studies, however, have found that corticosteroids may in fact play a useful role as adjunctive initial therapy and that patients treated with steroids may have fewer coronary artery abnormalities.<sup>134,135</sup> Infliximab, a chimeric monoclonal antibody to TNF- $\alpha$ , has been used increasingly for IVIG-resistant disease in hospitalized patients in the United States<sup>136</sup> and has become the most commonly used third-line agent for KD.<sup>137</sup> It has been shown to be both efficacious and safe when compared to a second infusion of IVIG in patients who had received initial IVIG therapy.<sup>138,139</sup> Etanercept, another TNF- $\alpha$  inhibitor, has also been demonstrated effective in smaller-scale studies.<sup>140,141</sup> Rituximab may also be a useful therapeutic agent for resistant KD.<sup>142</sup>

Long-term cardiac follow-up monitoring of patients with KD should include an echocardiogram once or twice during the first 2 months after illness onset with further follow-up study depending on the individual patient's coronary artery status. Children whose coronary arteries are normal at 2 months after the diagnosis of KD are considered free of cardiac disease, although several experts consider a history of KD to be a risk factor for the later development of coronary artery disease.<sup>100</sup> Vascular lesions in adult survivors of KD may include coronary artery aneurysms, calcification, and stenosis, as well as valvular incompetence and myocardial fibrosis, either focal or diffuse.<sup>143</sup> The outcomes for patients with KD who are diagnosed at the extreme ends of the age spectrum (<6 months or >9 years) appear to be sub-

optimal, with a greater incidence of coronary artery abnormalities.<sup>144</sup> "Recurrent fever syndrome," characterized by the reappearance of inflammatory symptoms after successful therapy for KD, has been observed in some patients; it may resemble the clinical entity known as periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA) syndrome and suggests a possible genetic predisposition to auto-inflammatory responses or environmental exposure susceptibility in these cohorts.<sup>145</sup>

The connective tissue (collagen vascular, rheumatic) disorders represent a group of diseases characterized by inflammatory changes of the connective tissue in various parts of the body. Among these, juvenile idiopathic arthritis (JIA), lupus erythematosus, juvenile dermatomyositis (JDM), systemic and localized forms of scleroderma, eosinophilic fasciitis, Sjögren syndrome, mixed connective tissue disease (MCTD), and antiphospholipid antibody syndrome (APS) exhibit specific cutaneous findings.

## Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is a group of seven arthritides of children under the age of 16 years that last longer than 6 weeks and are of unknown cause. JIA encompasses the former term *juvenile rheumatoid arthritis*, as well as other arthritides in children.<sup>1</sup> These include systemic arthritis (Still disease), oligoarthritis, rheumatoid factor (RF)-negative polyarthritis, RF-positive polyarticular arthritis, psoriatic arthritis, and enthesitis-related arthritis (Box 22-1).<sup>1,2</sup> Overall, juvenile arthritis has a prevalence of up to 1:1000 children under the age of 16 years.<sup>3</sup> Approximately 6% of these children have systemic-onset disease; 13%, RF-negative polyarticular arthritis; 2%, RF-positive polyarticular arthritis; 52%, oligoarthritis; 12%, enthesitis-related arthritis; 8%, psoriatic arthritis (see Chapter 4); and 8%, undifferentiated arthritis.<sup>4</sup> However, subtype distribution varies among countries; for example, although oligoarthritis is most common in Europe, polyarthritis is more common in New Zealand and India. RF, usually an immunoglobulin (Ig) M antibody against IgG, rarely occurs in children, especially children under 7 years of age, and is associated with greater synovial erosion with a poor prognosis. Antinuclear antibody (ANA) levels (which are positive in 10% of normal children, usually at a level of 1:40 to 1:80) are most commonly positive in children with oligoarticular disease (40% to 80%), especially in girls and with uveitis. The different subtypes of JIA are associated with human leukocyte antigen (HLA) types. Oligoarthritis is associated with HLABR8, HLABR6, and HLABR5, with chronic uveitis in oligoarthritis linked to HLABR5. RF-positive polyarticular JIA has been associated with HLABR4, whereas RF-negative polyarthritis has been linked to HLABR8, HLADPw3, and HLADQw4. Systemic-onset disease has been associated with HLABR4, HLABR5, and HLABR8, and the enthesitis-related arthritis (juvenile spondyloarthritis) with HLAB27 and a striking familial occurrence. Patients with JIA and coexisting atopy have been shown to have more active disease and worse outcomes, possibly because of ongoing immune dysregulation.<sup>5,6</sup>

Of the various forms of JIA other than psoriatic arthritis, systemic-onset disease is the only one with known cutaneous findings. Its underlying pathomechanism involving dysfunction in the innate immune system, its clinical features, and its poor response to therapies that ameliorate other forms of JIA have led several investigators to classify systemic JIA as an auto-inflammatory, rather than autoimmune, disease (see Chapter 25).<sup>7,8</sup> Systemic-onset disease affects boys and girls equally.<sup>9</sup> The eruption of systemic-onset JIA is usually intermittent, occurring most often when patients have their characteristic daily or twice daily spiking fevers. The fevers generally reach 39°C or higher, and the children appear acutely ill with exacerbation of joint pain when fevers occur. The characteristic flat to slightly elevated macules or occasionally papules may resemble urticaria but are not pruritic. They typically measure 2 mm to 6 mm in diameter. Lesions vary from salmon-pink to red and display a characteristic slightly irregular or serpiginous margin. The blanching macules are often evanescent and commonly subside during periods of remission and a few hours after defervescence. Individual lesions may coalesce to form

large plaques 8 to 9 cm in diameter. The eruption occurs predominantly on the trunk but often affects the extremities and occasionally the face (Fig. 22-1); it is accentuated by local heat or trauma. Seen in 25% to 50% of patients, it may precede fevers or visceral involvement by up to 3 years. In some patients the rash occurs during a period of only 1 week, in others for a year or more. Persistent pruritic papules and plaques can occur in children with systemic JIA (and more often in adults). Biopsy helps confirm the diagnosis and shows dyskeratosis of the upper epidermis and sparse inflammation.<sup>10</sup>

Many patients have extraarticular features, particularly hepatosplenomegaly, pleuritis, pericarditis, and lymphadenopathy, which may predate the joint manifestations by weeks to, rarely, years. Approximately 50% of affected individuals have a mild oligoarticular course with a good prognosis for remission; of the remaining 50%, approximately half will develop severe, recalcitrant, and destructive progressive polyarticular arthritis. Other complications of systemic-onset JIA include secondary amyloidosis, secondary infection, osteoporosis, and growth retardation.

Oligoarticular JIA occurs more often in girls than in boys and peaks between the ages of 2 and 4 years. Children with oligoarticular JIA often limp and show joints that are warm and effused, but not red and hot. In about 50% of cases, the onset is monoarticular with the knee, ankle, or elbow most commonly affected; small joints are usually spared. The acute onset of painful monoarthritis with refusal to bear weight is unlikely to be JIA, and infectious, traumatic, and malignant causes of joint pain should be considered. Approximately 20% to 30% of children with JIA have uveitis, which occurs most commonly in ANA-positive girls with early onset oligoarthritis.<sup>11,12</sup> The classic picture is a chronic bilateral anterior uveitis, which is usually asymptomatic until significant, and sometimes irreversible damage to intraocular structures occurs. Patients with oligoarticular JIA and uveitis have worse ocular outcomes relative to patients with other causes of uveitis, necessitating regular screening examinations.<sup>13</sup> Treatment of the uveitis includes topical corticosteroids, mydriatics, systemic immunosuppressive agents, and surgical management of complications.

Polyarthritis usually has an insidious onset, although it may be acute. It can involve both large and small joints (particularly of the hands and feet), and commonly involves the temporomandibular joints and cervical spine. Lymphadenopathy, hepatomegaly, and fevers may occur, although the fevers do not show the daily (quotidian) spikes seen in systemic JIA.

Children with enthesitis-related arthritis have inflamed tendons in addition to arthritis of one or more joints. Most affected individuals are boys over the age of 10 years. Although children rarely show typical ankylosing spondylitis at onset, spondyloarthropathy not uncommonly develops by adulthood.<sup>14</sup> Arthritis associated with inflammatory bowel disease is a subset of this type. Acute anterior uveitis can occur in up to 27% of children and tends to present as an acutely painful, red, photophobic eye in contrast to the asymptomatic uveitis seen in oligoarticular JIA.

Although more characteristic of SLE, scleroderma, and dermatomyositis, patients with JIA may also demonstrate cuticular telangiectasias. Subcutaneous nodules rarely are seen in children with JIA and occur most commonly in patients with RF-positive polyarthritis, particularly if the disease is recalcitrant to therapy. Barely palpable to several centimeters in size, they may be the first presenting sign of JIA. Their most common location is near the olecranon process on the ulnar border of the forearm. Less commonly they may occur on the dorsal aspect of the hands, on the knees and ears, and over pressure areas such as the scapulae, sacrum, buttocks, and heels. In the areas of fingers and toes, subcutaneous nodules are only a few millimeters

### Box 22-1 Subtypes of Juvenile Idiopathic Arthritis

#### Systemic-Onset Arthritis

Definition: Arthritis with or preceded by daily fever of at least 2 weeks' duration plus at least one of the following:

- Evanescent, nonfixed erythematous eruption
- Generalized lymphadenopathy
- Serositis
- Hepatosplenomegaly

#### Oligoarthritis

Definition: Arthritis that affects one to four joints during the first 6 months of disease. Two subtypes occur: 1) persistent oligoarthritis that never affects more than four joints; and 2) extended oligoarthritis that affects a total of five or more joints after the first 6 months of the disease

#### Exclusions:

- Family history of confirmed psoriasis in at least one first- or second-degree relative
- Family history of confirmed HLA B-27-associated disease in at least one first- or second-degree relative
- HLA-B27 positivity in a boy with the onset of arthritis after 8 years of age
- Positive RF testing
- Presence of systemic-onset arthritis as defined

#### Polyarthritis (RF-negative)

Definition: Arthritis that affects five or more joints during the first 6 months with RF-negative testing at least twice and at least 3 months apart. Systemic-onset JIA must be excluded

#### Polyarthritis (RF-positive)

Definition: Arthritis that affects five or more joints during the first 6 months of disease, associated with a positive RF test twice and at least 3 months apart. Systemic-onset JIA must be excluded

#### Psoriatic Arthritis

Definition: Must have arthritis and psoriasis, or arthritis and at least two of the following:

- Dactylitis
- Nail pitting or onycholysis
- Family history of confirmed psoriasis in at least one first-degree relative

#### Enthesitis-Related Arthritis

Definition: Arthritis and enthesitis, or arthritis or enthesitis and at least two of the following:

- Sacroiliac joint tenderness and/or inflammatory spinal pain
- HLA-27 positivity
- Family history of at least one first- or second-degree relative with confirmed HLA-27-associated disease
- Anterior uveitis that is usually symptomatic (pain, redness, photophobia)
- Onset of arthritis in a boy after the age of 8 years
- Systemic-onset JIA and confirmed psoriasis in at least one first- or second-degree relative must be excluded

HLA, Human leukocyte antigen; RF, rheumatoid factor; JIA, juvenile idiopathic arthritis.

**Figure 22-1** Juvenile idiopathic arthritis (JIA). Evanescent macular eruption occurred with fever in this boy with systemic-onset JIA.

in size. Subcutaneous nodules are firm and nontender and may be attached to the periarticular capsules of the fingers. They can be easily confused with the subcutaneous form of granuloma annulare (see Chapter 9). Rheumatoid nodules and JIA must also be distinguished from fibroblastic rheumatism, a rare disorder characterized by the sudden but sometimes progressive onset of cutaneous nodules (Fig. 22-2), flexion contractures, and polyarthritis.<sup>15,16</sup> Some affected individuals respond to methotrexate or interferon (IFN)- $\alpha$ . Methotrexate<sup>17</sup> and tumor necrosis factor (TNF) inhibitor<sup>18</sup> treatment have been linked to induction of subcutaneous nodules, most often in rheumatoid arthritis, but this nodulosis has only been described in adults.

Traditional nonsteroidal anti-inflammatory drugs (NSAIDs) continue to be the first-line therapy in all but those with systemic JIA,<sup>19,20</sup> in addition to physical therapy and psychosocial support.<sup>21</sup> NSAIDs that preferentially inhibit the cyclooxygenase-2 (COX-2) enzymes have fewer gastrointestinal (GI) adverse effects and may be preferred in some patients. Pseudoporphyria, presenting with tense blisters in photodistributed sites, has most commonly been associated with the use of naproxen sodium but has been reported after administration of other NSAIDs as well, including COX-2 inhibitors (see Chapter 19).

Intraarticular injections of corticosteroids are used for children who do not respond to NSAID therapy or as initial therapy for oligoarthritis.<sup>22</sup> Methotrexate is usually the second line of treatment for persistent, active arthritis but is best initiated early in the disease course. Patients with oligoarticular arthritis tend to respond most favorably.<sup>23,24</sup> Blockade of TNF with biologics (etanercept, infliximab, adalimumab) in combination with methotrexate, is particularly effective for children with polyarticular arthritis.<sup>25</sup> Sulfasalazine has largely been used for enthesitis-related arthritis.

Systemic-onset JIA responds poorly to NSAIDs and TNF- $\alpha$  blockers (30% response) but will typically respond to corticosteroids and often to anakinra or canakinumab (anti-interleukin [IL]-1 receptor antagonists),<sup>26,27</sup> tocilizumab (humanized anti-IL-6 receptor monoclonal antibody),<sup>28–30</sup> abatacept (T cell-activating agent/IgG1 fusion protein),<sup>31</sup> or methotrexate.<sup>32,33</sup> Moderate or high dosages of systemic corticosteroids, including pulse intravenous steroids to avoid long-term high-dose treatment, are occasionally used for short periods while awaiting the effects of other medications. As a chronic

**Figure 22-2** Fibroblastic rheumatism. Firm skin-colored papules and nodules on the fingers and palm of this young boy with juvenile idiopathic arthritis.

inflammatory disorder and in relation to usage of systemic corticosteroids, JIA is associated with an increased risk of osteoporosis, which can be countered by treatment with calcium and vitamin D supplementation, bisphosphonates, and calcitonin.<sup>34</sup>

### MACROPHAGE ACTIVATION SYNDROME

Macrophage activation syndrome (MAS), a severe, life-threatening complication of systemic-onset JIA and other connective tissue diseases,<sup>35</sup> is associated with hemophagocytosis of activated macrophages/histiocytes and multiorgan dysfunction. When observed in the absence of underlying connective tissue disease, this diagnosis is termed *hemophagocytic lymphohistiocytosis (HLH)* and can be primary (when familial) or secondary (typically in the setting of infection or malignancy) (see Chapter 10). The pathophysiology of both MAS and HLH are speculated to involve inability of natural killer (NK) or CD8 T cells to lyse infected antigen-presenting cells, leading to ongoing infection and resultant “cytokine storm.” Patients show the sudden onset of fever, hemophagocytosis with hepatic dysfunction, disseminated intravascular coagulation, and sometimes encephalopathy, respiratory distress, and renal failure. The disease may present as pancytopenia with a falling erythrocyte sedimentation rate (ESR), in contrast to the increased ESR associated with flaring JIA. Formal diagnostic criteria for MAS are currently lacking, but a recent international consensus survey of pediatric rheumatologists revealed the 10 most useful diagnostic features: decreasing platelet count, hyperferritinemia, evidence of macrophage hemophagocytosis in the bone marrow, increased liver enzymes, decreasing leukocyte count, persistent continuous fever greater than 38°C, falling ESR, hypofibrinogenemia, and hypertriglyceridemia.<sup>36</sup> Patients with MAS and systemic JIA have been shown to harbor defects in NK-cell function and in genes that encode proteins crucial to lymphocytic cytolytic activity, including Munc 13-4 and perforin, which are also implicated in primary familial hemophagocytic lymphohistiocytosis.<sup>37</sup> Early recognition of MAS and treatment with high-dose corticosteroids with or without cyclosporine, etoposide, and/or etanercept may be life saving.<sup>38</sup>

## Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a heterogeneous autoimmune disease characterized by autoantibody accumulation with immune complex deposition leading to end-organ damage. It often involves the skin but may affect almost any organ system. Autoantibodies are the hallmark of SLE, and activated B cells, T helper cells, and the cytokines that modulate inflammatory responses are thought to be the most appropriate targets for therapy. Both genetic and environmental factors are thought to play roles in its pathogenesis. Reports of familial cases and a high concordance for clinical disease in monozygotic, but not dizygotic, twins support a strong genetic contribution to the development of SLE. SLE has been linked to several genetic susceptibility loci that encode protein products involved in innate and adaptive immunity, particularly in pathways of apoptosis and immune complex clearance, activation of toll-like receptors (TLRs), and signaling of type I IFN and nuclear factor (NF)-κB.<sup>39–43</sup> The availability of whole exome sequencing has led to the discovery of pathogenic mutations in autosomal recessive juvenile-onset SLE (PRKCD, encoding protein kinase C $\delta$ ),<sup>44</sup> complement deficiency leading to SLE,<sup>45</sup> and autosomal recessive hypocomplementemic urticarial vasculitis (DNASE1L3).<sup>46</sup> Although most individuals with SLE do not have monogenic disease, these discoveries may increase understanding of the pathogenesis and lead to new ideas for therapy.

Environmental triggers, including ultraviolet (UV) light, medications, pesticides, heavy metals, tobacco, and infections, have all been linked to the development of SLE. In particular, exposure to UV light is a trigger, not only for cutaneous manifestations, but also for flares of systemic disease.<sup>47</sup>

Approximately 15% to 20% of all cases of SLE occur within the first 2 decades of life. Of these, 60% occur between the ages of 11 and 15 years, 35% between 5 and 10 years, and 5% in children younger than 5 years of age. Other than neonatal lupus erythematosus (NLE), the disorder is rarely seen before the age of 3 years. Disease onset in the

first decade of life is associated with a female to male ratio of 4:3, which increases to female predominance in the second decade (4:1), compared with a ratio of 9:1 in patients with adult-onset SLE. The overall prevalence is 5 to 10 out of 100,000 children, and both increased prevalence and severity are seen in African-American and Hispanic children, especially because of the increased prevalence of nephritis.<sup>48</sup> In comparison with SLE in adults, affected children have more severe disease in general, with an increased incidence of renal, neurologic and hematologic involvement at the time of diagnosis.<sup>49–51</sup> In one study, 77% of pediatric patients required moderate to high dosages of corticosteroids, compared with 16% of adult patients.<sup>52</sup>

About 80% of patients with SLE have cutaneous involvement at some time, often as the presenting sign. Diagnosis of SLE requires Systemic Lupus International Collaborating Clinics (SLICC) criteria that were established in 2012 (Table 22-1) and are more accurate at classification than the previous criteria established by the American College of Rheumatology (ACR) in 1982. The 1982 criteria included four mucocutaneous features: the malar eruption, discoid eruption, photosensitivity,<sup>53</sup> and oral ulcerations. In 2012, the dermatologic criteria for SLE were broadened to include the variety of subtypes of cutaneous lupus under either acute or chronic cutaneous lupus criteria. In addition, to prevent duplication of highly correlated terms related to cutaneous lupus, photosensitivity was replaced with diffuse, nonscarring alopecia.<sup>54</sup>

### Cutaneous Lupus Erythematosus

Cutaneous lupus erythematosus (CLE) may occur as an isolated finding or in the setting of underlying SLE. Features of CLE may be classified as lupus-specific or nonspecific, based on clinical and histopathologic characteristics. Lupus-specific subsets of cutaneous disease characteristically demonstrate lupus-specific features on histopathology, including interface dermatitis and mucin deposition. These include acute CLE (ACLE), subacute CLE (SCLE), intermittent CLE (ICLE), and chronic cutaneous lupus erythematosus (CCLE). Lupus-nonspecific cutaneous disease includes a variety of reactive phenomena, which are not pathognomonic or specific for SLE but typically occur in active disease.

ACLE may present with a malar or butterfly rash or a more generalized morbilliform photodistributed eruption. In particular, the malar rash, while seen in approximately 60% of patients with SLE,<sup>53</sup> is not specific, but when present is often a sign of underlying systemic disease. This erythematous, mildly scaling eruption (Fig. 22-3) often appears over the cheeks and bridge of the nose, resembling the shape of a butterfly. It can be confused with the malar erythema of seborrheic dermatitis, erythematotelangiectatic acne rosacea, parvovirus infection, or cutaneous lichenoid graft-versus-host disease<sup>55</sup>; seborrheic dermatitis typically involves the nasolabial fold and shows

**Figure 22-3** Systemic lupus erythematosus. Mild scaling and erythema of the malar rash.

**Table 22-1** Criteria for Classification of Systemic Lupus Erythematosus (SLICC)

Criterion*	Comments
<b>CLINICAL CRITERIA</b>	
1 Acute cutaneous lupus	Lupus malar rash (fixed erythema, flat or raised, over malar eminences, usually sparing nasolabial folds), bullous lupus, photosensitive lupus rash (not dermatomyositis), maculopapular lupus rash, or toxic epidermal necrolysis variant Subacute cutaneous lupus (nonindurated annular polycyclic or psoriasisiform lesions that resolve without scarring)
2 Chronic cutaneous lupus	Classic discoid eruption (erythematous plaques with adherent keratotic scaling and follicular plugging, often atrophic scarring and dyspigmentation if older lesion; localized if only above the neck, otherwise generalized), lupus panniculitis (profundus), hypertrophic (verrucous) lupus, lupus tumidus, chilblains lupus, discoid lupus/lichen planus overlap, mucosal lupus
3 Oral ulcers	Palate, buccal, tongue, or nasal mucosa (no other cause identified)
4 Alopecia, nonscarring	Diffuse thinning or hair fragility in the absence of other causes (such as alopecia areata, iron deficiency, drugs, or androgenetic alopecia)
5 Synovitis	Must involve two or more joints with swelling or effusion or tenderness and at least 30 minutes of morning stiffness
6 Serositis	Pleuritis, pleural effusions or pleural rub; pericardial pain, effusion, rub or pericarditis without other cause
7 Renal	Persistent proteinuria $>0.5$ g/day or red blood cell casts
8 Neurologic	Seizures, psychosis, myelitis, mononeuritis multiplex, peripheral or cranial neuropathy, acute confusional state (all without other known cause)
9 Hemolytic anemia	
10 Leukopenia	$<4000/\text{mm}^3$ at least once or lymphopenia of $<1000/\text{mm}^3$ at least once without other cause
11 Thrombocytopenia	$<100,000/\text{mm}^3$ at least once without other cause
<b>IMMUNOLOGIC CRITERIA</b>	
1 Positive ANA	Above laboratory reference range
2 Anti-ds DNA antibody	Above laboratory reference range ( $>2$ -fold if by ELISA)
3 Anti-Sm antibody +	
4 Antiphospholipid antibody +	+ Lupus coagulant or anti-β2-glycoprotein I, medium- or high-titer anticardiolipin antibody, or false positive
5 Low complement	C3, C4, CH50
6 Direct Coombs test	In the absence of hemolytic anemia

ANA, Antinuclear antibody; DNA, deoxyribonucleic acid; ds, double-stranded; ELISA, enzyme-linked immunosorbent assay; SLICC, Systemic Lupus International Collaborating Clinics; Sm, Smith.

\*At least four criteria are required, including at least one clinical and one immunologic criterion. Biopsy-proven lupus nephritis plus a positive ANA or anti-ds DNA is also sufficient.

**Figure 22-4** Systemic lupus erythematosus. Note periungual telangiectasia, but also the relative sparing of the skin overlying the joints, in contrast to the distribution of Gottron lesions in juvenile dermatomyositis.

scaling as well. Brightly erythematous papules and plaques can also be seen on the photo-exposed extremities and V-shaped region of the neck. When this eruption presents on the dorsal aspect of the hands in SLE, the areas overlying joints are typically spared (Fig. 22-4), in contrast to JDM.

SCLE, which represents 10% to 15% of all cases of CLE, only occasionally occurs in pediatric patients.<sup>56,57</sup> The cutaneous lesions of SCLE arise quite suddenly, mainly on the upper trunk, extensor surfaces of the arms, and dorsal aspect of the hands and fingers. The lesions may be annular and may enlarge and merge into psoriasisiform or polycyclic lesions with thin and easily detached scales (Fig. 22-5). UV light is usually associated with exacerbations, but lesions tend to be nonscarring. Although arthritis and fatigue are common, patients usually only have mild systemic manifestations. The majority of patients with SCLE have anti-Ro (SS-A) antibodies and many have anti-La antibodies. Nonbullos annular lesions that clinically and histologically resemble Sweet syndrome (see Chapter 20) can also be seen as a manifestation of SLE; biopsy shows unique histologic features called the *histiocytoid form* of neutrophilic dermatosis.<sup>58</sup> Rowell syndrome was originally described as an erythema multiforme-like eruption in association with lupus (classically CLE), anti-La antibodies, and speckled ANAs; although controversy exists, most of these cases are probably SCLE or the concurrence of lupus and erythema multiforme.<sup>59</sup> SCLE is treated by strict sun protection, topical anti-inflammatory agents, antimalarials, and occasionally systemic corticosteroids.

Tumid lupus (lupus erythematosus tumidus) is a form of ICLE. Red to purplish urticarial plaques, which are relatively fixed in shape and do not undergo atrophy or scaling, usually occur on the face or other exposed areas of the body as a sign of photosensitivity. The progression rate of lupus erythematosus tumidus to SLE is unknown.

CCLE is an umbrella term used to describe lesions of discoid lupus erythematosus (DLE), lupus panniculitis, and chilblain lupus.

**Figure 22-5** Subacute cutaneous lupus erythematosus. The annular and polycyclic erythematous scaling lesions arose suddenly on this adolescent's anterior chest after sun exposure.

**Figure 22-6** Discoid lupus erythematosus (DLE). This young girl showed well-circumscribed, elevated, indurated, red to purplish annular plaques of DLE.

Individual lesions of DLE are well-circumscribed, elevated, indurated red to purplish plaques with adherent scale (Figs. 22-6 and 22-7) and fine telangiectasia. When untreated or as a sequela, discoid lesions may develop persistent areas of hyperpigmentation or hypopigmentation with atrophy. Discoid lesions can be asymmetric and are often exacerbated by exposure to UV light. DLE is most commonly found on the face, often with lesions on the ear helices and conchal bowls. Although the face is often the sole site of DLE without SLE, the scalp, arms, legs, hands, fingers, back, chest, abdomen, and even mucosal areas (Fig. 22-8) may also be involved. At times the openings of hair follicles are dilated and plugged by an overlying scale. If the scale is thick enough, it can be lifted off in one piece. The undersurface then reveals follicular projections that resemble carpet tacks, a characteristic sign of LE. Discoid lesions have been described in a linear orientation that follows the lines of Blaschko.<sup>60,61</sup>

In childhood, DLE is rare, and less than 3% of patients with DLE develop disease before the age of 10 years. DLE may present as an isolated finding or, more commonly, as a manifestation of underlying SLE. Some patients develop full criteria for SLE over time, mandating serial clinical and serologic evaluations for systemic disease. In adults, the rate of progression of DLE to SLE is reported to range from 0 to 28%, with an interval between onset of DLE and SLE ranging from months to decades.<sup>62–64</sup> Some studies in both adults and children have demonstrated that patients with generalized lesions (above/below the neck) are at higher risk for SLE.<sup>65–67</sup> In addition, adults with rising

**Figure 22-7** Discoid lupus erythematosus (DLE). The ear is often involved with DLE. Note the well-defined plaques of purplish erythema, focal overlying scaling, and postinflammatory hyperpigmentation and depigmentation.

**Figure 22-8** Discoid lupus erythematosus. Dyspigmentation and atrophy of the hard palate.

ANA titers, elevated ESR levels, anemia, leukopenia, arthralgias, nail changes, and evidence of nephropathy may predict progression to systemic disease.<sup>68–71</sup> Small studies in children have demonstrated an early rate of progression to SLE approaching 25% to 30% during a variable follow-up duration of months to years.<sup>65,72–75</sup> However, children with DLE who develop SLE appear to follow a benign course of systemic disease, with 89% of patients in one study meeting SLE classification criteria with mucocutaneous limited manifestations and no evidence of end-organ damage over 5 years of follow-up study.<sup>72</sup>

Intense inflammation of the fat (lupus panniculitis, lupus profundus) occurs in approximately 2% of patients with CLE, and may be associated with DLE, SLE, or, not uncommonly, as an isolated

**Figure 22-9** Lupus panniculitis. This boy with systemic lupus erythematosus and lupus panniculitis (lupus profundus) developed tender nodules on the thighs that ulcerated.

disorder.<sup>76</sup> Lesions are seen as firm, often asymptomatic, sharply defined, rubbery dermal and subcutaneous plaques or nodules with a predilection for the scalp, forehead, cheeks, upper arms, breasts, thighs, and buttocks. Although the skin overlying the lesions usually appears normal, it often ulcerates (Fig. 22-9) or becomes depressed. Biopsy shows a perivascular lymphocytic, plasma cell, and histiocytic infiltration in the deep dermis and subcutaneous fat without accompanying fat necrosis. The panniculitis may be lobular alone or involve both septae and lobules; most specimens show mucin deposition. Direct immunofluorescence often reveals Iggs or C3 deposits at the basement membrane. Approximately 70% of patients with lupus panniculitis also have typical lesions of DLE, and 50% eventually develop systemic involvement or symptoms of SLE such as fever, arthralgia, and lymphadenopathy. Lesions of lupus profundus may persist for years and leave significant disfigurement. Although erythema nodosum (see Chapter 20) may occur in a patient with SLE, lupus panniculitis can often be distinguished by its lack of tenderness, greater chronicity, and lack of predilection for the lower legs. Lupus panniculitis must also be distinguished from subcutaneous lymphoma by histologic features and T-cell rearrangement studies. Inflammatory panniculitis followed by lipoatrophy, likely autoimmune in mechanism but not associated with SLE or dermatomyositis, can involve localized areas, such as the ankles or abdomen.<sup>77</sup> Lipoatrophic panniculitis can also be seen in type 1 diabetes, Hashimoto thyroiditis, and JIA, which may manifest years after the onset of the panniculitis. The tender erythematous nodules demonstrate lobular panniculitis on histopathology. With clearance, these nodules leave lipoatrophy that may progress to partial or even generalized lipodystrophy. Administration of systemic corticosteroids and/or steroid-sparing agents such as methotrexate can stop the development of nodules. Lipodystrophy and tender erythematous nodules are also a feature of chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE syndrome),<sup>78</sup> a proteasome auto-inflammatory disorder (see Chapters 20 and 25).

**Figure 22-10** Livedo reticularis. Bluish-red reticulated discoloration of the back in a teenager with systemic lupus erythematosus.

## Nonspecific Manifestations of SLE

Nonspecific manifestations of SLE are distinguished by the absence of lupus-specific changes on histopathology. These include a variety of reactive and inflammatory eruptions and are typically observed in active SLE. Livedo reticularis (Fig. 22-10, see also Fig. 12-81), blotchy bluish-red discoloration of the skin due to vasospasm, is seen in several collagen vascular disorders, among them SLE, drug-induced SLE, APS, and scleroderma. Aggravated by exposure to cold, the reticulated erythema tends to be persistent and is most commonly found on the lower extremities. Raynaud phenomenon, seen in 10% to 30% of patients with SLE, may precede the onset of SLE by months or years. This phenomenon is described in more detail in the section on systemic sclerosis (SSc). Pernio (chilblains) are tender cyanotic to reddish-blue nodular swellings on the fingers or toes (see Chapter 20). Chilblain lupus manifests as cold-induced, reddish-blue, inflammatory acral lesions that may ulcerate (see Chapter 20).<sup>79-82</sup> Although sporadic chilblain lupus has been described in adolescents, most of the affected younger children have a familial form of chilblains (see Chapter 20). Chilblains must be distinguished from stimulator of interferon genes (STING)-associated vasculopathy with onset in infancy (SAVI syndrome), a recently described auto-inflammatory disorder with acral vasculopathy that can be exacerbated by cold (see Chapter 25, Fig. 25-26).<sup>83,84</sup>

Chronic urticaria-like lesions (urticarial vasculitis) in children with SLE may be distinguished from classic urticaria by their tendency to persist longer than 24 hours and their lesser tendency to be pruritic (see Chapter 21, Fig. 21-14). A manifestation of immune complex deposition, urticarial vasculitis generally occurs in patients demonstrating clinical or serologic evidence of systemic disease activity, especially hypocomplementemia. Biopsy confirms the presence of leukocytoclastic vasculitis. Leukocytoclastic vasculitis can also be seen in biopsy specimens from purpuric lesions in patients with SLE. These purpuric lesions may ulcerate, leaving significant scarring. Erythema and papular telangiectasia of the palms and fingers (Fig. 22-11), linear telangiectasia of the cuticles and periungual skin (with or without thromboses), and periorbital or hand and feet edema,<sup>85</sup> are other nonspecific cutaneous features of SLE.

Although bullous or crusted lesions of SLE may simply reflect fragility of skin because of liquefaction degeneration of basal keratinocytes, a distinctive complication of SLE resembles bullous or epidermolysis bullosa acquisita (EBA) and has been called *bullosic (or vesiculobullous) SLE (BSLE)* (see Chapter 13, Fig. 13-32).<sup>86,87</sup> Indirect immunofluorescence on salt-split skin shows Ig and C3 deposits on the dermal side, and immunoblotting shows autoantibodies directed against type VII collagen, as in patients with EBA (see Chapter 13).<sup>88,89</sup> Subtle variations in IgG subtypes between EBA and BSLE have been shown by IgG subtyping. Other forms of immunobullous disorder, such as linear IgA disease, have also been described in association with SLE, emphasizing the need for immunofluorescence testing.<sup>90</sup>

**Figure 22-11** Systemic lupus erythematosus. Erythema and papular telangiectasia on the palm and fingers of a child with lupus erythematosus.

**Figure 22-13** Self-healing juvenile cutaneous mucinosis. The young girl developed numerous skin-colored to erythematous nodules and swelling on the fingers, and also on the periorbital areas and trunk. She was otherwise well, and the lesions cleared during the subsequent years without intervention.

**Figure 22-12** Papulonodular dermal mucinosis in systemic lupus erythematosus (SLE). This teenager with long-term SLE in good control developed firm pruritic induration of the upper back and proximal arms with some palpable nodularity (indicated by arrows). Deposition of mucin, resembling that of scleredema, was noted in biopsy sections.

**Figure 22-14** Systemic lupus erythematosus. The gingival and buccal mucosae are red, edematous, and eroded, with subtle whitening. Note the roughness and erythema of the lips with the subtle whitening of the vermillion border.

Mucin deposition is a typical characteristic seen on skin biopsy sections of individuals with SLE. However, skin-colored, sometimes pruritic papules and nodules involving primarily the trunk, upper extremities, and occasionally the face are a clinical feature of SLE that reflects large amounts of mucin in the mid-dermis between collagen bundles<sup>91,92</sup> (Fig. 22-12). Papulonodular (dermal) mucinosis of SLE may occur any time during the course, including before onset of other features, and has a course that is independent of the course of the SLE. Mucinosis in children is also a histologic feature of self-healing juvenile cutaneous mucinosis (SHJCM), an unusual disorder characterized by the acute onset of multiple skin-colored to dusky erythematous asymptomatic papules and nodules.<sup>93,94</sup> Lesions mainly occur on the head and periarticular areas, and can be a few centimeters in diameter (Fig. 22-13), in contrast to the more diffuse and, if discrete, papular lesions of the papulonodular mucinosis of SLE. Fever, muscle tenderness, arthralgias, and weakness may be associated.<sup>95</sup> Lesions spontaneously resolve during the subsequent months to a few years. Biopsy samples can be erroneously misdiagnosed as panniculitis or proliferative fasciitis,<sup>96</sup> but mucin stains allow the characteristic

deposition of large amounts of mucin to be identified so that the family can be reassured.

Mucosal membrane lesions (gingivitis, mucosal hemorrhage, erosions, and small ulcerations) are seen in 3% of patients with CLE and in up to 30% of pediatric patients with the systemic form of the disorder. A silvery whitening of the vermillion border of the lips is highly characteristic, and the lips may show slight thickening, roughness, and redness, with or without superficial ulceration and crusting (Fig. 22-14). The gingival, buccal, and nasal mucosae may also appear red, edematous, friable, and eroded, or may exhibit silvery white changes.

Several forms of alopecia may occur in patients with SLE (overall in about 30% of patients). First, discoid lupus may present with scarring alopecia associated with multiple well-demarcated patches (Fig. 22-15) that exhibit erythema, scaling, telangiectasia, atrophy, and plugging (the classic changes of DLE). Second, patients with SLE may develop hair fragility, especially with acute exacerbations, that leads to hair breakage several millimeters from the roots, resulting in a receding hairline with a short, unruly, broken hairs ("lupus hair"), especially at the temple and forehead. Telogen effluvium may also

**Figure 22-15** Systemic lupus erythematosus (SLE). Discoid plaque associated with scarring alopecia of the scalp in a patient with SLE.

occur in patients with SLE. Finally, there is an increased incidence of alopecia areata in patients with SLE, and these patients tend to have classic scalp dermoscopic findings including exclamation-mark hairs, black dots, broken hair, and yellow dots (see Chapter 7).<sup>97,98</sup>

The most common symptoms of SLE at presentation are constitutional (malaise, fever, and weight loss).<sup>53</sup> The arthritis, which occurs in up to 79% of pediatric patients,<sup>53,99</sup> is a symmetric polyarthritis involving both small and large joints. It is commonly quite painful (in contrast to the arthritis of JIA), often out of proportion to the clinical findings, and tends to be nondeforming. Approximately 55% of pediatric patients develop renal involvement, most often during the first year of the SLE. Four types of nephritis have been described based on renal biopsy pattern: mesangial lupus nephritis, focal proliferative, diffuse proliferative, and membranous glomerulonephritis. Diffuse proliferative glomerulonephritis occurs most commonly (40% to 50%) but carries the worst prognosis, leading to end-stage renal disease in approximately 10% to 15% of patients with lupus nephritis.<sup>100</sup> The presence of anti-double-stranded (anti-ds) deoxyribonucleic acid (DNA) antibodies and hypocomplementemia is commonly associated with severe renal damage. Pulmonary involvement, particularly pleuritis, occurs in up to 30% of patients. Cardiac manifestations, including pericarditis, myocarditis, vasculitis affecting coronary arteries, and Libman-Sachs endocarditis, occur in approximately 15% of patients. A recently recognized issue, however, is the long-term risk of accelerated atherosclerosis<sup>100</sup>; as a result, the overall survival for SLE has improved for all causes except cardiovascular disease. Individuals with childhood-onset SLE can develop myocardial ischemia as early as 20 to 30 years of age. Neuropsychiatric SLE (central nervous system [CNS] involvement) most commonly features headache, seizures, alterations in mental status, psychosis, and peripheral neuropathy, and is seen in 20% to 30% of affected children<sup>101</sup>; most show evidence of neuropsychiatric involvement during the first year of the disease, but cognitive dysfunction occurs in almost 25%. Neuroimaging studies may show structural abnormalities, such as infarction; the addition of single-photon emission computed tomography (SPECT) scans may show evidence of cerebral vasoconstriction and vasculitis as perfusion abnormalities and allow a diagnosis of lupus psychosis. Lymphadenopathy, although it occurs more commonly in adults, is seen in up to 40% of children with SLE. Ocular findings are seen in 25% of patients (cotton-wool patches, optic neuropathy, perivasculitis, and edema of the optic disk).

The diagnosis of SLE is chiefly clinical and is based on the presence of cutaneous lesions, systemic manifestations, and confirmatory laboratory tests (see Table 22-1). Biopsy of cutaneous lesions will confirm the diagnosis and shows: 1) hyperkeratosis with keratotic plugging; 2) epidermal atrophy; 3) liquefactive degeneration of basal cells; and 4) a patchy, chiefly lymphoid cell infiltrate, especially around appendages and vessels.<sup>102</sup> Biopsy of lesional skin in DLE or SLE usually shows the deposition of immunoreactants at the epidermal–dermal border (the lupus band test). Sun-exposed areas should be avoided for this biopsy

because of the risk of a false-positive lupus band test at sun-exposed sites.

Serologic examination is the most important evaluation for children thought to have SLE, and ANA is the most valuable screening test. The serologic profiles in children with SLE are similar to those of adults, although some authors have reported a slightly increased incidence of positive antibody tests. The ANA test is almost always positive when a human substrate is used (e.g., Hep-2 cells); in contrast, 5% to 10% of patients with SLE show a negative ANA test when nonhuman tissues are used for testing. Having a positive ANA test does not make a diagnosis of lupus. It can be seen in patients with several other collagen vascular disorders and is present in 5% to 10% of the normal population.<sup>103</sup> However, an ANA level of greater than 1:160 usually suggests an autoimmune disorder. Five patterns of ANA have been described: speckled (the most nonspecific); homogeneous; peripheral or shaggy (most patients with SLE and this pattern have anti-ds [also called native] DNA antibodies]; nucleolar pattern (often seen in patients with scleroderma); and centromere pattern (largely associated with calcinosis, Raynaud, esophageal dysmotility, sclerodactyly, and telangiectasia [CREST]; see discussion on SSc).<sup>104</sup>

Monitoring of serum complement is a critical test for determining lupus activity. The development of hypocomplementemia commonly signals the onset of renal disease. Total complement activity is monitored by functional hemolytic assay (CH50). Specific complement levels, particularly of C3 and C4, should be routinely checked by single radioimmunodiffusion assay. Not uncommonly, C4 levels may be depressed when C3 is normal, probably because patients with SLE are often missing one or more C4 alleles.<sup>104</sup>

One risk factor for the development of SLE, especially with onset during childhood, is hereditary deficiency of the early complement components, C1 (C1q and less often C1r/s), C4, C2, and C3.<sup>105</sup> Virtually all children with C1q deficiency develop SLE.<sup>106</sup> The SLE that occurs in complete C1- or C4-deficient individuals typically presents early during childhood. C2-deficient individuals tend to have a lower risk and less severe disease with lower titers of antinuclear antibodies, but increased anti-Ro antibodies. Lupus and other autoimmune disorders do not tend to occur in individuals with deficiency of the later components of complement, which instead are associated with an increased risk of developing infections, including neisserial infections. Lupus has also been associated with patients and carriers of chronic granulomatous disease, and in patients with IgA deficiency.

Children who may have lupus should be tested for the presence of anti-ds DNA antibodies, which are found in about 50% of patients with SLE and have been associated with an increased risk of renal disease, particularly if complement levels are low. In contrast, antiribosomal P antibodies are inversely associated with renal involvement in juvenile-onset SLE.<sup>49</sup> Anti-single-stranded (ss) DNA antibodies are found in about 70% of patients and are nonspecific. However, complement-fixing anti-ss DNA antibodies are associated with renal disease, even without anti-ds DNA antibodies. Some patients with SLE have antibodies directed against nuclear ribonuclear proteins (nRNPs). Patients with anti-nRNP antibodies (30% to 40%) have a lower risk of renal disease and a better prognosis. Anti-nRNP antibodies and a speckled ANA pattern have also been described in patients with an overlap syndrome of lupus in association with sclerodactyly, esophageal dysmotility, Raynaud phenomenon, and pulmonary disease (MCTD). The Raynaud phenomenon typically precedes the appearance of other signs and symptoms by several years in affected children. Fever, arthralgia, and myalgia are associated, and patients often have hypergammaglobulinemia, a positive RF, and normal complement levels.<sup>107</sup> The anti-Smith (Sm) antibody is specific for SLE, occurs in 20% to 35% of patients, and is associated with a higher risk of renal disease. Anti-Ro and anti-La antibodies are less common in children than in adults (except in NLE, see *Neonatal Lupus Erythematosus* section) and occur in about 20% (anti-Ro) and 10% (anti-La) of children with SLE; they are associated with the highest risk of photosensitivity. SCLE is rare in children, but anti-Ro and anti-La antibodies can also be seen in children with SLE and complement deficiencies or Sjögren syndrome (see *Sjögren Syndrome* section).<sup>108</sup> Antiphospholipid (aPL) antibodies can occur in up to 65% of children with SLE and should be monitored annually; they portend for the development of irreversible organ damage, not just a higher risk of thrombosis.<sup>109</sup>

**Table 22-2** Features of Drug-Induced Lupus Erythematosus

	<b>Skin Features</b>	<b>Noncutaneous Signs</b>	<b>Laboratory Findings</b>	<b>Most Common Pediatric Trigger(s)</b>
Drug-induced SLE	Photosensitivity, purpura, erythema nodosum, urticaria and urticarial vasculitis, necrotizing vasculitis Usually absent: malar or discoid rash (except TNF inhibitors), mucosal ulcers, alopecia, Raynaud phenomenon	Fever, arthralgias, myalgias, pericarditis, pleuritic, sometimes hepatitis Usually absent: CNS, renal, pulmonary involvement Hepatic changes from minocycline	ANA, antihistone antibodies, elevated ESR May be mild cytopenia	Minocycline, occasionally TNF- $\alpha$ inhibitors
Drug-induced SCLE	Annular polycyclic lesions and/or papulosquamous lesions, including on legs Less commonly, erythema multiforme-like or vesiculobullous lesions, necrotizing vasculitis	Usually no arthritis, serositis, or major organ involvement	ANA, anti-Ro, anti-La	Terbinafine, griseofulvin NSAIDs (piroxicam, naproxen)
Drug-induced CCLE	Discoid lesions in photosensitive distribution	Usually no other signs	ANA	TNF- $\alpha$ inhibitors

ANA, Antinuclear antibody; CCLE, chronic cutaneous lupus erythematosus/discoid lupus; CNS, central nervous system; ESR, erythrocyte sedimentation rate; NSAID, nonsteroidal anti-inflammatory drug; SLE, systemic lupus erythematosus; SCLE, subacute cutaneous lupus erythematosus; TNF, tumor necrosis factor.

Other useful laboratory tests include the ESR as a measurement of inflammation; complete blood counts to detect leukopenia, thrombocytopenia, and a Coombs-positive hemolytic anemia; and routine urinalysis with blood urea nitrogen (BUN) and creatinine levels to detect renal abnormalities. Renal biopsy and serial blood pressure measurements are important tools for managing children with SLE and evidence of renal disease. If a patient with SLE has cytopenia and unexplained fever, the diagnosis of MAS, as described under JIA, must be considered. The disease is best recognized by hyperferritinemia and subsequently hypertriglyceridemia and hypofibrinogenemia.<sup>110</sup>

Lupus may be triggered in pediatric patients by drugs, although the features tend to be milder and occurrence is considerably less than in adults, likely reflecting the more limited use of medications in children that are associated with the highest risk. These high-risk drugs are procainamide (occurrence 15% to 20%) and hydralazine (occurrence 5% to 8%).<sup>111-113</sup> The cutaneous features of drug-induced lupus can be divided into those of SLE, SCLE, and CCLE or DLE (Table 22-2). More than 80 drugs can cause drug-induced lupus, especially with SLE-like manifestations.<sup>113,114</sup> In drug-induced SLE, the typical cutaneous features of classic SLE are often absent (e.g., malar rash, discoid lesions, Raynaud phenomenon, mucosal ulcers, alopecia). Rather, photosensitivity, lesions involving the skin vasculature (livedo reticularis, palpable purpura, ulcers, bullae, urticaria and urticaria vasculitis) and erythema nodosum are most often described. The exception is reactions caused by TNF- $\alpha$  antagonists, which rarely cause drug-induced lupus but may manifest as the malar rash or discoid lesions.<sup>115-118</sup>

The most common cause of drug-induced SLE in pediatric patients is minocycline, primarily used by adolescents with acne (see Chapter 8); overall the risk is low. This reactivity to minocycline is specific and has not been described in patients who are administered tetracycline or doxycycline. Patients usually experience malaise in association with myalgia, arthralgia, or arthritis. Livedo reticularis, antineutrophil antibodies, and elevation of hepatic transaminase levels have been described, but evidence of vasculitis, renal disease, and neurologic involvement are unexpected. Drug-induced lupus from minocycline occurs most commonly in female patients and at an average of 2 years after starting the medication. Affected individuals usually show a symmetric polyarthralgia or polyarthritis involving the small joints of the wrists and hands. Isoniazid, hydralazine, and procainamides may lead to the polyserositis of lupus but rarely cause cutaneous or renal disease. Drug-induced lupus is usually associated with increased titers of antihistone antibodies, a positive ANA level, and often anti-ss DNA antibodies. Anti-ds DNA antibodies are usually absent and complement levels tend to be normal.

Drug-induced SCLE shows the typical cutaneous features of SCLE, appearing at sun-exposed areas as annular polycyclic or papulosqua-

mous lesions, but the legs are often involved, in contrast to classic SCLE. Disease usually develops 4 to 20 weeks after initiation of treatment. The most common drugs to trigger SCLE in children are antifungals (terbinafine and griseofulvin),<sup>119</sup> but other groups are antihypertensives, calcium channel blockers, angiotensin converting enzyme (ACE) inhibitors, statins, and IFNs.<sup>119,120</sup> Drug-induced CCLE is very rare, and usually results from use of TNF- $\alpha$  antagonists. Discontinuation of the offending agent is the most important intervention, with topical application of anti-inflammatory medications if needed and systemic corticosteroids if a vasculitis is present. Cutaneous changes may improve within weeks after drug discontinuation, but complete resolution may be prolonged over several months.

The prognosis for children with SLE has improved dramatically from nearly 100% mortality to a survival rate of greater than 90% because of earlier recognition and earlier and more aggressive therapy.<sup>121,122</sup> The main causes of death in children are renal failure, CNS lupus, myocardial infarction, cardiac failure, or infection. Although life expectancy is increased, the sequelae of disease activity and administration of systemic medications cause considerable morbidity in 88% of patients.<sup>123</sup> These include hypertension, growth retardation, chronic pulmonary impairment, premature atherosclerosis, ocular abnormalities, permanent renal damage, neuropsychiatric and neurocognitive impairment, osteoporosis, musculoskeletal damage, and gonadal impairment. Therapy for SLE currently depends on the extent of local and systemic involvement.<sup>124-126</sup> Discoid lesions without SLE usually respond to topical anti-inflammatory medications and sun protection, but antimarial and occasionally systemically administered corticosteroids may be needed for control.<sup>127</sup> Pulsed dye laser has reduced inflammation for facial lesions refractory to topical anti-inflammatory medications and hydroxychloroquine (see next paragraph).<sup>128</sup> Avoidance of exposure to sun and unshielded fluorescent light by wearing hats, sun-protective clothing, and appropriate broad-spectrum sunscreens with UVA as well as UVB protection is essential. These include sunscreens with a sun protection factor (SPF) of 30 or greater that contain good UVA blockers, such as titanium dioxide, zinc oxide, avobenzene, and/or the newer, more photostable UVA organic blockers (see Chapter 19). Cosmetic camouflage is an option for patients with residual dyspigmentation. Topical corticosteroids or calcineurin inhibitors (tacrolimus, pimecrolimus)<sup>129</sup> are effective for most inflamed cutaneous lesions, although relatively potent formulations may be required.

Antimalarial therapy is considered first-line systemic therapy for cutaneous lupus and is beneficial for long-term suppression of the disease.<sup>130,131</sup> In adults, hydroxychloroquine has been shown to delay disease onset, prevent flares, retard renal damage, and reduce autoantibody accumulation.<sup>132</sup> For patients who are not helped by hydroxychloroquine monotherapy, quinacrine can be added without increased

risk of retinal toxicity. In a study of adults with cutaneous lupus who were not successfully treated with hydroxychloroquine monotherapy, the addition of quinacrine 100 mg once daily to hydroxychloroquine produced significant clinical improvement in 67% of patients, as measured by reduction in the cutaneous lupus activity scale.<sup>133</sup> According to the recommendations of the American Academy of Ophthalmology, patients treated with an antimalarial should have a pretreatment ophthalmologic examination and annual screening after 5 years, or sooner if there is an unusual risk factor, to detect early retinopathy. In addition to standard testing of the parafoveal area (10-2 field evaluation), at least one form of the newer, more sensitive objective testing (multifocal electroretinogram, spectral domain optical coherence tomography, or fundus autofluorescence) should be performed.<sup>134</sup> The appropriate dosage of hydroxychloroquine for children is up to 6.5 mg/kg per day, with a maximum dosage of 400 mg/day. Several months of antimalarial therapy may be required before efficacy is seen.

For patients with severe refractory disease, thalidomide has proven efficacy in cutaneous lupus, although its side effect profile often limits routine use.<sup>135</sup> Lenalidomide, a thalidomide analog, may also be used for severe scarring disease. A small study of patients with refractory CLE found that 86% achieved clinical remission with no influence on systemic disease. The drug is associated with fetal embryopathy, cytopenias, and an increased risk of thrombosis but, in contrast to thalidomide, not peripheral neuropathy.<sup>136,137</sup>

Patients with mild disease and arthralgias without nephritis may respond to NSAIDs, although GI irritation is a risk. Although aspirin is generally not a treatment of choice for the arthralgias, 1 to 3 mg/kg per day or and 81 mg tablet is the recommended dosage for individuals with elevated levels of IgG aPL antibodies.

In patients with more than mild disease, corticosteroids are the mainstay of therapy. In general, children are treated more aggressively than adults, with 97% receiving systemic steroids and 66% receiving other immunosuppressive drugs.<sup>138</sup> High dosages of systemic corticosteroids are usually given until complement and anti-ds DNA antibody levels normalize with improvement noted in the clinical state. High-dosage pulsed intravenous methylprednisolone (30 mg/kg) is generally administered for significant acute flares. Corticosteroids can then be administered orally and tapered slowly to the lowest possible level that controls the disease. Both alternate-day and single-morning dose therapy may be effective for maintenance, although alternate-day dosing is preferable to lower the risk of growth retardation. Avascular necrosis occurs more commonly in children than in adults (10% to 15%) from steroid usage. Children with SLE and immunosuppressive medications are at increased risk of infection, including pneumococcal infection; unfortunately the response to administration of pneumococcal vaccination has been poor. Patients should not receive live vaccinations during corticosteroid administration, and placement of a tuberculin test before starting therapy is recommended.

Given the association of chronic use of systemic corticosteroids with adverse effects on major organs (renal, cardiac, neurologic) and the recalcitrance of many patients to steroids alone, other immunosuppressive medications have also been administered to achieve or maintain disease control. The addition of an immunosuppressive agent to the corticosteroid has been shown to be more beneficial for patients with nephritis than the corticosteroid alone and allows a reduction of steroid dosage.<sup>139</sup> Azathioprine, methotrexate, and, more recently, mycophenolate mofetil<sup>140</sup> may reduce disease activity or allow lowering of the steroid dosage.<sup>141</sup> The recommended pediatric dosage for azathioprine is 2.5 to 3.5 mg/kg per day. For methotrexate the dosage is 0.4 to 0.6 mg/kg per week with folate given daily or on days without methotrexate, and for mycophenolate mofetil, it is 0.5 to 3 g/day (600 to 1200 mg/m<sup>2</sup> per day). Cyclophosphamide use is most commonly reserved for patients with CNS disease or severe nephritis. The major potential side effects of these agents are hemorrhagic cystitis and sterility (cyclophosphamide); hepatitis (azathioprine); and aplastic anemia, infection, and malignancy (both cyclophosphamide and azathioprine). Mycophenolate mofetil has a better side-effect profile. Dapsone is of little value for SLE but can be quite effective for BSLE. Autoantibodies and polyclonal B-cell activation are thought to be important in the pathomechanism of SLE; targeting of specific B cells with rituximab (anti-CD20 chimeric mouse/human monoclonal antibody) has led to improvement, particularly for lupus nephritis and

autoimmune cytopenia. Use of higher dosages than used for lymphoma (e.g., 750 mg/m<sup>2</sup> rather than 350 mg/m<sup>2</sup>), repeated therapy, and combination therapy (e.g. with cyclophosphamide and corticosteroids) has led to improved disease activity and decreased steroid burden without an increased risk of infection requiring hospitalization.<sup>142</sup> For end-stage renal disease, dialysis and transplantation are therapeutic options. Autologous stem-cell transplantation has been associated with significant morbidity and mortality, as well as high relapse rates in pediatric cases.<sup>124</sup>

Levels of 1,25-dihydroxy vitamin D and intact parathyroid are significantly lower in children with SLE, especially if they are overweight.<sup>143</sup> Preventive therapy for osteopenia in pediatric patients with SLE should include high dietary calcium intake with supplemental calcium and vitamin D (osteocalcin) as needed.<sup>144</sup> Maintenance of a good exercise program and minimizing steroid weight gain are also helpful. Although bisphosphonates are not routinely given to pediatric patients, their use in patients with pathologic fractures secondary to steroid-induced osteoporosis should be considered.

## Neonatal Lupus Erythematosus

Neonatal lupus erythematosus (NLE) is a unique variant of lupus erythematosus found in infants born to mothers with, or who have a tendency for, SLE, Sjögren syndrome, or undifferentiated autoimmune syndrome (Box 22-2).<sup>145-147</sup> The occurrence of NLE is not related to titers and is not strictly genetic, based on its discordance in identical twins.<sup>148</sup> Nevertheless, developing the skin manifestations of NLE has been linked to carrying a polymorphism in the TNF- $\alpha$  receptor (308A; increases TNF- $\alpha$  expression in response to UV light) and the HLA genotypes DRB1\*03.<sup>149</sup> Cardiac block has been increased with DRB1\*04 and Cw\*05<sup>150</sup> and a polymorphism in TGF- $\beta$  (Leu10, associated with increased fibrosis)<sup>151</sup>; DRB1\*13, and Cw\*06 are protective.<sup>150</sup> The diagnosis of NLE is most important as a marker for the mother, who is at risk. Approximately half of mothers of affected infants are asymptomatic at the time of delivery, and about half of these originally asymptomatic mothers develop SLE, Sjögren syndrome, or, most often, undifferentiated autoimmune syndrome within a median of 3 years. In addition, mothers with undifferentiated disease may progress to reach a diagnosis of SLE, Sjögren syndrome, or overlap syndromes.<sup>152</sup> Thus mothers of affected infants with NLE must be monitored and evaluated regularly.

Approximately 50% to 78% of babies with NLE show cutaneous manifestations at some point, with onset usually by a few weeks of age.<sup>153</sup> However, up to 23% of affected babies show manifestations at birth, especially the cardiac manifestations and occasionally the cutaneous features.<sup>154</sup> Typically, new lesions do not occur after approximately 3 months of age. Lesions are most commonly localized to sun-exposed areas, particularly on the head and neck, and the extensor surfaces of the arms, but they may occur anywhere on the skin surface. Lesions have been described in the genital area and on the palms and soles in 5% of patients.<sup>155</sup>

A variety of cutaneous manifestations have been described. Annular lesions or periorbital erythema (termed *raccoon eyes*, *owl eyes*, or *eye mask*) (Figs. 22-16 through 22-18) should always trigger consideration of the diagnosis in an infant. The annular lesions (see Fig. 22-17; Fig. 22-19) may be confused with annular erythema of infancy, Sweet syndrome,<sup>156,157</sup> or neonatal dermatophyte infection.<sup>158</sup>

### Box 22-2 Neonatal Lupus Erythematosus

- Seen in infants born to mothers with a tendency for systemic lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, or undifferentiated connective tissue disease
- May present as lupus-like rash, often in areas of sun exposure; facial erythema, especially periorbitally (*raccoon eyes*), annular lesions, discoid lesions, atrophic lesions, and/or telangiectasia
- Associated with anti-Ro (SS-A), anti-La (SS-B), and anti-U,RNP (nRNP) antibodies
- Congenital atrioventricular heart block in 15% to 30%

**Figure 22-16** Neonatal lupus erythematosus. Raccoon eyes and annular forehead plaques.

**Figure 22-19** Neonatal lupus erythematosus. (A) and (B) Annular plaques without detectable scale on the face, scalp, trunk and extremities.

**Figure 22-17** Neonatal lupus erythematosus. Annular scaling plaques on the cheeks of this 6-week-old boy.

**Figure 22-18** Neonatal lupus erythematosus. Purplish erythema with focal atrophy in a reticular pattern on the face and scalp.

**Figure 22-20** Neonatal lupus erythematosus. Discoid lesions with atrophy and dyspigmentation on the face of a 2-month-old infant. His mother first showed signs of systemic lupus erythematosus 1 year after this baby was born.

marmorata telangiectatica congenita<sup>160,161</sup> or an extensive capillary malformation.<sup>162</sup> An infant with congenital varicelliform lesions has also been described.<sup>163</sup> In addition to the cutaneous eruption, mucosal ulcerations have been noted in several affected babies.

NLE is the most common cause of congenital heart block. Congenital heart block occurs in 15% to 30% of affected patients, owing to *in utero* inflammation, fibrosis, and calcifications of the atrioventricular node and sometimes the sinoatrial node; 10% of patients with cardiac disease have cardiomyopathy.<sup>148,164</sup> Although the cardiomyopathy is

Discoid lesions (Fig. 22-20), scaly atrophic macules and patches, and telangiectasia<sup>159</sup> have also been described. Atrophic lesions may resemble round ice-pick scars, are often congenital, and commonly localize to the temporal areas of the forehead. The telangiectasia may be more petechial or may resemble the reticulated lesions of cutis

usually apparent early, rarely it first manifests several months after birth.<sup>165</sup> Unlike the cutaneous complications of NLE, congenital heart block is usually irreversible. Some infants with first-degree and, rarely, with second-degree heart block have shown spontaneous resolution during the first few months of life, but the majority of patients progress rapidly to third-degree block, including after birth. Two-thirds of infants with heart block require pacemakers.<sup>166</sup> Cardiac disease results in a 20% mortality<sup>167</sup> not only from the heart block, but also congestive heart failure or other associated complications such as transposition of the great vessels, patent ductus arteriosus, septal defects, and endocardial fibroelastosis.

Other systemic complications include liver involvement in 10% to 26% of patients (generally manifested by hepatomegaly and abnormalities of liver function tests, but occasionally cholestatic disease and liver failure),<sup>148,164</sup> splenomegaly, lymphadenopathy and hematologic abnormalities in 27% of affected infants, including leukopenia, thrombocytopenia,<sup>168</sup> and anemia (both Coombs positive and Coombs negative). Subclinical evidence of CNS disease has been seen on computerized tomographic scans and ultrasounds,<sup>169</sup> but clinical neurologic features are unusual.<sup>170,171</sup> Hydrocephalus has recently been described as an uncommon complication, suggesting that imaging studies are appropriate for NLE infants with a head circumference greater than the 95th percentile.<sup>172</sup> CNS vasculitis and stroke have also been described.<sup>173,174</sup>

NLE results from the transplacental passage of maternal antibodies.<sup>175</sup> In 95% of cases, these antibodies are anti-Ro (SS-A) antibodies, often in association with anti-La (SS-B) antibodies. These antibodies have been found at sites of pathology in the epidermis and heart.<sup>176</sup> A subset of infants with neonatal lupus and their mothers have anti-U<sub>1</sub>RNP (nRNP) antibodies, although cardiac disease is extremely rare in this subset.<sup>163,177</sup> Infants and mothers may also demonstrate a positive ANA titer and aPL antibodies.<sup>176</sup> Breastfeeding has not been shown to alter antibody levels or affect the development of cutaneous lesions.<sup>178</sup>

The anti-Ro antibodies have been shown to be causative for the cardiac block. Anti-Ro antibodies bind to fetal, but not to adult, cardiac myocytes and selectively injure the conducting system, a process that involves plasmin<sup>179</sup>; anti-U<sub>1</sub>RNP antibodies do not bind to cardiac myocytes. When pregnant mice are injected with anti-Ro/La antibodies intraperitoneally, the antibody binds to the heart, epidermis, and liver, sites of inflammation in NLE, and is associated with tissue apoptosis.<sup>180</sup> Overall, 10% to 20% of babies of women with anti-Ro with/without anti-La antibodies develop cutaneous NLE; 1% to 2% develop heart block, and 27% show laboratory abnormalities.<sup>181</sup>

The diagnosis of NLE is aided by the presence of typical cutaneous lesions, systemic manifestations, and confirmatory laboratory studies (positive anti-Ro, anti-La, or anti-U<sub>1</sub>RNP antibody tests of the infants and mothers). Because of the possibility of involvement of internal organs, a thorough physical examination, complete blood cell count with platelet count, and liver function tests are often recommended for infants suspected of having NLE. Infants with bradycardia or a murmur deserve an electrocardiogram and echocardiography. If any question regarding the diagnosis remains, cutaneous biopsy of a skin lesion can be performed and will show histopathologic features of lupus with injury to the basal epidermal cells as a prominent feature.<sup>182</sup>

Clearance of cutaneous lesions generally occurs by 6 to 12 months of age, concurrent with the waning of the maternally derived antibodies. In a few patients, however, the cutaneous lesions disappeared within 1 month, and the eruption has lasted up to the age of 26 months. Affected individuals may show residual telangiectasia, dyspigmentation, atrophy, and/or scarring<sup>183,184</sup>; however, most cutaneous lesions clear without sequelae. Appropriate treatment of NLE includes avoidance of sun exposure and treatment of visceral complications, which may necessitate administration of systemic corticosteroid therapy. Low-to mid-potency topical steroids or topical calcineurin inhibitors can be used to treat the cutaneous lesions, but lesions clear spontaneously, and the use of topical anti-inflammatory agents has not been shown to affect residua.<sup>184</sup>

Patients with NLE do not show an increased risk of developing lupus and other autoimmune disorders beyond that of their siblings, suggesting that the small increased risk in this group of patients reflects their familial tendency, not the previous occurrence of NLE.<sup>185</sup>

Mothers who have had a child with NLE, however, have a 36% overall risk of having a second affected child.<sup>149</sup> The risk of cutaneous manifestations in the second child is 23%, and the risk of cardiac issues is almost 13%, sixfold higher than the overall risk congenital heart block in a first affected baby. A mother with a previous baby with NLE involving skin can have a subsequent baby with congenital heart block and vice versa. Fetal echocardiograms (weekly to every other week) between 16 and 26 weeks' gestational age, the peak period of cardiac injury, are recommended for at-risk pregnancies. Systemic corticosteroids administered during pregnancy may decrease the risk of first- or second-degree heart block<sup>186</sup> but have not been shown to prevent the progression toward third-degree heart block, which can occur quickly *in utero*.<sup>187-189</sup> Antimalarials, particularly hydroxychloroquine, are not teratogenic<sup>190</sup> and have been found to decrease the risk of cardiac, although not noncardiac, manifestations of NLE.<sup>191</sup> The combination of steroids with intravenous Ig and plasmapheresis is under investigation.<sup>192</sup>

## Antiphospholipid Antibody Syndrome

Antiphospholipid antibody syndrome (APS) is an autoimmune thrombotic disorder, characterized by venous and/or arterial thrombosis and the persistence of at least one circulating aPL antibody. aPLs are a heterogeneous group of autoantibodies reactive against either negatively charged phospholipids (e.g. phosphatidyl serine and cardiolipin) or proteins that are complexed with them (e.g.,  $\beta$ 2 glycoprotein I). aPL antibodies are commonly found after bacterial and viral infections in children, leading to the requirement that two levels of aPL antibodies be tested at least 12 weeks apart for diagnosis.<sup>193,194</sup>

In approximately half of affected pediatric patients, APS is a primary syndrome. The disorder can also occur secondarily, most commonly in children with SLE (38% of children overall).<sup>193,194</sup> However, 30% of the patients with SLE and APS initially have primary APS, with a mean duration of 1.2 years before the onset of SLE.<sup>193,194</sup> The age of onset is significantly younger in children with primary APS (8.7 vs. 12.7 years), and 45% of tested children also have one or more inherited thrombophilic risk factors. These inherited prothrombotic disorders include methylenetetrahydrofolate reductase C677T polymorphism, factor V Leiden, protein S or protein C deficiency, prothrombin G20210A heterozygosity, and antithrombin III deficiency.

Manifestations may range from headache or livedo reticularis to stroke or severe tissue necrosis (Box 22-3).<sup>195-198</sup> The most common cutaneous manifestations of APS in children are livedo reticularis and Raynaud phenomenon, each occurring in approximately 6% of affected children. Livedo reticularis is characterized by prominent reticulated cutaneous vasculature, most commonly noted on the lower extremities (see Fig. 22-10 and Chapter 12, Fig. 12-81). Thrombosis, is the most serious manifestation (see Box 22-3), and venous thromboses involving the lower extremities occur most commonly. Recurrent thromboses occur in approximately 20% of children,<sup>193,194,199</sup> especially with inadequate anticoagulant therapy and with an underlying inherited thrombophilia. The clinical triad of livedo reticularis, hypertension, and cerebrovascular disease, or Sneddon syndrome, is linked to aPL antibodies in individuals and has rarely been described in children.<sup>200</sup>

Five percent of children have life-threatening thrombotic disease with the rapid occurrence of thrombosis involving at least three organ systems (catastrophic APS).<sup>201,202</sup> Affected children are likely to be female and suffer from primary APS (each about 70%). The catastrophic event is often the first sign of APS in children (87%). Infections are often a precipitating factor (61%) and peripheral vessel thrombosis occurs in 52% of affected children.

aPL antibodies have been associated with a high risk of miscarriage in pregnant women. In successful pregnancy, transplacental passage of maternal aPL antibodies can rarely lead to neonatal thrombosis,<sup>199</sup> most commonly manifesting as stroke. The risk may be increased in aPL-positive neonates by acquired thrombotic risk factors such as central lines, sepsis, prematurity and heart disease, or the hereditary prothrombotic diseases previously mentioned. Neonates with stroke may have persistently elevated aPL titers for years that show no concordance with maternal aPL levels.<sup>203</sup>

### Box 22-3 Antiphospholipid Antibody Syndrome in Children

#### Cutaneous and Subcutaneous Features

Livedo reticularis  
Raynaud phenomenon  
Palpable purpura/leukocytoclastic vasculitis  
Superficial vein thrombosis  
Deep venous thrombosis with ulceration  
Pyoderma gangrenosum-like ulceration  
Degos-like disease  
Gangrene

#### Noncutaneous Features\*

Thromboses\*  
Pulmonary thromboembolism, hypertension  
Strokes, transient ischemic attacks  
Transverse myelopathy  
Cerebral venous sinus thrombosis  
Retinal vein thrombosis  
Renal artery thrombosis  
Hematologic abnormalities (38%)  
Evans syndrome  
Thrombocytopenia  
Leukocytopenia  
Autoimmune hemolytic anemia  
Neurologic abnormalities, nonthrombotic (16%)  
Migraine headaches  
Chorea  
Seizures  
Hepatomegaly, enzyme elevation

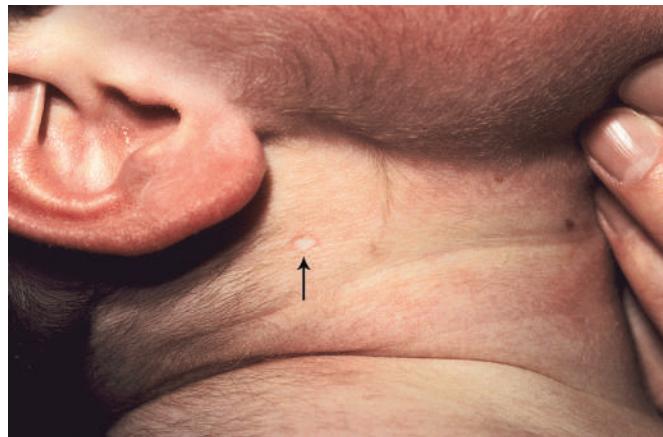

\*Venous thromboses occur in 60% of patients; arterial thromboses in 32% (45% of patients with primary antiphospholipid antibody syndrome [APS] and 18% with secondary APS); mixed thromboses in 3% of patients; and small vessel thromboses, particularly leading to digital infarctions in 6% of patients.

aPL antibodies in APS are thought to be pathogenic, rather than merely a serologic marker. Anticardiolipin, lupus anticoagulant, and anti-β2 glycoprotein I antibodies are found in 81%, 72%, and 67% of patients, respectively, without a significant difference between primary and secondary types of APS. Only 33% of pediatric patients have all three aPL subtypes, and 48% have two simultaneously, emphasizing the need to evaluate all three antibodies for diagnosis. Of note, having more than one aPL antibody does not increase the risk of thrombosis. ANAs and anti-ds DNA antibodies are detected much more commonly in children with secondary APS (86% vs. 35% and 59% vs. 6%, respectively).

Despite the established association between aPL antibodies and thromboses, most individuals with circulating aPL antibodies do not show evidence of thrombosis. As such, it remains controversial whether to treat individuals prophylactically who show persistently positive aPL antibody levels but have no history of thromboses. There is currently no evidence to support the routine administration of low-dose aspirin in individuals with IgM or low titers of IgG antibodies; however, anticoagulants (e.g., aspirin at 1 to 3 mg/kg per day or an 81 mg tablet) should be considered in patients with higher levels of aPL antibodies, especially patients who will be immobilized or undergoing surgery. Administration of hydroxychloroquine may be protective against the development of thrombosis in aPL+ children with SLE.<sup>204</sup> In addition, at-risk adolescents should be discouraged from smoking or treatment with estrogen-containing oral contraceptives. Children with aPL antibodies and thrombosis require anticoagulant therapy, but the use of these medications should be weighed in very active children and noncompliant adolescents because of the greater risk of hemorrhage. Children with catastrophic APS are treated with intravenous anticoagulation, plasmapheresis, and sometimes rituximab.<sup>202</sup>

## Degos Disease

Degos disease, also known as *malignant atrophic papulosis*, is an often-fatal disorder characterized by multiple infarcts in the skin and viscera

**Figure 22-21** Degos disease. Note the atrophic, porcelain-white center surrounded by telangiectasia. Note the hypertrichosis in this young boy from administration of prednisolone.

owing to a thrombotic vasculopathy of unknown cause. Altered platelet function or fibrinolysis have been noted in some patients. The condition is particularly rare in children but has been reported to occur in infants as young as 1 day of age.<sup>205</sup> Typical lesions are asymptomatic 3- to 10-mm papules with an atrophic, porcelain-white center surrounded by an erythematous, telangiectatic border (Fig. 22-21). Lesions may appear in crops and typically involve the trunk and extremities; one adolescent with cutaneous Degos-like lesions has been described with localized unilateral involvement of the abdomen.<sup>206</sup> Biopsy of lesional skin shows a characteristic acellular, ischemic wedge-shaped area of dermis underlying an atrophic but hyperkeratotic epidermis. The GI tract<sup>207</sup> and CNS<sup>208</sup> are the most commonly affected organs. Although involvement of the GI tract is most typical, of the 25 reported pediatric cases of Degos disease, 56% showed CNS involvement and 48% had GI involvement. Acute hematemesis, abdominal pain, dyspepsia, abdominal distension, diarrhea, and constipation are signs of GI tract involvement, and patients may develop peritonitis, bowel infection, or perforation.<sup>209</sup> CNS manifestations include fatal hemorrhagic or ischemic strokes, polyradiculoneuropathy, and nonspecific neurologic symptoms, especially headache. In most cases, the skin lesions precede the occurrence of other manifestations by months to years. Most affected patients die within 2 to 3 years, particularly from sepsis from peritonitis, CNS bleeding, or pleural or pericardial involvement. Approximately 36% of affected children have a more benign course without evidence of systemic involvement,<sup>206</sup> in contrast to 15% of patients of all ages. Familial cases have been described.<sup>210</sup> Degos-like lesions have been described in patients with aPL antibodies and/or SLE and, less commonly, dermatomyositis,<sup>197</sup> suggesting that Degos disease is a distinctive disease pattern rather than a unique entity.<sup>211</sup> In patients with SLE and dermatomyositis, the lesions tend to be more telangiectatic and show more mucin deposition. Administration of medications that inhibit increased platelet aggregation (especially aspirin and dipyridamole) may be helpful in some cases. Immunosuppression may worsen the skin lesions of Degos disease.

## Juvenile Dermatomyositis

Juvenile dermatomyositis (JDM) is an inflammatory disorder with an incidence of three per million children per year that primarily affects the skin, striated muscles, and occasionally other internal organs (Box 22-4).<sup>212-216</sup> In cases in which cutaneous changes are absent, the term *polymyositis* is used. Because the clinical and pathologic features of involved skin and muscles are similar, dermatomyositis and polymyositis are believed to be variants of the same disease process; however, 85% to 95% of children with an inflammatory myopathy have JDM.<sup>217</sup>

The criteria to make a diagnosis of JDM were originally described in 1975<sup>218</sup> and remain largely the same today, except that

#### Box 22-4 Clinical Features of Juvenile Dermatomyositis

##### General

Fever  
Lethargy  
Adenopathy

##### Skin, Subcutaneous, Mucosae

Heliotrope rash  
Gottron papules  
Nailfold capillary changes  
Malar or facial eruption  
Mouth ulcers  
Gingival telangiectasia, bleeding gingivae  
Skin ulcers  
Limb edema  
Xerosis and pruritus of skin, including scalp  
Poikiloderma  
Calcinosis  
Lipodystrophy

##### Muscle

Muscle tenderness and myalgias  
Muscle weakness

##### Joints

Arthralgia  
Arthritis  
Contractures

##### Gastrointestinal

Dysphagia/dysphonia  
Gastrointestinal symptoms, especially pain

##### Pulmonary

Dyspnea from interstitial lung disease

##### Cardiac

Murmurs, cardiomegaly, pericarditis  
Rarely, myocarditis, conduction abnormalities

#### Box 22-5 Diagnostic Criteria for Juvenile Dermatomyositis

- Progressive symmetric weakness of the proximal muscles (limb girdle and anterior neck flexors), with or without dysphagia or respiratory weakness
- Muscle biopsy evidence of myositis and necrosis
- Elevation of muscle-derived serum enzyme levels
- Evidence of myopathy on electromyography/magnetic resonance imaging
- Typical cutaneous findings of dermatomyositis

A definitive diagnosis of dermatomyositis can be made when specific skin findings and three of the above criteria (excluding the rash) are present; a probable diagnosis of dermatomyositis requires two of the above criteria plus the rash.

electromyographs, which are painful and technically challenging, have largely been replaced by magnetic resonance imaging (MRI) evaluation (Box 22-5). Muscle biopsies, although performed to diagnose the disease in only 61% of patients, provide important diagnostic and prognostic information<sup>212</sup> and are critical if the cutaneous features are not typical.

JDM occurs more often in girls than boys (2.3:1) and shows a bimodal age distribution, with one peak between 2 and 5 years of age and another at 12 to 13 years of age, giving a mean age of onset of 7 years of age; 35% of children have the onset of JDM before 5 years of age.<sup>219</sup> Overall approximately 25% of all individuals afflicted with dermatomyositis are younger than 18 years of age at the time of onset. Malignancy is associated with adult dermatomyositis in about 20% of cases but is rare in pediatric patients.<sup>220</sup> In contrast to adults, children

tend to have more inflammation and necrosis of muscle, calcinosis, periungual and gingival telangiectasias, ulceration, and small vessel vasculopathy, but fewer myositis-specific antibodies, less interstitial lung disease and amyopathic disease, and a lower mortality rate.<sup>215</sup> The histologic features in muscle and IFN gene signature of JDM are similar in both adult and childhood disease.

The immune alterations that drive the small-vessel occlusive vasculopathy of JDM are still poorly understood, but recent studies suggest important roles for environmental triggers, immune dysfunction, and specific tissue responses. Although the onset shows seasonality and many children have preceding infectious features, no evidence of an associated infectious agent has been discovered. Maternal microchimerism has also been implicated in causing JDM, and has been noted in 70% of peripheral blood T lymphocytes and 80% to 100% of muscle tissue samples from patients.<sup>221,222</sup> The major histocompatibility complex alleles HLAB8, HLADQA1\*0501, HLADQA1\*0301, HLADRB\*0301, and HLADPB1\*0101 confer increased risk. In addition, several other polymorphic gene loci have been shown to be risk factors.<sup>212</sup> A polymorphic variant of the TNF- $\alpha$  promoter that increases TNF- $\alpha$  expression (TNF-308A), including in response to UV light, is associated with a higher risk of calcinosis, ulcerations, and disease chronicity.<sup>223,224</sup> Polymorphisms in IL-1 and the IL-1 receptor antagonist also increase the risk of the development of calcinosis and JDM, respectively.<sup>225,226</sup>

The onset of JDM is insidious in approximately 50% of affected children with subtle weakness, anorexia, malaise, abdominal pain, and the gradual development of a rash. In about 30% of children, the onset of the disorder is fulminant, with fever, profound weakness, and severe multisystemic involvement. The remainder have a subacute onset, often with the cutaneous eruption preceding the appearance of constitutional symptoms or evidence of myopathy by 3 to 6 months, although occasionally by as long as several years; hypomyopathic disease occurs in the presence of skin signs but subclinical muscle disease. An amyopathic form, characterized by typical cutaneous manifestations without clinical or laboratory evidence of myositis for at least 6 months, is less common in children than in adults. In one study, 26% of these children with "amyopathic JDM" develop evidence of myositis during a mean follow-up period of 3.9 years, and the 4% who developed calcinosis all developed myositis, suggesting that children without myositis can be treated with antimalarials and topical anti-inflammatory medications, but may not need aggressive immunosuppressive management.<sup>227,228</sup> However, given the known increased risk of calcinosis without early intervention, there is continued controversy about management of amyopathic disease.

The cutaneous features of JDM may be striking or so minor that they might be easily overlooked. A variety of cutaneous findings may be noted (see Box 22-4). Characteristic cutaneous lesions are inflammatory and telangiectatic and are found in 75% of affected children at presentation. A purplish-red erythema occurs on the face, especially on the eyelids, and is called the *heliotrope rash*, because it matches the color of reddish purple flower of the heliotrope plant (Fig. 22-22). The eruption can also be seen on the upper cheeks, forehead, temples, and ears (Fig. 22-23). Sometimes the facial lesions are very edematous, leading to a periorbital and cheek edema. The facial edema and discoloration may be asymmetric, reflecting asymmetric disease activity; JDM has also first manifested in a Blaschkoid facial distribution with later involvement in a generalized distribution.<sup>229</sup> Violaceous, often confluent, telangiectatic erythema with fine scaling may also appear at the hairline of the scalp, nape of the neck, extensor surfaces of the arms and shoulders, the elbows and knees, and the shoulder and center of the upper anterior trunk (the shawl sign) (Fig. 22-24). These telangiectatic eruptions are often accentuated when the affected area is dependent (e.g., with lowering the face for facial lesions). The distribution of the eruption and the common sparing of sun-protected areas suggest photosensitivity; UV light exposure is known to trigger both cutaneous and muscle signs.

Periungual telangiectasia (Fig. 22-25) is a characteristic feature of JDM and provides a good indication of cutaneous, rather than muscle, disease activity.<sup>230</sup> Viewing the nailfold area through a dermatoscope, ophthalmoscope, or otoscope to magnify the area after local application of mineral oil improves visualization. Nailfold capillary microscopy has shown that the periungual telangiectasia represents bushy

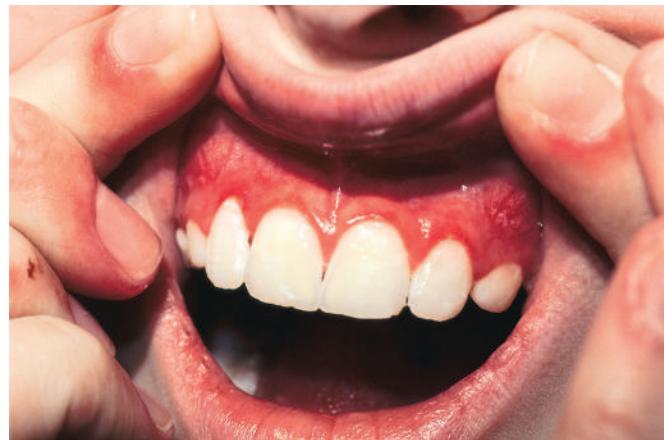

**Figure 22-22** Juvenile dermatomyositis. Telangiectasia and inflammation of the face. Note the sparing of the infraorbital, sun-shielded area.

**Figure 22-25** Juvenile dermatomyositis. Periungual telangiectasia with cuticular hypertrophy.

**Figure 22-23** Juvenile dermatomyositis. Facial inflammation and telangiectasia. Note the involvement of the ear.

**Figure 22-26** Juvenile dermatomyositis. Telangiectasias of the gingivae are commonly associated. Note the periungual telangiectasia as well.

**Figure 22-24** Juvenile dermatomyositis. Telangiectasia and atrophy induced by sun exposure in this young girl, whose relatively uninvolved area was covered by her bathing suit.

capillary loops adjacent to avascular areas, perhaps a form of compensatory neovascularization. Erythema of the cuticle at the base of the nails commonly accompanies the periungual telangiectasia. At times, the cuticles may also be thickened, hyperkeratotic, and irregular, giving an appearance of excessive picking or manicuring. Pitted

ulcerations of the fingertips, pressure points such as the elbows, lateral aspects of the trunk, axillae, and lateral ocular canthi are usually seen at presentation or with disease flares.<sup>214</sup> Thought to be a marker of severe disease, these ulcers leave residual atrophic scars. Even though not exposed to sun, the mucous membranes often show telangiectatic involvement, with erythema of the palate and buccal mucosa, with or without ulceration, and telangiectasia of the gum margin (Fig. 22-26).

Telangiectatic erythema may overlie the dorsal interphalangeal joints (Gottron sign), and when a component of a flat-topped papule, is a pathognomonic sign of JDM (Gottron papule) (Fig. 22-27). Coupled with the facial eruption, these inflammatory lesions on the dorsum of the hand may be misdiagnosed as contact dermatitis. When the papule resolves, atrophy, telangiectasia, and hypopigmentation may persist (Fig. 22-28). Inverse Gottron papules have also been described with papules on the palmar surface; in one report these were the only cutaneous feature and were associated with interstitial lung disease.<sup>231</sup>

Other cutaneous features include palmar erythema and thickening, which can be mistaken for dermatitis and sometimes has so much hyperkeratosis and fissuring that it has been compared with a mechanic's hand.<sup>232</sup> A more generalized hyperkeratotic disorder that resembles pityriasis rubra pilaris, and generalized erythroderma with scaling, have also been described.<sup>233,234</sup>

Sclerodactyly may be seen in children with overlap syndrome that includes SSc. Panniculitis may manifest clinically as tender, indurated

**Figure 22-27** Juvenile dermatomyositis. Gottron papules overlying the joints of the hands. Note the telangiectasia and cuticular hypertrophy of the periungual areas.

**Figure 22-28** Juvenile dermatomyositis. Atrophy, telangiectasia, and depigmentation are residual signs after clearance of the Gottron papules in this patient with chronic skin changes.

plaques and nodules, especially on the arms, thighs, and buttocks; however, panniculitis is often observed in biopsy specimens and is not noted clinically. Limb edema is noted in some patients at presentation, but anasarca is rare and should prompt consideration of nephritic syndrome.<sup>235</sup>

Several cutaneous features of JDM are seen more commonly with disease chronicity. Many children and adolescents with chronic disease have intensely pruritic, xerotic skin that shows poikiloderma (Fig. 22-29), which is the combination of cutaneous atrophy, telangiectasia, and dyspigmentation (see Chapter 11). The scalp is dry, scaling, and pruritic as well.

Cutaneous calcinosis develops in 18% to 24% of children,<sup>217,236,237</sup> in contrast to the up to 70% incidence of earlier reports. This decreased incidence of calcinosis can be attributed to both earlier diagnosis and to more aggressive, earlier treatment (see below). Nevertheless, calcinosis is a major cause of morbidity in JDM and is linked to younger age at disease onset, more persistent disease activity, and the presence of anti-NXP2 (anti-p140) autoantibodies before the calcinosis develops, which are found overall in 20% of JDM patients.<sup>238</sup> Most commonly seen at sites of trauma, particularly on the buttocks, elbows, knees, and fingers, and around the shoulders, subcutaneous calcium deposits may produce local pain and can be extruded, leading to

**Figure 22-29** Juvenile dermatomyositis. Poikilodermatos changes on the legs, characterized by telangiectasia, atrophy, and subtle reticulated hyperpigmentation.

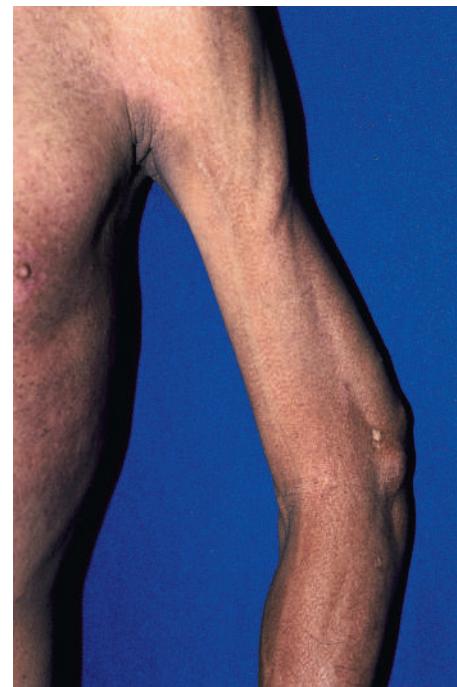

**Figure 22-30** Juvenile dermatomyositis with multiple calcifications. Even small calcifications over a joint may be exquisitely painful.

ulcers, sinuses, or cellulitis (Fig. 22-30). Ulcerations may also appear in children with dermatomyositis without calcifications, especially over joints (Fig. 22-31). Calcifications (see Chapters 9 and 23) appear as hard, irregular nodules that may drain a whitish, chalky material through their openings to the surface that resembles gritty toothpaste. The mean time to occurrence of calcinosis after onset is 2.5 to 3.4 years, although 3% of patients have calcinosis at diagnosis,<sup>239</sup> even

**Figure 22-31** Juvenile dermatomyositis. Note calcinosis on the fingertips.

**Figure 22-33** Juvenile dermatomyositis (JDM). Profound lipodystrophy on the limbs of a young adult with a history since elementary school of JDM.

**Figure 22-32** Juvenile dermatomyositis (JDM). Facial lipoatrophy and persistent telangiectasia in an older adolescent. The onset of her JDM was 8 years earlier; although the myositis has been controlled, she had residual disfiguring cutaneous and subcutaneous manifestations with extensive, problematic calcifications.

**Figure 22-34** Juvenile dermatomyositis. Acanthosis nigricans of the axillary area.

without evidence of myositis. Sometimes patients have widespread calcification along fascial planes, encasing muscles (universal form) or even appearing as an exoskeleton on radiographic examination.

Contractures have been associated with the calcinosis and occur in 17% to 30% of patients with JDM. Lipodystrophy is a common feature in children with chronic disease, especially if poorly controlled and of longer duration, overall occurring in 9.7% of patients<sup>236</sup> (Figs. 22-32 and 22-33). The lipodystrophy may be generalized or partial and is characterized by a slowly progressive symmetric loss. The lipodystrophy is associated with insulin resistance and hyperlipidemia (hypertriglyceridemia and low levels of high-density lipoprotein [HDL]).<sup>240</sup> These cardiac risk factors can be present in patients with chronic disease, even without the lipodystrophy. Acanthosis nigricans has been described in 10% of patients later in the disease course (Fig.

22-34). The insulin resistance correlates with muscle atrophy, proinflammatory circulating cytokines, and a family history of diabetes, but not with corticosteroid use.<sup>241</sup>

The myopathy of JDM affects primarily the proximal groups of muscles, especially the triceps and quadriceps, usually in a symmetric distribution. Muscle tenderness or stiffness is not uncommon but usually occurs later in the course rather than as a presenting sign. Affected children often complain of great fatigue and are unable to do

simple tasks, such as rising, squatting, walking, or reaching. In young children, muscle weakness may manifest as more demanding behavior. Physical therapists may be helpful as assessors of muscle strength, particularly in younger children. Speech may become nasal because of nasopharyngeal muscle weakness, and approximately 10% to 15% of patients complain of difficulty with swallowing.

A nondestructive, generally nondeforming arthritis occurs in approximately half of affected children at some time during the disorder, most commonly an asymptomatic arthritis of the knees; large and small joint polyarthritis has also been described.<sup>239</sup> Vasculopathy of the GI tract may lead to ulceration, perforation, pneumatoisis intestinalis, or hemorrhage. D-xylose absorption has been decreased in patients with JDM, suggesting the decreased absorption of nutrients and medications, including oral corticosteroids, and leading to the suggestion that the disorder be treated with intravenous methylprednisolone for acute cases.<sup>242</sup> Dysphagia from impaired muscle function may lead to esophageal reflux and aspiration pneumonia, requiring intravenous feeding. Children with JDM have occasionally been described with hepatomegaly, cholestasis, or pancreatitis.

The majority of patients with JDM show a reduced ventilatory capacity without respiratory complaints, probably owing to respiratory muscle weakness and poor chest wall compliance. Decreased diffusion capacity and evidence of interstitial lung disease is uncommon, but may present with dyspnea on exertion. Cardiac disease is rare in children with JDM, and mainly involves murmurs and cardiomegaly. Although pericarditis occurs, conduction defects and acute myocarditis are uncommon but severely damaging. Nevertheless, systolic dysfunction has recently been noted after long-term follow-up study (16.8 years) and is correlated with skin disease scores, not muscle disease activity.<sup>243</sup> Central or peripheral nervous system disease is very rare, in contrast with SLE. Similarly, other than conjunctival vessel tortuosity, eye disease is usually limited to cataracts from administration of systemic corticosteroids. IgA nephropathy has been described, but renal disease is not generally a feature of JDM.<sup>244</sup>

The presence of arthritis, significant dysphagia, renal disease, Raynaud phenomenon, or neuropathy should also prompt consideration of evaluation for overlap disease. Up to 10% of children with JDM show an overlap syndrome with features of SLE, SSc, or JIA.

The diagnosis of JDM is suspected on clinical grounds, based on the typical cutaneous manifestations and evidence of muscle weakness and/or tenderness. Increased levels of muscle enzymes and the demonstration of increased signal intensity on fat-suppressed T2-weighted MRI scans<sup>245</sup> provide evidence of muscle inflammation,<sup>237</sup> and whole body MRIs have been advocated to estimate total inflammatory burden.<sup>246</sup> The increased signal intensity on MRI scans relates to accumulated extracellular water content. It is indistinguishable from other inflammatory myopathies or rhabdomyolysis but can be differentiated from muscular dystrophies. Several enzyme levels should be assessed concomitantly (serum aldolase, aspartate aminotransferase, lactic dehydrogenase, and serum creatine phosphokinase levels); aldolase is most commonly elevated and serum creatine phosphokinase is normal in about 35% of affected children with active disease.<sup>237</sup> Muscle biopsy of a site shown to be affected by clinical examination or MRI testing can be performed to confirm the presence of perifascicular and perivascular lymphocytic infiltration with atrophy, necrosis, and late fibrosis of the muscle fibers. Skin biopsy is usually not valuable.

Children with active JDM are often lymphopenic but show a relative increase in the percentage of B cells, as defined by anti-CD19 monoclonal antibody binding. Overall, 70% of children with JDM have one or more detectable myositis-specific and myositis-associated antibody if full serologic testing is performed.<sup>212</sup> The high incidence in adults of myositis-specific antibodies, particularly anti-Jo-1, is a distinguishing feature between adult and pediatric disease. Indeed, anti-Jo-1 antibodies (against histidyl-tRNA synthetase) are found in fewer than 3% of patients with JDM, and anti-Mi-2 antibodies (against a DNA helicase) have been found in about 5%. However, other more recently recognized autoantibodies targeting intracellular proteins (anti-TIF1-γ, anti-NXP2, and anti-MDA5) have been found in JDM and are useful biomarkers for defining distinct clinical subsets and predicting prognosis.<sup>216,247,248</sup> Anti-TIF1-γ(p155) antibodies are detected in approximately 25% of children and are linked to more severe cutaneous involvement with generalized lipodystrophy. Anti-NXP2 (also called

*anti-MJ* or *anti-p140*) antibodies, found in about 20% of patients, are associated with a substantially increased risk of greater disease severity, and of developing calcinosis<sup>238</sup> and contractures.<sup>249</sup> Anti-MDA5 (also called *anti-CADM*) antibodies, noted in 7.4% of JDM patients, predict a distinct phenotype that includes skin and oral ulcers, arthritis, milder and shorter duration muscle disease activity, and, in a minority of patients, interstitial lung disease.<sup>250-252</sup>

Children with overlap disease may have anti-PM-Scl (5% to 7%) or anti-U<sub>1</sub>RNP (<6%) antibodies. ANAs are also present in 60% to 70% of newly diagnosed children, usually in a coarse speckled pattern.

The course of JDM can be monophasic (lasting remission within 1 or 2 years, 37%), chronic (60%), or polyphasic (3%).<sup>253</sup> Of JDM patients observed into adulthood (median time from diagnosis, 16.8 years), 90% of patients had persistent damage to the skin (77%), muscle (65%), and skeletal (57%) systems.<sup>254</sup> Unfortunately, prediction of disease course has been a challenge, although inadequate treatment is a strong predictor of poor outcome. A shorter duration of untreated disease and a lower JDM skin disease activity score at onset of disease are correlated with a monocyclic course.<sup>230</sup> The presence of persistent skin eruptions (especially Gottron papules) 3 months after initiation of treatment predicts a longer time to remission, and if Gottron papules and nailfold capillaroscopy are both abnormal at 6 months after initiation, the outcome is particularly poor.<sup>253</sup> Organ damage 6 months after onset of treatment is also a predictor for poor prognosis.<sup>254</sup> By 36 weeks, persistent nailfold capillary changes, which correlate with skin disease rather than muscle disease, also predict a nonmonocyclic disease.<sup>230</sup>

During the active phase of dermatomyositis, children are particularly at risk for sudden, overwhelming Gram-negative sepsis, sometimes masked by corticosteroids. Hospitalization may be advisable in the acute stage, especially if the disease involves palatal-respiratory muscles, to prevent aspiration and to ensure adequate respiration, including by feeding intravenously and using mechanical ventilation if necessary. A high index of suspicion must be maintained for aspiration because of weak palatal-respiratory function or perforation of a viscus, and early aggressive therapy must be instituted when necessary. Nevertheless, the mortality rate, formerly about 30%, generally because of these complications, has been markedly reduced by intervention, and most recently was found to be 3% to 4%.<sup>217,236</sup>

The course of JDM can be classified as monophasic in 47%, polyphasic in 18%, and chronic in 35%.<sup>237</sup> The Pediatric Rheumatology International Trials Organisation (PRINTO) criteria and a Myositis Disease Activity Assessment Tool (MDAAT) have been developed to define disease activity versus inactivity.<sup>255,256</sup> In one cohort with a median follow-up period of 16.8 years after symptom onset, 50% to 73% of patients had continuing disease activity, most commonly in the skin (59%).<sup>257</sup>

Most JDM is treated with high-dosage corticosteroid therapy, and many specialists now initiate pulsed intravenous steroids (30 mg/kg or up to 1.5 g), administered every 24 to 48 hours until laboratory values normalize.<sup>258</sup> Usage of pulse steroids, followed by oral corticosteroids or intermittent pulses if needed for continued control, has been shown to decrease the duration of rash, cause less functional impairment, and markedly reduce calcifications in comparison with those children treated with oral corticosteroids only. Side effects are not increased with pulse steroids, and the overall dosage of required corticosteroids tends to be less than that with oral treatment.

Some patients may fail to respond even to very large doses of corticosteroids. Methotrexate is generally the second-line treatment for JDM, when the disease is recalcitrant or corticosteroid usage is problematic. Treatment of severe JDM early in the course with both intravenous methylprednisolone and methotrexate appears to be more useful than with either agent alone,<sup>259</sup> and patients with milder cases have responded to methotrexate (or intravenous immunoglobulin [IVIG]) alone.<sup>260</sup> Methotrexate can be administered orally or, preferably, by subcutaneous injection at a dosage of 1 mg/kg per week with a maximum of 40 mg/week. Intravenous gammaglobulin has also been found to be an effective steroid-sparing agent, especially for cutaneous manifestations. Other cytotoxic agents such as azathioprine in dosages of 1 to 3 mg/kg (up to 200 mg/day) or cyclosporine (5 mg/kg per day) may be used in severe life-threatening forms of dermatomyositis, or when the disease cannot be adequately managed with

prednisone alone. However, biologics, and particularly rituximab, are showing promise. Rituximab has been generally well tolerated, with infections and infusion reactions as the main adverse events. Although the onset of action can be slow, the response is good, including with more than one course.<sup>216,261,262</sup> TNF- $\alpha$  has been implicated in the pathogenesis and severity of JDM, and some patients have shown benefit, especially with administration of infliximab<sup>263</sup>; however, other patients have not responded, particularly with etanercept, or have even worsened on a TNF- $\alpha$  antagonist. Disease that is refractory to immunosuppressants, including rituximab, can be treated with autologous stem-cell transplantation.<sup>264</sup>

The response of the cutaneous features of JDM to treatment may not correlate with the response of muscle; skin manifestations may persist for years despite resolution of other signs of disease. Oral antimalarial agents, especially hydroxychloroquine (generally 5 to 6.5 mg/kg per day), have been helpful in controlling the cutaneous manifestations of dermatomyositis. Topical corticosteroids and calcineurin inhibitors do little to reverse the skin signs of JDM, although topical flucinolone 0.01% in oil has been helpful with the pruritus of chronic scalp involvement. Counseling about sun protection is critical (see discussion for SLE).

The problematic calcinoses may gradually disappear but can cause considerable morbidity. Despite the long list of medications that have been used successfully in anecdotal reports in an effort to hasten clearance, no agent has been helpful in the majority of cases. Nevertheless, bisphosphonates in combination with aggressive immunosuppression have led to dramatic improvement in some patients.<sup>265,266</sup> Sodium thiosulfate can help clear calcinoses when given intravenously, orally, or even topically, but it is often poorly tolerated (e.g., oral administration may lead to severe diarrhea).<sup>267</sup> The combination of abatacept and sodium thiosulfate reduced the muscle and ulcerative skin disease activity, as well as calcifications.<sup>268</sup>

Surgical procedures may also be useful in selected situations.<sup>269</sup> Occlusive dressings (such as DuoDerm) over joint areas, particularly when areas are ulcerated and draining, have promoted healing. Physiotherapy is important for patients with or at risk for contractures to prevent deformity and increase muscle strength. MRI evaluations, myometry, and blood studies did not show increased muscle inflammation after exercise, suggesting that a moderate exercise program is acceptable with active myopathy.<sup>270</sup>

## Systemic Sclerosis (Scleroderma)

Fewer than 5% of patients with SSc have their onset before the age of 16 years. Juvenile SSc (jSSc) has a mean age of onset of 8 years but has been observed in children as young as 0.4 years of age. On average it requires 1 to 4 years to make the diagnosis, because the onset is often insidious.<sup>271</sup> As in adult-onset SSc, jSSc predominantly affects females (female/male ratio of 2.1 to 10.5 : 1), including in prepubertal patients.<sup>272–276</sup> jSSc features pathologic thickening and tethering of skin, as well as visceral fibrosis and small vessel vasculopathy. jSSc is classified into three major groups: diffuse cutaneous (dc) SSc, with diffuse and rapidly progressive skin thickening of the extremities to the elbows and knees, which is associated with early organ involvement (lungs, heart, kidneys); limited cutaneous (lc) SSc, with limited and nonprogressive skin thickening of the distal extremities, in which visceral disease (largely pulmonary arterial hypertension and malabsorption) occurs late; and overlap SSc, in which the dcSSc or lcSSc is associated with another connective tissue disease, such as SLE or JDM.<sup>277,278</sup> Other scleroderma-like disorders include chronic graft-versus-host disease (see Chapter 25), eosinophilic fasciitis, scleroderma from toxins, nephrogenic systemic fibrosis (NSF), and sclerodermatosus plaques in progeria, Werner syndrome (Chapter 6) and phenylketonuria (Chapter 24). In the neonate, stiff skin syndrome (Chapter 6) can be confused with SSc.

Major and minor criteria for jSSc<sup>279</sup> are shown in Box 22-6, with symmetric proximal skin sclerosis/induration being the major criterion for diagnosis. This classification distinguishes jSSc from overlap disease, which is more common in children than in adults (29% vs. 9%).<sup>280</sup> dcSSc occurs in 90% to 100% of patients with jSSc. The organs involved (lung, kidney, joint, muscle, and heart) are similar in children

### Box 22-6 Proposed Criteria for Diagnosis of Juvenile Systemic Sclerosis

Must be younger than 16 years at onset

**Major Criterion (Required)**

Skin induration/thickening proximal to the MCP or MTP joints

**Minor Criteria (2 Required) (Scleroderma-Specific Organ Involvement)**

Cutaneous	Sclerodactyly
Peripheral vascular	Digital-tip ulcers Nailfold capillary changes (megacapillaries and avascular areas) Raynaud phenomenon
Gastrointestinal	Dysphagia Gastroesophageal reflux
Cardiac	Arrhythmias Cardiac failure
Renal	Scleroderma renal crisis New arterial hypertension
Respiratory	Decreased DLCO Pulmonary arterial hypertension (echocardiography; primary or secondary to interstitial lung disease) Pulmonary fibrosis (chest radiograph or high-resolution CT)
Neurologic	Neuropathy Carpal tunnel syndrome
Musculoskeletal	Tendon friction rubs Arthritis Myositis
Serologic	Antinuclear antibody SSc-selective autoantibodies (antitopoisomerase 1 [Scl-70], anticentromere, anti-RNA polymerase III, anti-PM-Scl)

CT, Computed tomography; DLCO, diffusing capacity for carbon monoxide; MCP, metacarpophalangeal; MTP, metatarsophalangeal; RNA, ribonucleic acid; SSc, systemic sclerosis.

**Figure 22-35** Raynaud phenomenon. Note the blue discoloration of the thumbs and fingers with the sharply demarcated white coloration of the distal aspect of the third finger.

and adults with SSc.<sup>281</sup> In comparison with adults, jSSc has less visceral involvement but a greater prevalence of arthritis and myositis.<sup>282</sup> Some children have a rapidly progressive and fatal illness with cardiac involvement, but more commonly children have a chronic course with less overall mortality.<sup>283</sup>

Raynaud phenomenon is seen in 70% at onset and ultimately in virtually all affected children (Fig. 22-35). The condition may occur

**Figure 22-36** Systemic scleroderma. Smooth atrophic skin, pinched nose, and fixed grimace are evident on the face of this adolescent.

in children as young as 1 year of age. In jSSc, it is associated with vascular intimal hyperplasia and fibrosis that manifests as dilated, sausage-shaped capillary loops and avascular areas. Capillary microscopy of the nailfolds can be performed with an ophthalmoscope, otoscope, or dermatoscope after a drop of mineral oil is placed on the nailfold area. The capillary changes are indistinguishable from those of patients with JDM, distinct from those of SLE, and not seen in patients with isolated Raynaud disease, acrocyanosis, or morphea. Raynaud phenomenon is precipitated by cold or emotional stress, and is characterized by pallor, cyanosis, and hyperemia with pain, burning, numbness, tingling, swelling, and hyperhidrosis of the affected fingers or toes. Rarely, Raynaud phenomenon affects the nose, lips, cheeks, or ears. Nail changes in which the distal portion of the nailbeds adheres to the ventral surface of the nail plate and obliterates the space that normally separates these two structures have also been described. Digital infarcts affect 10% to 28% of children and calcinosis up to 18%.

Overall, 69% of children with Raynaud phenomenon have primary disease (without an underlying collagen vascular disease).<sup>284</sup> In both primary and secondary forms of Raynaud phenomenon, girls predominate (80%). The age of onset, presence of livedo reticularis, and presence of aPL antibody cannot distinguish secondary from primary disease, but a positive ANA test and abnormal capillary pattern correlate strongly with the presence of an underlying disease.<sup>284</sup> Primary Raynaud phenomenon is also not associated with digital tip pitting and/or ulceration. Raynaud phenomenon must be differentiated from acrocyanosis, which is common in thin adolescent girls as a purplish discoloredation. The discoloration of acrocyanosis tends to affect the toes more than the fingers, to be mottled, and to largely persist with warming. Nailfold capillary changes are absent in acrocyanosis, but distal pulses may be faint. Raynaud phenomenon must also be distinguished from blue toe syndrome induced by mixed amphetamine salts, thought to be a reversible vasoconstrictive phenomenon.<sup>285</sup>

At onset, 60% of children have the characteristic early edema, sclerodactyly, and induration of the hands (53% have both Raynaud phenomenon and skin induration of the hands). The hands become shiny, with tapered fingertips and, ultimately, restricted movements as the tendons become shortened. Rarely, the more proximal extremities, trunk, or face are involved at onset. With time, however, the face may develop a characteristic appearance. The forehead becomes smooth and cannot be wrinkled, and atrophy and tightening of the skin give a characteristic appearance because of a fixed stare, pinched nose, prominent teeth, pursed lips, reduced oral aperture, and a perpetual grimace-like facies (Fig. 22-36). Skin thickness is scored serially (modified Rodnan score), leading to a skin thickness progression rate. Telangiectases (especially with calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia [CREST syndrome]), calcification (Fig. 22-37), ulceration (Fig. 22-38), and dyspigmentation may also be seen with chronic disease. The pigmentary

**Figure 22-37** Systemic scleroderma. Calcinosis on the finger. Note the tightness of the skin.

**Figure 22-38** Systemic scleroderma. Ulceration overlying a joint.

**Figure 22-39** Systemic scleroderma. Speckled depigmentation on the upper chest in this boy with systemic scleroderma.

changes in jSSc may be homogeneously hypopigmented or hyperpigmented, or may have a “salt and pepper”-like appearance because of retained perifollicular hyperpigmentation in areas of hypopigmentation (Fig. 22-39).

Early scleroderma is often associated with arthralgias and limited joint mobility. Patients may complain initially of weight loss, fatigue, GI symptoms, and exertional dyspnea. Muscle weakness is seen in up to 40% of children and often is associated with evidence of myositis. Overall, GI manifestations have been described in up to 75% of children. In addition to the acid reflux<sup>286</sup> and decreased esophageal motility, patients have reported constipation, bloating, discomfort,

**Figure 22-40** CREST syndrome. Telangiectatic mats on the face. This adolescent boy showed myriads of calcifications, Raynaud phenomenon, esophageal dysmotility, and sclerodactyly as well.

regurgitation, weight loss, and malabsorption. Cardiac and pulmonary abnormalities are usually screened by chest X-ray, pulmonary function tests, and echocardiogram. Pulmonary function testing usually shows restrictive lung disease (54% of children), even if clinically silent.<sup>287</sup> High-resolution computed tomography (CT) scanning can capture the early alveolitis that precedes pulmonary fibrosis. Pulmonary function testing reveals the decrease in forced air capacity and diffusing capacity for carbon monoxide that are particularly concerning.<sup>288</sup> Cardiac disease (occurring in 15%) is the major cause of pediatric mortality. It may be secondary to pulmonary hypertension or may be primary (pericarditis, arrhythmia, cardiac failure). Severe cardiomyopathy has been described in children with SSc/myositis overlap.<sup>289</sup> Up to 60% of children have shown evidence of renal involvement, usually the result of renal vasculopathy and during the first 3 years of diffuse scleroderma. However, fewer than 5% develop renal failure (scleroderma renal crisis) and 0.7% experience scleroderma renal crisis. Regular monitoring of blood pressure is critical to identify rapid progression and hypertensive renal crisis. CNS involvement affects only 3% of affected children.

CREST syndrome (Fig. 22-40), a form of lcSSc, is quite rare in children. Patients generally have a more slowly progressive form of the disease and have anticentromere antibodies. Although some patients with the CREST syndrome may develop severe pulmonary hypertension, more extensive cutaneous lesions, and visceral involvement, the patients with this subset generally tend to have a relatively benign course.

The diagnosis of SSc is easily established when cutaneous sclerosis of the face and hands is present, particularly when it is associated with Raynaud phenomenon, nailfold telangiectasia, and visceral involvement. Laser Doppler imaging can help visualize the microvascular abnormalities.<sup>290</sup> Symptoms or signs of dysphagia or gastroesophageal reflux help confirm the diagnosis. A new severity score (J4S) grades general, vascular, skin, osteoarticular, muscle, GI, respiratory, cardiac and renal features as normal (0) to end stage (5).<sup>291,292</sup>

The presence of autoantibodies correlates with disease subset. Antitopoisomerase antibody (Scl70) is found in 20% to 34% of children and predicts rapid skin disease progression and interstitial lung disease, but not poorer survival in children. In contrast, anticentromere antibody (ACA) is found in only 2% to 16% of patients and is associated with lcSSc and pulmonary arterial hypertension. Anti-U<sub>1</sub>RNP and polymyositis-scleroderma (PM-Scl) antibodies are also detected in 2% to 16% of children and often described with overlap syndromes and in association with myositis and arthritis. RNA polymerase III (POL3) antibody, which portends the risk for scleroderma renal crisis, is rare in children, but is found in 30% of adult-onset SSc. Most children with SSc have ANAs (81% to 97%), often of the speckled or nucleolar configuration; about 20% to 23% of children with SSc have a positive ANA test with a scleroderma-related autoantibody.

The 10-year survival rate for jSSc is 98%, considerably better than in adults with SSc (75%).<sup>272,279</sup> Most deaths result from cardiac (most common), pulmonary, or renal disease. Treatment of SSc in children is challenging and similar to that in adults. Early treatment before the occurrence of the irreversible fibrotic damage to tissue is ideal. General measures include avoidance of factors producing vasospasm (tension, fatigue, stress, cold weather, and smoking in adolescents) and minimizing trauma to the hands. Heated gloves are available, and emollients and dressings can be applied to ulcerated cutaneous sites. Calcium channel blockers such as nifedipine or nicardipine, which reduce smooth muscle contraction by reducing the uptake of calcium, are considered first-line therapy for Raynaud phenomenon. Pentoxifylline, which lowers blood viscosity, thus increasing blood flow, can also help control the severity of Raynaud phenomenon and digital ulcers. Intravenous infusion of iloprost or other prostacyclins are used for severe jSSc-related Raynaud phenomenon and digital ulcers. Physiotherapy is important to limit contractures.

The arthritis may respond to NSAIDs or salicylates. Proton pump inhibitors (e.g., omeprazole and lansoprazole) are the treatment of choice for reflux esophagitis. General measures for treating reflux include elevating the head of the bed, staying upright after eating, a bland diet, and restricting the size of meals. Prokinetic drugs such as domperidone may improve motility, and antibiotics administered in rotation may decrease the risk of malabsorption from bacterial overgrowth. Intravenous pulse therapy cyclophosphamide has been recommended at a dosage of 0.5 to 1 g/m<sup>2</sup> every 4 weeks for at least 6 months for interstitial lung disease. Good hydration and frequent voiding are important to decrease the risk of cystitis. Endothelin receptor antagonists or phosphodiesterase inhibitors, followed by intravenous infusions of prostacyclin analogues have been used for the pulmonary artery hypertension.<sup>293</sup> Oxygen, antibiotics, and diuretics may also be required for lung disease, especially with congestive heart failure.

Immunosuppression with methotrexate or mycophenolate mofetil has been shown to improve the skin manifestations and have been particularly useful for children with overlap disorders. Corticosteroids do not appear to help the sclerodermatosus process and may trigger renal crisis; however, systemic steroids may be used with caution to treat severe disabling arthritis or myositis. ACE inhibitors such as losartan and captopril are critical in controlling hypertension and stabilizing renal function. The renal disease may require dialysis. Several children who have not responded to other therapies have been treated with autologous stem cells with improvement in clinical signs and stabilization of pulmonary function.<sup>294,295</sup> Bosentan has been helpful for pulmonary hypertension in jSSc<sup>296</sup> and, in adults with SSc, for promotion of healing of cutaneous ulcerations.<sup>297</sup>

The pathogenesis of SSc involves alterations in the immune system, vasculature, and connective tissue. Cytokine mediators, such as transforming growth factor-β (TGF-β), platelet-derived growth factor (PDGF) and connective tissue growth factor (CTGF), are particularly important in inducing fibroblast activation and differentiation to myofibroblasts,<sup>298</sup> triggering collagen synthesis. An imbalance between matrix metalloproteinases and tissue inhibitors of matrix metalloproteinases may also play a role. Also of major importance are the presence of autoantibodies and the vasospastic phenomena with endothelial damage that precede digital, pulmonary, and renal fibrosis. Imatinib, which targets TGF-β/Smad<sup>299</sup> and PDGF<sup>300</sup> signaling, has shown some benefit. Support groups for patients with scleroderma are the Scleroderma Foundation ([www.scleroderma.org](http://www.scleroderma.org)); the Scleroderma Society ([www.sclerodermasociety.co.uk](http://www.sclerodermasociety.co.uk)), and the Scleroderma Society of Canada ([www.scleroderma.ca](http://www.scleroderma.ca)).

## Eosinophilic Fasciitis

Eosinophilic fasciitis (diffuse fasciitis with eosinophilia) is a sclerodermatosus disease characterized by diffuse infiltration of the skin of the extremities and trunk without visceral involvement or Raynaud phenomenon (Box 22-7).<sup>301,302</sup> Seen rarely in children, eosinophilic fasciitis may evolve into generalized or localized morphea (localized scleroderma),<sup>303-306</sup> suggesting that the disorder is a deep variant within the spectrum of severe morphea.<sup>307</sup> In contrast to adults with

### Box 22-7 Eosinophilic Fasciitis

- Scleroderma-like disease without Raynaud phenomenon or visceral involvement
- Painful swelling and induration of skin and subcutaneous tissue
- Usually acute onset after trauma, stress, or strenuous physical activity
- Cobblestone or puckered appearance; may resemble scleroderma later
- Eosinophilia and hypergammaglobulinemia common; occasional elevation in antinuclear antibodies or aldolase
- Usually good initial response to systemic corticosteroids

eosinophilic fasciitis, the childhood form has a better prognosis and shows a female predominance, more muscle involvement, common involvement of the hands with painless contractures and sclerosis, and is associated with arthritis in only 25% of cases (vs. 44% of adults).<sup>308</sup> The hematologic abnormalities that have been noted in adults (aplastic anemia, thrombocytopenic purpura) have not been described in children. However, renal involvement, especially IgA nephropathy, has been noted.

The disorder is characterized by a sudden onset of usually painful swelling, induration, and scleroderma-like changes of the skin with marked thickening of the subcutaneous fascia. The skin has a cobblestone or puckered appearance and often has a yellowish or erythematous color. It is indurated, taut, and bound down without pigmentary change; the “groove sign,” in which a vein is depressed, is seen in up to 50% of patients and is a clue to diagnosis, reflecting the depth of involved fascia. The hands, forearms, feet, and legs are most commonly affected initially, although the disease may progress to the trunk and face. When painless (which is unusual), the disorder has been mistaken for angioedema.<sup>309</sup> In the majority of patients, the onset of the disorder follows trauma or excessive physical exertion. Although systemic changes are usually absent in affected children, patients show peripheral eosinophilia early in the disease, hypergammaglobulinemia, and an elevated sedimentation rate. The ANA test may be positive during the course, but is usually negative, especially at onset. A deep biopsy to include fascia may be necessary to confirm the diagnosis, but MRI is also helpful in demonstrating the depth of the inflammatory involvement. Sections show edema and infiltration of the lower subcutis and deep fascia by lymphocytes, plasma cells, and histiocytes. Eosinophils may be detected in early lesions; thick, sclerotic dermis is characteristically seen late in the disorder.

Patients usually show a good initial response to oral or pulse intravenous systemic corticosteroids, sometimes in combination with methotrexate, with resolution of soft-tissue induration and correction of laboratory abnormalities.<sup>310</sup> However, gradual progression during one or more years to cutaneous fibrosis and/or painless flexion contractures, especially of the hands and feet, occurs in the majority of affected children.<sup>303</sup> Younger age at onset (<7 years of age) and greater disease severity have been correlated with a higher risk of progression to residual fibrosis. Physiotherapy is important adjunctive therapy. In children who do not respond to systemic corticosteroids, other broadly immunosuppressive medications, IVIG,<sup>311</sup> dapsone,<sup>312</sup> infliximab,<sup>309,313</sup> rituximab,<sup>314</sup> retinoids, and UVA1 irradiation<sup>307,315</sup> may be considered. Eosinophilic fasciitis must be distinguished from eosinophilia-myalgia syndrome, which has rarely been described in children and results from oral ingestion of contaminated L-tryptophan.<sup>316</sup> These patients show pronounced eosinophilia with myalgias, especially centrally, and vasculitis of the skin and other organs (Fig. 22-41). The associated myopathy and sometimes elevated muscle enzymes can lead to confusion with an overlap autoimmune syndrome (of scleroderma and dermatomyositis).<sup>310,317</sup> Cutaneous lymphoma and hypereosinophilia syndrome must also be considered.

## Nephrogenic Systemic Fibrosis

Nephrogenic systemic fibrosis (NSF; previously known as *nephrogenic fibrosing dermopathy*) has increasingly been recognized as a sclerosing disorder predominantly seen in patients with renal dysfunction who receive gadolinium-based contrast media as part of MRI testing.

**Figure 22-41** Eosinophilic fasciitis. This girl has swelling, induration and cobblestoning of the skin of the arms, hands, legs and feet. Although many respond to systemic steroids, this girl required several other systemic immunosuppressants for response.

Although NSF was first described in 2000,<sup>318</sup> the first pediatric cases were reported in 2003<sup>319</sup>; in total, 23 pediatric cases have been described.<sup>320</sup> The signs of NSF may develop 2 to 75 days after exposure to the gadolinium.<sup>321</sup> Lesions are characterized by indurated papules and plaques, brawny thickening of skin with a *peau d'orange* appearance, and sometimes joint contractures. The extremities, buttocks, and trunk are usually involved, and the face is typically spared. Patients usually complain of associated pruritus, burning, and pain. Biopsy sections of skin show widened septae in with subcutaneous tissue with increased collagen and fibroblasts. Calcinosis cutis and perforating collagenosis may be seen concomitantly in biopsy sections. The disorder must be distinguished from scleroderma, scleromyxedema, and scleredema. The US Food and Drug Administration (FDA) warns against the use of all gadolinium agents in patients with glomerular filtration rates (GFRs) less than 30 mL/min, and the European guidelines specify a GFR of 30 to 60 mL/min.<sup>322</sup> The most successful treatment is renal transplantation or recovery of the acute renal injury to improve renal function.

## Scleredema

Scleredema (scleredema adultorum of Buschke) is a rare disorder of diffuse large areas of induration of skin that must be distinguished from scleroderma.<sup>323</sup> The condition most commonly occurs in adults with diabetes, but 29% of described cases are in children, half of these cases during the first decade of life.<sup>324,325</sup> Although scleredema may begin spontaneously, 65% to 95% of patients have the onset of their disorder within a few days to 10 weeks after an acute febrile illness. Of these, 58% of the infections are streptococcal; scleredema may also follow infections from influenza, measles, mumps and varicella.<sup>326,327</sup>

The skin changes usually begin suddenly on the neck and then gradually spread to the upper trunk, and occasionally the arms and face, as nonpitting thickening. The abdomen and lower extremities, if involved, tend to show less thickening than the upper half of the body. The texture of skin has been described as brawny or woody, and children with facial involvement may show a mask-like facies. Although affected individuals are usually asymptomatic, some patients display a prodromal period with fever, malaise, and myalgias. In general the condition is benign, although involvement of the skeletal and cardiac muscles has been reported. Tachycardia, arrhythmias, and pericardial effusions have been noted.<sup>328</sup> In addition, the tongue has been involved, making protrusion and mastication difficult. The thickening results from deposition of acid mucopolysaccharide, largely hyaluronic acid, which can easily be detected with colloidal iron or Alcian blue stains of lesional biopsies. The mechanism by which infection triggers scleredema in children is unclear. Therapy is generally unsuccessful,

although high-dosage intravenous corticosteroids may have been helpful in one affected child.<sup>329</sup> Lesions usually resolve spontaneously within months to 2 years. Scleredema has rarely been described in a generalized form in sick neonates (sclerema neonatorum) and must be distinguished from subcutaneous fat necrosis of the newborn in this age group (see Chapter 2).

## Morphea

Morphea is an autoimmune disorder characterized by localized areas of cutaneous sclerosis.<sup>277,278,330–334</sup> Although sometimes termed *localized scleroderma*, use of the term *morphea* decreases the potential confusion with SSc, or scleroderma, a disorder with significantly greater morbidity that shares similar pathogenic features of immune activation and increased collagen production.<sup>308,335,336</sup> The presence of sclerodactyly and/or Raynaud phenomenon should alert the physician to consider a systemic form of scleroderma, rather than morphea.

Morphea has been divided into five subgroups based on pattern and lesional depth: circumscribed, linear, generalized, mixed, and pansclerotic (Padua criteria<sup>337</sup>) (Box 22-8). In children, linear morphea (or linear scleroderma) is most common (42% to 65%), followed by the relatively localized circumscribed type (26% to 37%); in contrast, the circumscribed type of morphea is the most common form (60%) in adults.<sup>338–340</sup> Circumscribed morphea now includes deep morphea forms (morphea profunda, subcutaneous morphea). The development of bullae within lesions is very rare. Linear scleroderma includes the *en coup de sabre* and Parry–Romberg syndrome forms, in which facial involvement occurs. Morphea can be more extensive in distribution (generalized morphea, 7% to 11%) or depth (disabling pansclerotic morphea, extending from the dermis to the bone). Patients may show more than one type concurrently, most commonly linear and circumscribed types (mixed type, 8% to 15%).

The incidence of morphea is 0.4 to 1:100,000 individuals, occurring more often in Caucasians than other racial groups.<sup>338,339</sup> In children, morphea occurs at least 10 times more often than SSc.<sup>287</sup> The disorder occurs primarily in children and young adults with a 2 to 3:1 female-to-male ratio. The mean age in children is 5.2 to 8.2 years of age,<sup>338,340,341</sup> but morphea has been described in infants and even neonates. A family history of rheumatic or autoimmune disorders is reported in the first- or second-degree relatives of 12% to 24% of children, but only 2% of relatives have morphea. Of individuals with childhood-onset morphea, 5% developed a concomitant autoimmune disorder, including skin-localized disorders (psoriasis, alopecia areata, vitiligo).<sup>339</sup>

The unilateral nature of the disorder in most patients and the patterning of lesions have led investigators to hypothesize that affected patients have genetically susceptible cells in this distribution that are triggered by environmental exposure to develop morphea. Some

patterns of morphea seem to follow lines of Blaschko, but others are clearly distinct. The potential link with *Borrelia* infection in European patients remains controversial.<sup>342</sup> Administration of valproic acid was thought to trigger morphea in two patients.<sup>343</sup> Trauma, including from vaccination,<sup>344,345</sup> has also been postulated to trigger lesions of pediatric morphea, and this possibility is supported by the rate of activation of morphea when corrective procedures are performed;<sup>346</sup> however, trauma is so common in children that controlled studies would be required to further consider its role.

The onset of circumscribed morphea is insidious, and superficial plaque-type lesions begin as flesh-colored, erythematous or lilac-colored patches that evolve during weeks to months into firm, hyperpigmented or ivory plaques, with or without a surrounding lilac or violaceous inflammatory zone. The ivory plaques may resemble lesions of lichen sclerosus et atrophicus (LSA) but tend to evolve with the development of hyperpigmentation (Fig. 22-42). Occasionally, patients have 1- to 3-mm papules of morphea (guttate morphea). Affected areas, in order of decreasing incidence, are the trunk, neck, extremities, and face. Morphea may also show localized areas of atrophy and resemble atrophoderma of Pasini and Pierini (Fig. 22-43), a disorder that many experts consider within the morphea spectrum<sup>347</sup> and may be indurated or associated with classic lesions of morphea.<sup>348</sup> The atrophoderma usually begins on the trunk during the late teens or early 20s but may even be congenital.<sup>349–351</sup> The atrophic patches extend very slowly with a depressed center and a “cliff-drop” border. Lesions of atrophoderma of Pasini and Pierini tend to increase in number for 10 years or more, primarily on the trunk, neck, and proximal extremities, and then generally persist without apparent change.

**Figure 22-42** Morphea. (A) Ivory-colored, indurated plaque with surrounding active violaceous border and residual hyperpigmentation. (B) Central depigmentation with peripheral hyperpigmentation. Note the evidence of residual atrophy, including venous prominence.

### Box 22-8 Subsets of Morphea (Localized Scleroderma)

- Circumscribed morphea (round and oval lesions)
  - Superficial (limited to epidermis and dermis)
    - Plaque-type morphea
    - Guttate morphea
    - Atrophoderma of Pasini and Pierini
    - Lichen sclerosus-like
  - Deep morphea (subcutaneous)
- Linear morphea/linear scleroderma (can be deep to muscle and bone)
  - Linear morphea
  - En coup de sabre*
  - Progressive hemifacial atrophy (Parry–Romberg)
- Generalized morphea (>4 plaques, each >3 cm in diameter, involving at least 2 of 7 anatomic areas: head/neck, right and left upper extremities, right and left lower extremities, anterior and posterior trunk)
- Mixed morphea (combination of 2 or more of the above subtypes)
- Pansclerotic morphea (circumferential limb involvement to all depths of skin, including muscle and bone; tends to spare digits)

**Figure 22-43** Morphea. Atrophodermic patches in a girl with generalized morphea. Some of the lesions on the upper shoulders demonstrate the “cliff drop” depression of lesions.

**Figure 22-44** This girl with generalized morphea and uncomfortable sclerosis of the chest had resultant deformity of the breasts. Note the taut breasts, areolar prominence, and shininess from skin atrophy.

In the plaque type, lesions typically vary from a few centimeters to several inches in diameter; fusion of many plaques may result in the more generalized form of morphea. Circumscribed deep morphea feels indurated at a deep level; the skin surface may appear slightly puckered or hyperpigmented, but often appears normal.

Linear lesions (linear scleroderma) generally affect the limbs (occasionally the head or trunk). Their clinical appearance is similar to that of circumscribed plaque-like forms, but the violaceous peripheral ring is inconspicuous or only present at the advancing border. Lesions usually present as broad linear bands of induration with dyspigmentation (both hyperpigmentation and hypopigmentation). Much less commonly, a thin linear band of involvement with atrophy and hyperpigmentation may occur and is sometimes called *linear atrophoderma of Moulin*. Associated atrophy of the skin and underlying subcutaneous tissue leads to a puckered or indented appearance with prominent veins; atrophy may also affect the underlying muscles, fascia, and bones. Linear scleroderma involving an extremity is associated with a risk of undergrowth, both linear and circumferential, of the affected limb, and involvement of the breast area can lead to undergrowth and severe deformity in female adolescents (Fig. 22-44). Impaired joint mobility and contractures (Fig. 22-45) are additional risks when the sclerodermatosus area overlies a joint. Occasionally, roughening of one surface of the long bones underlying a linear area of morphea may be noted. This disorder, termed *melorheostosis*, is characterized radiographically by a picture suggesting that of wax flowing down the side of a candle. Calcinosis is occasionally present in plaques of linear scleroderma, and the underlying muscle may show an interstitial myositis.

Linear scleroderma involving the frontal or frontoparietal region of the scalp (with or without associated facial hemiatrophy) is called *en coup de sabre* (“cut of a saber”). Although usually unilateral, bilateral cases of *en coup de sabre* have rarely been described.<sup>352,353</sup> This variant begins with a purplish to brown patch that becomes sclerotic and often progresses to a linear depressed groove. The initial presentation may be confused with a port wine stain if purplish in color without induration or depression,<sup>354</sup> but pulsed dye laser does not lead to improvement.<sup>355</sup> With loss of subcutaneous tissue, it thus resembles a saber wound or cut on the frontoparietal scalp (Fig. 22-46). The groove may extend downward into the cheek, nose, and upper lip, and, at times, may involve the mouth, gum, chin, or neck. Extension to the scalp or periocular area leads to associated alopecia of the scalp in a linear distribution (Fig. 22-47) or local loss of eyebrow or eyelashes.

The *en coup de sabre* variety may represent a more superficial form of progressive facial hemiatrophy (the Parry–Romberg syndrome), a condition of slowly progressive atrophy of the soft tissue of half of the face with (Fig. 22-48, A) or without (Fig. 22-48, B) associated dermal sclerosis. Either *en coup de sabre* or Parry–Romberg syndrome may be accompanied by alopecia, seizures, headaches, trigeminal neuralgia, enophthalmos, myopathy of external eye muscles, and atrophy of the

**Figure 22-45** Linear scleroderma. Flexion contraction of the hand in a girl with linear scleroderma. This is the extent to which she can straighten her fingers.

ipsilateral half of the upper lip, gum, and tongue. Of these manifestations, headaches are most common, occurring in 67% of patients<sup>356</sup> and often meeting the criteria for migraines.<sup>357</sup> Intracerebral atrophy, white matter hyperintensity, and calcifications may be seen on MRI and CT evaluations of affected patients,<sup>352,358–360</sup> especially in patients with neurologic abnormalities.<sup>356</sup> The severity of *en coup de sabre* morphea does not correlate with neuroimaging changes.<sup>356</sup>

Severe, generalized involvement which may extend to bone has been termed *disabling pansclerotic morphea*.<sup>361</sup> This variant, usually

**Figure 22-46** *En coup de sabre*. Extensive soft-tissue atrophy in a linear pattern on the forehead.

**Figure 22-47** *En coup de sabre*. Note the extension into the scalp, leaving cicatricial alopecia.

affecting girls from 1 to 14 years, tends to have a relentless disabling course and may produce marked disability. Nonhealing ulcers and squamous cell carcinoma may develop at sites of involvement.<sup>362,363</sup>

In most pediatric patients, the diagnosis of localized scleroderma is made clinically. However, histologic evaluation of lesional skin shows early inflammation with edema, subsequent sclerosis, and eventual atrophy. The dermis progressively thickens, and dermal appendages are lost. In contrast to SSc, there is more inflammation and more sclerosis of the papillary dermis. Although the development of the cutaneous sclerosis occurs in both morphea and SSc, the clinical features and prognosis of these two autoimmune disorders differs. Raynaud phenomenon and nailfold capillary dilation and dropout are seen in SSc, but rarely in morphea. Arthralgias occur in 15% to 24% of children affected by morphea<sup>338,364</sup> and have been described more commonly with linear scleroderma, generalized morphea, and circumscribed deep morphea. Dysphagia is not uncommon, and ocular (especially anterior segment inflammation)<sup>365</sup> and renal<sup>366</sup> abnormalities have also been described. However, the restrictive pulmonary and esophageal complications of SSc very rarely arise in morphea.<sup>338</sup> Children with extracutaneous manifestations other than as noted for *en coup de sabre* morphea tend to have more severe skin disease (e.g., pansclerotic morphea, extensive linear scleroderma, generalized morphea). Morphea may also occur in patients with other collagen vascular disorders as part of an overlap syndrome (4.9%).<sup>339</sup>

**Figure 22-48** Parry–Romberg syndrome. Hemifacial atrophy, with (A) or without (B) induration of the overlying skin. In (A) the superficial sclerosis and atrophy is clearly visible.

Several laboratory tests may be abnormal in individuals with morphea, although to date they do have no significant diagnostic or prognostic value. ESR may be increased, especially in children with linear and deep morphea.<sup>340</sup> Eosinophilia is seen in 15% overall, most often in the deep type.<sup>340</sup> ANA positivity, especially speckled and nucleolar patterns, occurs in 30% to 42% of affected children,<sup>339,367</sup> and RF is positive in 16% of patients. Autoantibodies (ANA, ssDNA, antihistone antibodies) are correlated with more extensive body surface area involvement, functional limitations, and higher skin scores in linear morphea.<sup>367</sup> Antitopoisomerase II antibodies have been detected in 76% of patients with localized scleroderma (and 85% in generalized morphea); these antibodies (in contrast to Scl70 antibodies) have been found in 14% of patients with SSc and are detectable in less than 10% of normal children and children with SLE or JDM.<sup>368</sup> Serum levels of B-cell activating factor (BAFF) are increased in morphea (as well as in SSc and SLE), but not in autoimmune blistering disorders such as pemphigus or pemphigoid.<sup>369</sup> In addition, antimatrix

**Figure 22-49** Linear scleroderma with limb length discrepancy. Severe circumference and linear hypotrophy of the bone and soft tissue of the affected leg led to gait disturbance and compensatory scoliosis.

metalloproteinase-1 antibodies are markedly increased in about 50% of patients with morphea or SSc, suggesting that decreased collagen I degradation may contribute.<sup>370</sup> Finally, IP-10 has been detected in both the serum and tissue of pediatric morphea.<sup>371</sup>

Morphea lesions can be subtle in their appearance and difficult to monitor for activity. Active lesions may show erythema, skin induration, and enlargement, but these characteristics can be subtle and difficult to appreciate. Skin thickening (especially centrally), atrophy, and dyspigmentation are part of the damage left behind. A Localized Scleroderma Cutaneous Assessment Tool (LoSCAT) has been used to track clinical changes.<sup>372</sup> Thermography, laser Doppler flowmetry, and high-frequency ultrasound have been recommended as sensitive and noninvasive means for evaluating disease activity and risk of further tissue damage.<sup>277,373-375</sup>

Plaque type morphea lesions tend to improve within 3 to 5 years, but the residual hypopigmentation, hyperpigmentation, and occasional atrophy may persist indefinitely. Lesions of linear scleroderma tend to last longer, even having long periods of quiescence followed by reactivation.<sup>376</sup> In one study, 31% of patients reported disease activity after 10 years.<sup>377</sup> Virtually all patients show residual persistent atrophy and dyspigmentation, especially of the atrophy of the *en coup de sabre*/facial hemiatrophy variant, and 38% with linear scleroderma have functional limitations.<sup>377</sup> Sequelae can be serious and range from significant cosmetic impairment to functional disability from joint contractures, limb length discrepancies (Fig. 22-49), loss of skin adnexae, calcinosis in linear lesions, and ocular or CNS dysfunction.

Treatment for morphea depends on the extent of involvement, activity of the disease, and cosmetic or functional ramifications. Potent topical or intralesional corticosteroid therapy may hasten resolution of lesions but can result in localized atrophy. Calcipotriene ointment is the topical treatment of choice and has been shown to stop the progression of morphea and linear scleroderma when used early in the course, especially twice daily under occlusion,<sup>378</sup> but does not reverse tissue loss. Calcipotriol-betamethasone dipropionate<sup>379</sup> and imiquimod<sup>380</sup> have also shown benefit. The combination of physiotherapy, massage, warm baths, and exercise are often helpful for patients with linear morphea in whom the involvement overlies a joint because of the risk of contractures.

The first-line systemic therapy for disfiguring or disabling morphea/linear scleroderma is the combination of methotrexate and corticosteroids.<sup>381,382</sup> Systemic corticosteroids (1 mg/kg per day) are given (either orally or pulse intravenous) for the first 2 to 3 months, and methotrexate 0.3 to 0.6 mg/kg or 15 mg/m<sup>2</sup> per week (either orally or subcutaneously) is given initially and on a continuing basis. Approximately 75% of children show disease improvement that is usually maintained on medication for a mean of more than 2 years.<sup>383-385</sup> In one trial of 10 patients with localized scleroderma, all patients responded to this therapy and skin lesions became inactive.<sup>381</sup> The mean time to response was 3 months, and relapses were seen after the methotrexate was discontinued. Mycophenolate mofetil has more recently been used in individuals who have failed to respond to steroids and methotrexate or in combination with methotrexate for greater effect. In a study of 10 patients, all patients treated with 600 to 1200 mg/m<sup>2</sup> per day experienced improvement that allowed withdrawal or reduction in steroid and methotrexate within 3 to 6 months.<sup>386</sup> There is also anecdotal evidence of improvement with rituximab<sup>387</sup> and IVIG.<sup>388</sup> In one child, the addition of imatinib to steroids and methotrexate achieved control.<sup>389</sup> Oral calcitriol has also led to significant improvement in some children with linear scleroderma,<sup>390</sup> but is limited by its risk of excessive urinary excretion of calcium, leading to renal calcium stones. Dietary calcium must be restricted, and serum calcium and phosphorus as well as the calcium/creatinine ratio in a 24-hour collection of urine must be monitored. In children, the starting dosage is 0.25 mcg/day with increases to a maximum of 0.75 mcg/day in children and 1.5 mcg/day in adolescents.

Psoralen plus UVA light (PUVA) has been shown to be efficacious for morphea, but its toxicity restricts its use in children. Medium-dose (70 J/cm<sup>2</sup>) UVA1 (340 to 400 nm) significantly reduces the skin thickness of morphea.<sup>391</sup> Although UVA1 light has been thought to work best in lighter skin, good effects are seen as well in darker skin.<sup>392</sup> Home therapy may be an option in children without other UVA1 access. Twice-daily application of calcipotriol ointment combined with UVA1 phototherapy has led to significant softening and repigmentation of morphea lesions, but it is unclear whether these results are superior to topical calcipotriol or UVA1 therapy alone.<sup>393</sup>

Successful repair of contractures may be performed by release and coverage with grafts.<sup>394</sup> Leg-shortening procedures to the normal leg may be performed after full growth is achieved, when the affected leg is significantly shortened by linear scleroderma. Orthodontic devices can assist in craniofacial development and minimize the progressive asymmetry of the lower face from Parry-Romberg syndrome.<sup>395</sup> For residual lesions with atrophy, excision can be considered if the affected area is small or the site can be hidden (such as the scalp). Facial lesions can be corrected by transplants of fat, bone, or cartilage, introduction of fillers, and pedicled or free flaps. Laser has been used to lighten the associated hyperpigmentation.<sup>396</sup> Fat transplants have been most successful for forehead lesions, with a mean of 51% to 75% improvement after at least a year, but have a poorer outcome on the chin, infraorbital, and nose areas.<sup>396</sup> In one study in adolescents with facial linear scleroderma (mean age, 15 years), 65% of whom had undergone multiple procedures, 90% were satisfied with their intervention and 100% would recommend surgical intervention to other patients.<sup>397</sup> Ideally, repair should be delayed until the lesion is inactive.

## Lichen Sclerosus et Atrophicus

Lichen sclerosus et atrophicus (LSA; LS&A) is a disorder primarily of females (85% to 90%) with a prevalence of greater than 1 in 900 girls.<sup>398-401</sup> It has its onset before 13 years of age in 10% to 15% of affected individuals; 70% of these childhood cases occur before 7 years of age, and the condition has been described during the first weeks of life. The mean age at development of symptoms is 5 years, with a mean age at diagnosis of 6.7 years. Mosaic distribution of extragenital lichen sclerosus has been described.<sup>402</sup> The Koebner phenomenon has been documented in cases of LSA in childhood; lesions may develop in surgical scars or sites of vaccination, and exacerbations of quiescent lesions may occur after local trauma or irritation. Lesions of LSA, usually extragenital, occur in 6% of patients with morphea, although

**Figure 22-50** Lichen sclerosus et atrophicus. Ivory atrophic plaque in a girl who also showed genital area involvement.

more commonly in affected adults,<sup>403</sup> and overall 15% have another autoimmune disease. Autoantibodies have been demonstrated against extracellular matrix protein-1 and, more recently, against BP180.<sup>404</sup> Autoimmune disease in a parent or grandparent has been found in 65%.<sup>405,406</sup>

The eruption of LSA is characterized by sharply defined, small, pink to ivory white, slightly raised, flat-topped papules a few millimeters in diameter that aggregate and coalesce into plaques of various sizes (Fig. 22-50). As the condition progresses, atrophy and delling (fine follicular plugs on the surface of macules) may become highly diagnostic features of the disorder. In fact, white comedo-like openings are seen by dermoscopy.<sup>407</sup>

The anogenital region is involved in 75% of affected children. Of those who have extragenital lesions, up to 42% have anogenital involvement as well. Exogenous lesions are asymptomatic and may begin asymmetrically but eventually become distributed in a symmetric manner, primarily on the trunk, neck, and extremities.<sup>408</sup>

In females the anogenital lesions commonly tend to surround both the vulvar and perianal regions in an hourglass or figure-8 pattern (Fig. 22-51). LSA in children most commonly presents in the genital area in girls with itching (70%), soreness (80%), pain with urination (43%), and bleeding (61%) from the vulvar and perianal areas; constipation occurs in more than 10%.<sup>398,409</sup> In studies of girls with vulvar disease or vulvar pruritus, 18% and 11% have lichen sclerosus, respectively.<sup>410,411</sup> A vaginal discharge from the lichen sclerosis may precede the vulvar lesions in about 20% of affected girls, but secondary bacterial vaginosis has also been described.<sup>412</sup> Anogenital lesions uncommonly extend to include the skin on the inner aspect of the thighs. In many girls, erythema, purpuric areas (Figs. 22-52), blistering, and excoriations predominate, especially on the labia minora and clitoris.

When seen on the dorsum of the glans penis in males, the disorder has been termed *balanitis xerotica obliterans*.<sup>413,414</sup> Clinical evidence of lichen sclerosus of the genital area in boys is less common than in girls, but lichen sclerosis is found in biopsy sections in 15% to 35% of circumcisions and has been blamed for 60% of cases of acquired phimosis.<sup>415,416</sup> Perianal involvement in boys is rare. Lichen sclerosus of the lips tends to be asymptomatic and less destructive, resembling vitiligo.<sup>417</sup>

Lichen sclerosus is often misdiagnosed when present in the genital area of girls as irritant dermatitis because of the associated itching and erythema, or as sexual abuse, owing to the purpura and bleeding. The associated white coloration may lead to confusion with vitiligo or postinflammatory hypopigmentation (Fig. 22-52). The anal pruritus often raises the possibility of pinworm infestation, and the inflammation and discharge should cause one to consider candidiasis or bacterial vulvovaginitis.<sup>412</sup> The associated constipation or dysuria often leads to unnecessary GI or urinary tract investigations as well. Lichen sclerosus has been described in girls with an infantile perianal

**Figure 22-51** Lichen sclerosus et atrophicus. Whitening, atrophy, inflammation, and purpura of the labia.

**Figure 22-52** Lichen sclerosus et atrophicus (LSA). This dark-skinned girl with advanced LSA shows partial obliteration of the clitoris. Note the associated purpura and depigmentation.

pyramidal protrusion (see Chapter 15, Fig. 15-34), a benign tag-like lesion that has been associated with constipation in many patients.<sup>418-420</sup> Although biopsies of lesional skin show characteristic epidermal atrophy with subepidermal vacuolization, a hyalinized superficial dermis, and a band-like infiltration of lymphocytes beneath

it, the diagnosis of lichen sclerosus is usually made on clinical grounds and confirmatory biopsy is both traumatic and unnecessary.

Application of clobetasol for 6 to 12 weeks is the treatment of choice to alleviate symptoms, followed by a taper in potency or frequency and intermittent use as needed.<sup>421</sup> Eighty-three percent of patients experience remission after initial treatment. In one study, relapses after initial treatment with clobetasol occurred in more than 40% and required an average of 3 years of intermittent maintenance therapy.<sup>422</sup> In prepubertal boys with phimosis, skin stretching and application of potent topical corticosteroids twice daily for 6 weeks led to a retractable prepucle, including in 67% of the boys with clinically detectable lichen sclerosus.<sup>416</sup> Topical tacrolimus 0.1% ointment has been used successfully to clear lichen sclerosus in girls, both as initial treatment and to promote continued remission.<sup>423–425</sup> Complete circumcision is the treatment of choice in boys with phimosis, but 7% to 19% require late surgery for meatal stenosis.<sup>426</sup> Precircumcision topical steroids<sup>426</sup> or topical tacrolimus ointment 0.1% ointment for 3 weeks after therapeutic circumcision may help decrease the rate of later meatal pathology and maintain control.<sup>427</sup> Plastic surgery may be required to correct labial fusion or clitoral obliteration from scarring. Treatment of extragenital lichen sclerosus is much more challenging than treatment of genital region disease. Although topical steroids and retinoids are occasionally helpful,<sup>428</sup> UVA light treatment (especially UVA1) and systemic medication used to treat morphea, such as methotrexate or mycophenolate mofetil (see Morphea section) may be required.<sup>429,430</sup>

Lichen sclerosus has been reported to improve or disappear at puberty in 60% of affected girls, although a recent study suggested that signs of the disease persisted in 75% postpubertally.<sup>431</sup> In females, atrophy of the clitoris and labia minora may occur, with fusion of the latter and stricture of the introitus. In patients in whom improvement has taken place, the disorder may be reactivated years later by trauma, pregnancy, or the administration of anovulatory drugs.

Although vulvar LSA in childhood does not predispose a patient to neoplasia, the incidence of lesional squamous cell carcinoma in adult cases has been estimated as 4.4%. Patients with cases persisting beyond puberty or having onset after puberty should be observed at intervals of 6 to 12 months for the possibility of leukoplakia or carcinoma. Newly arising nodules, erosions, or ulcers in lesions of LSA that persist for more than a few weeks require histologic examination. Development of genital carcinoma has been reported in an adult after clearance of lichen sclerosus during childhood.<sup>432</sup>

## Anetoderma

Anetoderma (from the Greek, meaning *relaxed skin*) describes an idiopathic atrophy of the skin characterized by oval lesions of thin, soft, loosely wrinkled, depigmented outpouchings of skin that result from weakening of the connective tissue of the dermis.<sup>433</sup> The disorder may be classified as primary macular anetoderma, which arises from apparently normal skin, or as secondary macular anetoderma, which follows previous inflammatory and infiltrative dermatoses. Some of these dermatoses include lupus erythematosus and other collagen vascular disorders, secondary syphilis, sarcoidosis, leprosy, tuberculosis, urticarial lesions, purpura, lichen planus, acne vulgaris, urticaria pigmentosa, molluscum contagiosum,<sup>434</sup> varicella,<sup>435</sup> juvenile xanthogranuloma,<sup>436</sup> and pilomatrixomas.<sup>437,438</sup> A peculiar laxity of the eyelid (blepharosclerosis) may also follow chronic or recurrent dermatitis of the eyelids. When eyelid changes are seen in association with adenoma of the thyroid and progressive enlargement of the lips resulting from inflammation of the labial salivary glands, the disorder is termed *Ascher syndrome*.

Based on whether an inflammatory reaction occurred before the appearance of the atrophy, two types of primary macular anetoderma have been described: anetoderma of Jadassohn–Pellizzari, in which the atrophic lesions are preceded by inflammation; and anetoderma of Schweninger–Buzzi, in which there is no evidence of inflammation. Although the underlying etiopathogenesis of primary anetoderma has not been established, serologic and direct immunofluorescent findings suggest that immunologically mediated mechanisms play a role in the elastolytic process seen in individuals with this disorder.

**Figure 22-53 Anetoderma.** Well-demarcated circles of cutaneous atrophy developed progressively over 3 years on the anterior trunk and neck of this young boy. aPL antibodies were negative.

Anetoderma of Jadassohn–Pellizzari is characterized by crops of round or oval pink 0.5- to 1-cm macules that develop on the trunk, shoulders, upper arms, thighs, sacral area, and occasionally face or scalp (Fig. 22-53). Usually seen in females in their teens to 30s, and occasionally in children, the anetoderma begins with a sharply defined red spot that grows peripherally and becomes round or oval and slightly depressed. As the redness disappears, the characteristic atrophic, wrinkled, and pale herniation ensues. The herniation yields on pressure, admitting the finger through the surrounding ring of normal skin. Much like an umbilical hernia, the bulge reappears when the finger is released, and, at times, fatty tissue may infiltrate the lesions, giving them a more firm, soft, tumor-like appearance.

Anetoderma of Schweninger–Buzzi is manifested by the sudden appearance of large numbers of bluish-white macules, some of which are protuberant, without any preceding inflammatory eruption. Women are affected more commonly than men. Lesions are generally seen on the trunk, neck, face, shoulders, extremities, and back, and range from 10 to 20 mm in diameter. Seen during childhood or adult life, the disease is slowly progressive, and new lesions appear one by one or in groups, a few at a time, over several years. The essential difference in this form of anetoderma is a lack of inflammation and the relative absence of coalescence of lesions.

Anetoderma has also been described in premature infants after use of gel electrocardiographic electrodes, perhaps because of local hypoxemia from the pressure of the electrodes (see Chapter 2).<sup>439,440</sup> More widespread congenital anetoderma of unclear cause has also been described.<sup>441</sup> Drug-induced anetoderma has been described after administration of penicillamine, particularly in patients with Wilson disease. Prothrombotic abnormalities and aPL antibodies have been detected in the majority of patients in more than one investigation, and criteria for the diagnosis of APS have been fulfilled in some patients.<sup>198,442,443</sup> A hereditary form has rarely been described<sup>444</sup> and can manifest with skin lesions alone or in association with bony, neurologic, and ocular anomalies; the disorder most likely is autosomal dominant with incomplete penetrance, but the underlying pathogenesis is unclear. In all forms of macular anetoderma, the primary histopathologic feature is the destruction and loss of elastic fibers. No therapy is effective.

## Relapsing Polychondritis

Relapsing polychondritis is an uncommon disorder in children characterized by inflammation of cartilage.<sup>445,446</sup> Most patients have demonstrated circulating antibodies against type II collagen and matrillin-1, both components of cartilage, suggesting an autoimmune pathomechanism with a strong IFN pathway component.<sup>447</sup> This concept is supported by the report of an infant with transient

disease born to a woman with the condition.<sup>448</sup> Some patients have, or develop, concomitant collagen vascular disorders, especially lupus erythematosus.<sup>449</sup>

Erythema, swelling, and pain of the ear is the most common manifestation (90%), with typical involvement of the auricle but sparing of the earlobe. With chronic disease, the ear cartilage is destroyed, resulting in a scarred "cauliflower" ear. Nasal cartilage inflammation occurs in 70% of affected individuals and can eventuate in a saddle nose deformity. Nonerosive arthritis has been described in approximately 80% of patients, particularly involving the sternoclavicular, sternomanubrial, and costochondral joints. Approximately 65% of patients have ocular inflammation (conjunctivitis, episcleritis, uveitis, corneal ulceration, or inflammation of the optic nerve).

The most serious potential feature is respiratory tract involvement.<sup>450</sup> Patients may show hoarseness, dyspnea, cough, wheezing, or anterior neck tenderness with palpation of the trachea. Secondary pulmonary infection, airway collapse, or airway obstruction may ensue. Renal and cardiac manifestations have rarely been described. A variety of dermatologic features have been associated, among them aphthous ulcerations, palpable purpura, panniculitic nodules, pyoderma gangrenosum,<sup>451</sup> livedo reticularis, and neutrophilic disorders of skin, such as Sweet syndrome.

In children, the most commonly seen disorder to be considered in the differential is otomelalgia (red ear syndrome), a condition characterized by erythema, swelling, and pain of the entire ear that does not spare the earlobe. The condition is short-lived, responds to application of ice, and is episodic, rather than persistent (see Chapter 12; Fig. 12-83). Red ear syndrome can be associated with migraines.

The treatment of choice for relapsing polychondritis is systemic corticosteroids (1 mg/kg per day initially) and NSAIDs. TNF inhibitors, dapsone, and methotrexate have been used as steroid-sparing agents.<sup>452</sup> Rituximab has been successful in treating resistant pediatric cases.<sup>453</sup> Emergency tracheostomy and/or airway stents may be required for upper respiratory tract involvement.<sup>450,454</sup> One child responded to oral ingestion of type II collagen as a tolerogen.<sup>455</sup>

## Sjögren Syndrome

Sjögren syndrome is a chronic autoimmune disorder of unknown etiology that is uncommon in children.<sup>456</sup> Characteristic features are keratoconjunctivitis sicca (inflammation of the cornea and the conjunctiva with dryness and atrophy), xerostomia (dryness of the mouth from lack of normal secretion), and enlargement of the salivary and lacrimal glands (as a result of lymphocytic and plasma cell infiltration) (Box 22-9). Sjögren syndrome can occur alone (primary) or in association with virtually any other autoimmune disorder (secondary), although the most common are JIA and SLE. The manifestations of Sjögren syndrome may precede the onset of another autoimmune disorder by years.

### Box 22-9 Sjögren Syndrome

#### Major Clinical Features

- Inflammation and chronic enlargement of salivary glands
- Keratoconjunctivitis sicca (dryness and atrophy of cornea and conjunctiva)
- Xerostomia (dryness of mouth)
- Fatigue
- May be associated with other autoimmune disorders, especially juvenile idiopathic arthritis

#### Cutaneous Features

- Dryness and scaling of skin (with partial or complete loss of perspiration)
- Sparse, dry, brittle hair
- Hypergammaglobulinemic purpura (usually lower extremities)
- Raynaud phenomenon

#### Laboratory Abnormalities

- Positive antinuclear antibodies; rheumatoid factor, anti-Ro, anti-La antibodies in majority
- Tests to show decreased tear formation and salivary flow

In a review of 39 pediatric cases, the female/male ratio in children was greater than 3:1, with a mean age at onset of 8 years.<sup>457</sup> In children, the presenting sign is usually parotitis (62.5% vs. 13% in adults) with parotid gland enlargement, which may be bilateral.<sup>458–460</sup>

Bacterial parotitis and lymphoproliferative disease must be included in the differential diagnosis. Almost 10% of the children have an extraglandular manifestation, and 51% experience at least one extraglandular manifestation during the course of the disease. The most common extraglandular feature is leukopenia (35%) with or without splenomegaly. Arthritis occurs in 15% of children (vs. 38.5% of adults). Purpura and intense residual hyperpigmentation, especially on the lower extremities (hypergammaglobulinemic purpura), is the most common cutaneous manifestation (12% of children) (Fig. 22-54). Annular erythema, erythema nodosum, mesangial proliferative glomerulonephritis,<sup>461</sup> and lipodystrophy have also been described.

The most prominent mucosal manifestations are associated with dryness of the gingiva and mucous membranes of the mouth and, at times, the conjunctivae, nose, pharynx, larynx, vagina, and respiratory tract.<sup>462</sup> The tongue may become smooth, red, and dry, and in severe cases there may be difficulty in swallowing dry food. The lips may be cracked, fissured, or ulcerated, particularly at the corners of the mouth; the teeth commonly undergo rapid and severe decay; the eyes may be reddened and moist; and thick, tenacious secretions formingropy mucous strands in the inner canthi may be noted (particularly when the patient first arises in the morning). Other ocular manifestations include a burning sensation, as if a foreign body is present in the eye, and the inability to produce tears in response to irritants or emotion.

A positive ANA test has been seen in 67% of children (vs. 92% of adults), and RF in 71%. Positive anti-Ro and/or anti-La antibodies are detected in 73% of children with Sjögren syndrome, but the minority of children with these antibodies develop Sjögren syndrome.<sup>463</sup> Patients may show a decreased stimulated salivary flow rate and positive Schirmer (<5 mm wetting of a strip of filter paper inserted under the lower eyelid) and rose bengal (conjunctival staining) tests of the eyes. Sialography, ultrasound,<sup>464</sup> and CT scans of the parotid glands may show evidence of enlargement and inflammation.

Although no criteria for diagnosis have been established for pediatric Sjögren syndrome, which is more difficult to diagnose, in adults

**Figure 22-54** Hypergammaglobulinemic purpura. Recurrent episodes of purpuric lesions on the lower extremities left darkly hyperpigmented macules that persisted. Joint pain and high levels of anti-Ro and anti-La antibodies as well as immunoglobulin G were associated. Administration of hydroxychloroquine eliminated joint pain and dramatically suppressed cutaneous flares, leading to gradual fading of the hyperpigmentation.

### Box 22-10 Mixed Connective Tissue Disease (Kasukawa Criteria)

**Criteria: Must Meet All Three to be Diagnosed with MCTD**

Raynaud phenomenon and/or swollen fingers or hands  
Positive anti-RNP antibody  
Must have at least one abnormal finding from two or more groups of findings  
SLE-like findings (facial eruption, polyarthritides, serositis, lymphadenopathy, leukopenia, thrombocytopenia)  
Scleroderma-like findings (sclerodactyly, pulmonary fibrosis, vital capacity <80% of normal, carbon monoxide diffusion <70% of normal, decreased esophageal motility)  
Polymyositis-like findings (muscle weakness, elevated serum levels of muscle enzymes, myogenic pattern on EMG)

**Mucocutaneous Features**

Alopecia  
Heliotrope rash  
Hypopigmentation and/or hyperpigmentation  
Livedo reticularis  
Lupus-like lesions, including malar telangiectasia and/or erythema  
Mucosal dryness  
Periungual telangiectasia  
Photosensitivity  
Raynaud phenomenon  
Sclerodactyly

**Musculoskeletal Features**

Arthritis or arthralgia  
Proximal muscle weakness  
Tapered or sausage-shaped fingers

**Gastrointestinal Features**

Abnormal esophageal motility

**Cardiac Features**

Aortic insufficiency  
Congestive heart failure  
Pericarditis/myocarditis

**Pulmonary Features**

Abnormal pulmonary function tests  
Pulmonary fibrosis

**Neurologic Features**

Headache  
Peripheral neuropathy  
Seizures

**Renal Features**

Glomerulonephritis

**Laboratory Abnormalities**

Elevated anti-RNP titer  
Speckled ANA

Mier RJ, Shishov M, Higgins GC, et al. Pediatric-onset mixed connective tissue disease. *Rheum Dis Clin North Am* 2005;31:483–96, vii.  
ANA, Antinuclear antibody; MCTD, mixed connective tissue disease; RNP, ribonuclear protein; SLE, systemic lupus erythematosus.

they include: 1) positive serum anti-SSA/Ro and/or anti-SSB/La or positive RF and ANA titer at least 1:320; 2) labial salivary gland biopsy exhibiting focal lymphocytic sialadenitis; and 3) keratoconjunctivitis sicca, with specific criteria for the biopsy features and severity of the keratoconjunctivitis that may not be applicable to children.<sup>465</sup> The management of Sjögren syndrome includes treatment of the dry skin, keratoconjunctivitis, and xerostomia with lubricants, and therapy for the associated collagen vascular disorder if present. Although systemic corticosteroids are capable of reducing the swelling of the salivary glands, they usually do not improve the function of affected glands, and their use is reserved for severely affected patients. Rituximab has been shown benefit for the mucosal dryness and systemic manifestations in adults.<sup>466</sup>

## Mixed Connective Tissue Disease

Only 0.6% of all pediatric patients with rheumatologic disease have mixed connective tissue disease (MCTD; overlap syndrome), which begins before 16 years of age in 23% of individuals with MCTD.<sup>467</sup> At least 85% are female, and the earliest age of onset described has been 2 years of age (mean onset at age 9.5 to 12 years).<sup>468</sup> The disease is characterized by the combination of clinical features and laboratory data similar to those of SLE, scleroderma, and dermatomyositis (Box 22-10). The most common presenting features of pediatric-onset MCTD are fatigue and pain (polyarthralgias, myalgias) and Raynaud phenomenon (mean, 73% of children).<sup>469</sup> In one study, myositis was the most common manifestation at onset, with SLE-like features least common.<sup>467</sup> Although some patients with MCTD have deforming arthritis, an evanescent nonerosive, nondeforming polyarthritides similar to that seen in patients with SLE is more common.

Approximately two-thirds of children with MCTD have cardiovascular involvement, including pericarditis, myocarditis, congestive heart failure, aortic insufficiency, and/or pulmonary arterial hypertension<sup>470</sup>; about 10% have clinical evidence of renal disease (more by biopsy evaluation);<sup>471</sup> and about 10% of individuals have neurologic abnormalities (trigeminal sensory neuropathy, vascular headaches, seizures, multiple peripheral neuropathies, and cerebral infarction or hemorrhage). Severe thrombocytopenia appears to be limited to

childhood forms, and the incidence of renal and cardiac involvement is higher in children than in adults.<sup>471</sup> However, the course is more slowly progressive, overall shows a lower risk of renal disease, and responds to lower doses of steroids than SLE or scleroderma. Progression toward scleroderma can be predicted by changes on capillaroscopy.

The distinguishing laboratory marker for this disease is the demonstration of serum antibody specific for nRNP (U<sub>1</sub>RNP), a ribonuclease-sensitive component of extractable nuclear antigen (ENA). In addition, most patients with MCTD have high serum titers of ANA in a speckled pattern. Up to 50% of patients show a high titer of RF.

Immunosuppressive medications, particularly systemic corticosteroids, hydroxychloroquine and methotrexate, are most commonly used as therapy. Immunoabsorption onto protein A in combination with low-dosage systemic steroids and bosentan led to remission in a recalcitrant patient.<sup>472</sup> Long-lasting remission occurs in only 3% of patients; inflammatory manifestations (fever, arthritis, skin eruption) are most responsive to treatment, whereas the sclerodermatous features (sclerodactyly, esophageal disease) and vasculopathy (including Raynaud disease) tend to persist. In one study with 12 children, 92%, 79%, and 52% were free of organ involvement at 2, 5, and 10 years, respectively.<sup>468</sup> Mortality is lower in children than in adults, especially if organ involvement can be detected and treated early.

Endocrinologic diseases often display cutaneous features that may provide diagnostic clues, and patients with these disorders may be more susceptible to a variety of mucocutaneous problems. Some of these conditions and their therapy, where applicable, are reviewed here. A thorough discussion of all endocrine disorders and their treatment is beyond the scope of this chapter.

## Thyroid Disorders

Patients with hyperthyroidism or hypothyroidism may show a variety of skin findings. In some cases associated hair or nail defects may also be seen. Some of these findings are related to the imbalance in thyroid hormone, which may play a role in skin homeostasis via its influence on proteoglycan synthesis, epidermal differentiation, hair formation, and sebum production.<sup>1</sup>

### HYPERTHYROIDISM

**Box 23-1** summarizes the various cutaneous changes that may be seen in hyperthyroidism. This disorder is most often caused by an autoimmune thyroid disease, Graves disease. It may also be associated with a hyperfunctioning thyroid nodule, thyroid multinodular goiters, non-Graves thyroiditis, excessive thyroxine intake, or hypersecretion of thyroid-stimulating hormone (TSH). Cutaneous features occur most commonly in association with Graves disease, and these manifestations may more often be the result of autoimmune mediation rather than direct effects of thyroid hormones.<sup>2</sup>

The clinical features of hyperthyroidism include nervousness, emotional lability, tachycardia and palpitation, heat intolerance, weakness, fatigue, tremors, hyperactivity, increased appetite, weight loss, increased systolic and pulse pressure, accelerated growth, sleep disturbances, school problems, vomiting, diarrhea and occasionally exophthalmos. An enlarged thyroid gland is often present. Specific findings that suggest Graves disease include thyroid ophthalmopathy, pretibial myxedema (PTM), and acropachy. The ophthalmopathy is secondary to periorbital deposition of glycosaminoglycans and may present with proptosis, ocular paralysis, or lid lag.

#### Pretibial Myxedema

Pretibial myxedema (PTM; also known as *thyroid dermopathy*) is manifested as plaques on the anterior tibial surfaces and is related to localized accumulation of acid mucopolysaccharides. Other locations of involvement are occasionally reported, including the dorsal feet. The majority of patients with PTM have ophthalmopathy.<sup>3,4</sup> The onset of PTM usually follows the diagnosis of hyperthyroidism. Examination reveals nonpitting edema, nodules, and plaques with pink to yellow-brown discoloration. The overlying epidermis is thin with a waxy and sometimes translucent quality. Hypertrichosis with dilated hair follicles and a “peau d’orange” appearance may be noted. Polypoid or elephantiasis forms occur less commonly.<sup>3</sup> Although the pretibial surfaces are most commonly involved, other areas including the face, scalp, upper extremities, and trunk may reveal similar changes. The differential diagnosis may include cellulitis, trauma, erythema nodosum, or other mucinoses, and PTM can be confirmed by tissue examination of skin-biopsy material in conjunction with laboratory findings. Histologic evaluation may reveal mucin deposition and reduced elastic fibers.

#### Thyroid Acropachy

Thyroid acropachy is more common in adults with hyperthyroidism, only occasionally occurs in children, and classically presents as the

triad of digital clubbing, soft-tissue swelling of the hands and feet, and periosteal changes. Examination reveals thickening of the soft tissues over the distal extremities and (secondary to diaphyseal periosteal proliferation) of the distal bones. Drumstick-like clubbing, enlargement of the hands and feet, and radiographic changes (fluffy, spiculated, or homogeneous subperiosteal thickening with new bone formation) may be seen. Associated extremity and joint pain may be reported, and nail clubbing may also be seen. Thyroid acropachy and diabetic dermopathy (DD) are indicators of more severe Graves ophthalmopathy.<sup>5,6</sup>

Less specific cutaneous changes in hyperthyroidism include skin that is warm, velvety, moist, and smooth. Hair may be fine and thin. Facial flushing, increased sweating (particularly of the palms and soles), and palmar erythema are common, especially in the advanced state of the disease, called *thyrotoxicosis*. The nails grow rapidly, are shiny, and may reveal onycholysis (separation or loosening of the nail plate from the nailbed) with distal upward curvature (Plummer nails). Koilonychia (spoon-shaped nails; **Fig. 23-1**) and clubbing may also be noted. Chronic urticaria and generalized pruritus are uncommon manifestations of thyrotoxicosis, and chronic active hyperthyroidism can be complicated by Addison disease-like hyperpigmentation. However, the hyperpigmentation of hyperthyroidism is distributed differently, primarily on the shins (**Fig. 23-2**), posterior feet, and nailbeds.<sup>7</sup> Patients with hyperthyroidism may also have an increased incidence of alopecia areata and/or vitiligo.<sup>8,9</sup> Gynecomastia may be present in males and may be caused by increased conversion of testosterone to estradiol. Scleromyxedema, a condition marked by white-yellow papules, weight loss, monoclonal gammopathy, esophageal dysmotility, myopathy, and Raynaud phenomenon, has also been reported in patients (mainly adults) with hyperthyroidism.<sup>10</sup>

### HYPOTHYROIDISM

**Box 23-2** summarizes the various mucocutaneous changes that may be seen in hypothyroidism. Hypothyroidism in pediatric patients may be congenital or acquired. Clinical features of congenital hypothyroidism are shown in **Box 23-3**. Symptoms may be subtle in both forms of hypothyroidism, but decreased linear growth is an important indicator of both types of disease. Hypothermia, lethargy, and poor feeding are all characteristic of congenital disease, which is most often diagnosed on routine newborn screening examinations. Children with acquired hypothyroidism tend to be quiet and well behaved and as a result often receive high grades in school.

Congenital hypothyroidism may develop as a result of agenesis or dysgenesis of the thyroid gland (the most common cause); defective synthesis of thyroid hormone caused by an enzymatic defect; the presence of antithyroid antibodies in a pregnant mother; the lack of maternal iodine during pregnancy (endemic goiter); or the ingestion of antithyroid medications such as propylthiouracil or methimazole by a pregnant woman being treated for thyrotoxicosis. Iodine toxicity from iodine-containing skin antiseptic solutions has been implicated as a potential cause of transient hypothyroidism in newborn infants, although recent studies refute this association.<sup>11,12</sup> Acquired hypothyroidism in children younger than 5 or 6 years of age may be caused by a delayed failure of thyroid remnants (with thyroid dysgenesis); by inborn defects of thyroid-hormone synthesis; by ingestion of antithyroid agents; by thyroidectomy or ablation after radiation; or by chronic thyroiditis or hypothalamic-pituitary disease. After the age of 5 or 6 years, although the same etiologies may be involved, chronic lymphocytic thyroiditis (Hashimoto thyroiditis) is the most common cause. Although iodine deficiency is the most common cause of hypothyroidism worldwide, it is uncommon in the United States.

### Box 23-1 Cutaneous Manifestations of Hyperthyroidism

Warm, velvety, moist, erythematous, smooth skin  
 Thin, fine hair; diffuse nonscarring alopecia  
 Hyperpigmentation (especially of palmar creases, soles, gingivae, buccal mucosa)  
 Facial flushing  
 Palmar erythema  
 Increased sweating  
 Nail changes (onycholysis, curvature, koilonychia, clubbing, yellow nails)  
 Pretibial myxedema  
 Periorbital edema  
 Chronic urticaria  
 Generalized pruritus  
 Thyroid acropachy (clubbing)  
 Increased incidence of vitiligo, alopecia areata  
 Gynecomastia (in men)

### Box 23-2 Mucocutaneous Manifestations of Hypothyroidism

Dry, coarse, pale, cool skin  
 Dull, brittle hair with thinning  
 Cutis marmorata  
 Generalized myxedema (especially hands, feet, periorbital)  
 Carotenoderma  
 Nail changes (ridged, brittle, grow slowly)  
 Alopecia (diffuse, lateral eyebrows)  
 Hypertrichosis (back and shoulders usually)  
 Easy bruising  
 Ichthyosis  
 Eruptive or tuberous xanthomas  
 Livedo reticularis  
 Periorbital edema  
 Dermatitis herpetiformis (has been reported with Hashimoto thyroiditis, atrophic variant)  
 Protuberant lips  
 Macroglossia  
 Urticaria  
 Pruritus

### Box 23-3 Clinical Features of Congenital Hypothyroidism

Puffy (myxedematosus) facies  
 Sallow complexion  
 Wide anterior fontanel and sutures  
 Macroglossia and thick lips  
 Hypertelorism, depressed nasal bridge  
 Coarse, brittle hair  
 Hoarse cry  
 Translucent ("alabaster") ears  
 Umbilical hernia and abdominal distention  
 Heart murmur  
 Hypotonia and slow reflexes  
 Short stubby fingers and broad hands  
 Short lower extremities  
 Scalp seborrhea, purpura  
 Prolonged relaxation phase of tendon reflexes  
 Cold, mottled, or jaundiced skin  
 Sluggishness and inactivity  
 Delayed motor development, mental retardation  
 Lack of coordination and ataxia  
 Poor weight gain, stunted growth  
 Subnormal body temperature, poor circulation, and intolerance to cold  
 Delayed/defective dentition  
 Myxedema (some cases)

**Figure 23-1** Koilonychia. These spoon-shaped nails may occur in disease states (such as hyperthyroidism) or as a normal variant in young children, as in this infant.

**Figure 23-2** Hyperpigmentation of hyperthyroidism. Diffuse hyperpigmentation of the lower extremities was present in this young Hispanic female with Graves disease.

occur in hypothyroidism, again as a result of mucopolysaccharide deposition in skin. It most commonly occurs in the hands, feet, and periorbital locations and may also be deposited in the tongue, giving rise to macroglossia. Generalized puffiness may be present, and the skin may take on a yellow hue as a result of carotenemia (Fig. 23-3). The hair is dull and brittle, and nails are ridged, brittle, and grow very slowly. Patients may have a dull, expressionless facies. Hypertrichosis of the back and shoulders may be seen, and alopecia may involve the lateral portions of the eyebrows (termed *madarosis*) or occur in a more diffuse pattern.<sup>13</sup> A collodion baby with concomitant congenital hypothyroidism has been reported.<sup>14</sup>

## Parathyroid Disorders

Disorders of the parathyroid glands (hyperparathyroidism and hypoparathyroidism) may affect the skin in various ways and often present

Cutaneous features of hypothyroidism are a reflection of the hypometabolic state with reduced body temperature and reflex vasoconstriction. Patients often have dry, coarse, pale, and cool skin. Cutis marmorata (physiologic mottling) may be prominent. Hypohidrosis may lead to acquired palmoplantar keratoderma.<sup>10</sup> Myxedema may

**Figure 23-3** Carotenemia. This yellow-orange skin coloration (carotenoderma) is especially prominent on the palms and soles. It may be seen in association with disease states (i.e., hypothyroidism) or with high intake of  $\beta$ -carotene-containing foods such as prepared baby foods containing orange vegetables, as in this healthy infant.

with cutaneous features that can assist the primary or consulting physician in diagnosis and management. Although primary parathyroid disease is uncommon in children, these glands play a major role in the regulation of calcium and phosphorus metabolism, and associated abnormalities manifest distinctive clinical patterns. Parathyroid hormone (PTH) is one of the two main calcitropic hormones (the other one being calcitriol); these hormones regulate phosphate and calcium homeostasis.

### HYPERPARATHYROIDISM

Primary hyperparathyroidism, one of the least common endocrine disorders of infancy and childhood, is rarely diagnosed in children younger than 16 years of age. When seen, it is usually the result of a familial, genetically determined hyperplasia of the parathyroid, which may present as an isolated hyperparathyroidism or as the hyperparathyroidism-jaw-tumor syndrome, in which case ossifying tumors of the maxilla or mandible are present.<sup>15</sup> A malignant neoplasm of the parathyroid, or an association with some other disease such as is seen in patients with multiple endocrine adenomatosis (multiple endocrine neoplasia [MEN]; see below) or chronic renal insufficiency may also result in hyperparathyroidism.<sup>16,17</sup>

The majority of cases of hyperparathyroidism are sporadic, most often being caused by a single adenoma in the parathyroid gland. The clinical features of hyperparathyroidism include systemic effects of hypercalcemia: failure to thrive, muscular weakness, lethargy, anorexia, vomiting, fever, headache, constipation, weight loss, polydipsia, polyuria, mental retardation, metastatic calcification, and with marked hypercalcemia, stupor or death. Of these, metastatic calcification is the most common cutaneous manifestation, and in patients with sporadic hyperparathyroidism, this may be the only cutaneous finding. Hypercalcemia may also produce an ophthalmologic finding known as *band keratopathy*, which is the result of calcium and phosphate deposition beneath the Bowman capsule. Band keratopathy appears as a superficial corneal opacity resembling frosted or ground glass in a band-like configuration with white flecks or "holes" in the band resulting in a "Swiss cheese"-like appearance. It is not specific for hyperparathyroidism but may also be seen as a manifestation of hypercalcemia secondary to vitamin D intoxication, uremia, or sarcoidosis. It is not commonly found in patients with hyperparathyroidism when serum phosphorus levels are low and glomerular function is maintained.

Patients with chronic renal failure may experience several types of cutaneous manifestations. The skin of the patient with uremia may be pruritic, dry, scaly, sallow, and hyperpigmented; the sallow appearance is partially caused by anemia, and the hyperpigmentation appears to be the result of decreased renal clearance of melanocyte-stimulating hormone (MSH). Hyperparathyroidism secondary to chronic renal failure results from impaired synthesis of 1,25-

dihydroxyvitamin D<sub>3</sub>, which leads to hypocalcemia from impaired intestinal calcium absorption and ultimately increased levels of PTH. Hyperphosphatemia may result in a high serum calcium phosphate product and produce secondary calcification of the skin. This calcinosis cutis (see Chapter 9) manifests as hard calcium deposits in skin and subcutaneous tissues, especially in periarticular locations. These lesions may resolve spontaneously with correction of the serum calcium and phosphate levels. In addition to being seen in hyperparathyroidism, it may also be noted in association with paraneoplastic hypercalcemia, milk alkali syndrome, sarcoidosis, and hypervitaminosis D.

When the calcification is more progressive and involves blood vessels, ischemic necrosis of skin and soft tissues occurs and is termed *calciphylaxis*. This rare (especially in children) and life-threatening condition results from vascular calcification and is most commonly reported in patients with end-stage renal disease. Clinically, it is manifested as ecchymotic or infarcted areas of skin, bullous lesions, and plaques of calcinosis with periodic extrusion of calcium. Lesions of pediatric calciphylaxis are most commonly noted on the upper and lower extremities.<sup>18</sup> They are very painful, and mortality related to gangrene and sepsis is high. Extensive calcification in the heart and lungs may result in cardiorespiratory failure.<sup>19</sup> Parathyroidectomy is often, but not always, useful in this setting.<sup>20-22</sup> Histologically, calciphylaxis shows calcification of the walls of small and medium-sized blood vessels in the dermis and subcuticular regions.

The diagnosis of hyperparathyroidism is established by consistent elevations of total serum calcium above 12 mg/dL, the reduction of serum phosphorus concentrations below 4 mg/dL, and elevated levels of PTH. High alkaline-phosphatase levels usually indicate bone disease. This complication of hyperparathyroidism may be demonstrated radiographically by generalized demineralization of bones, destructive changes at the growing ends of long bones, subperiosteal erosions (particularly in the phalanges, metacarpals, and lateral portions of the clavicles), and in more advanced disease, generalized rarefaction, cysts, tumors, fractures, and deformities. Radiographs of the abdomen may reveal renal calculi or nephrocalcinosis, and ultrasonography and radioisotope scanning can confirm the diagnosis of primary hyperparathyroidism associated with an isolated parathyroid adenoma. In infants with parathyroid hyperplasia, cupping and fraying at the ends of long bones and ribs may suggest rickets, and severe demineralization and pathologic fractures are common.

### HYPOPARATHYROIDISM/DIGEORGE SYNDROME

Hypoparathyroidism is characterized by hypocalcemia and inappropriate response of the parathyroid glands or, less often, with elevated PTH levels and lack of response to the hormone (see Pseudohypoparathyroidism section). In childhood, hypoparathyroidism may develop as a congenital idiopathic disorder but usually appears in the neonatal period, in later infancy, or during childhood or as an acute condition after inadvertent removal or damage of the parathyroid glands during thyroid surgery. Congenital hypoparathyroidism may occur alone; may be seen as an autoimmune disorder, where it may occur alone or with other endocrine disorders; or may be a hereditary condition associated with an increased familial incidence of other endocrinologic disorders (Addison disease, pernicious anemia, and Hashimoto thyroiditis), candidiasis, and/or vitiligo. When associated with hypoplasia of the thymus and immunologic defects, the condition is known as *Digeorge syndrome* (see below).

Idiopathic or congenital hypoparathyroidism usually is first manifested by tetany or seizures and in 25% to 50% of patients, ectodermal defects. The skin of affected individuals is rough, dry, thick, and scaly; the hair and eyebrows are sparse; and the nails are short and thin with brittleness, crumbling, or longitudinal grooving. When hypoparathyroidism occurs during tooth development, pitting, ridging, absence of dental enamel, and absence or hypoplasia of the permanent teeth may result. Extensive calcification of skin and subcutaneous tissues has been reported in an infant with congenital primary hypoparathyroidism, although this is exceedingly rare.<sup>23</sup> Other clinical manifestations include convulsions, carpopedal spasm, muscle cramps and twitching, numbness or tingling of the extremities, laryngospasm or bronchospasm, exfoliative dermatitis, mental retardation, chronic diarrhea (especially in infants), photophobia, keratoconjunctivitis,

blepharospasm, and cataracts. Mucocutaneous candidiasis is seen as a complication in 15% of patients with idiopathic hypoparathyroidism. Electrocardiography may reveal prolongation of the QT interval, and head imaging may show calcifications of the basal ganglia.<sup>15</sup> The combination of candidiasis, endocrinopathy, and ectodermal dysplasia has been termed *autoimmune polyendocrinopathy, candidiasis and ectodermal dystrophy (APECED)* as well as *autoimmune polyglandular syndrome (APS) type 1* or *autoimmune polyendocrinopathy syndrome type 1* and is discussed in more detail below in the section Autoimmune Polyglandular Syndromes (see also Chapter 17).

The cutaneous manifestations of hypoparathyroidism associated with surgical removal or injury of the parathyroid glands differ from those seen in patients with idiopathic or congenital hypoparathyroidism. These include thinning or loss of hair, the development of horizontal grooves (Beau lines) in the nails, or a complete loss of nails after episodes of tetany (these abnormalities revert to normal when hypocalcemia is controlled). Hyperpigmentation (predominantly on the face and distal extremities) may resemble melasma, pellagra, or Addison disease and also may occur in cases of postthyroidectomy hypoparathyroidism. Although cutaneous calcification has been noted, this complication is relatively uncommon. In a series of 21 patients with acquired hypoparathyroidism, the most common cutaneous manifestations were hair loss (especially axillary and pubic), coarsening of body hair, and dry skin.<sup>24</sup>

DiGeorge syndrome is a T-cell deficiency disorder that develops as a result of faulty embryologic development of the thymus and the parathyroid glands (a congenital malformation of the third and fourth pharyngeal pouches and the surrounding arches). The classic triad consists of cardiac malformation, hypocalcemia, and T-cell immunodeficiency. Defects of the great vessels may include truncus arteriosus, interrupted aortic arch, double aortic arch, or aberrant subclavian artery. Oral candidiasis is an almost constant finding in patients with this disorder, and overwhelming fungal, viral, or bacterial infection usually leads to death early in infancy. Hypocalcemia and tetany may occur at an early age, and other features include chronic diarrhea, interstitial pneumonia, failure to thrive, micrognathia, hypertelorism, low-set ears, bifid uvula, shortened philtrum, bowed mouth, chronic purulent rhinitis, mental retardation, calcification of the central nervous system, and nephrocalcinosis.<sup>25</sup>

DiGeorge syndrome is associated with a deletion in the long arm of chromosome 22, and is also referred to as a *chromosome 22q11.2 deletion syndrome* or *velocardiofacial syndrome*.<sup>26</sup> The candidate gene for this disorder is termed *TBX1*, which encodes the T-box transcription factor 1. Approximately half of patients with DiGeorge syndrome are hemizygous for 22q11, and they have occasionally been found to have overlapping deletions in the 10p13/14 boundary.<sup>27,28</sup> These patients are at increased risk for developing psychiatric disorders, with one in four developing schizophrenia and one in six developing major depressive disorders.<sup>29</sup> Other reported psychiatric morbidities include attention-deficit/hyperactivity disorder, oppositional defiant disorder, and anxiety disorders.<sup>30</sup> When the immunodeficiency is severe, thymic or bone marrow transplantation should be considered.<sup>31</sup>

### PSEUDOHYPOPARATHYROIDISM/ALBRIGHT HEREDITARY OSTEODYSTROPHY

Pseudohypoparathyroidism (PHP) is a hereditary disorder in which there is decreased target tissue responsiveness in the receptor tissues, particularly the kidneys and skeletal system, to PTH (rather than a true deficiency). PHP is subclassified into types Ia, Ib, Ic, and type II (which involves a different mechanism of resistance to PTH). *Albright hereditary osteodystrophy (AHO)* refers to PHP in conjunction with a clinical constellation of physical features, including short stature, central obesity, brachydactyly, ectopic ossification, and variable degrees of mental retardation.<sup>32,33</sup>

*Pseudopseudohypoparathyroidism (PPHP)* is a term used to describe individuals with AHO who have normal end-organ responsiveness to PTH. These patients do not develop hypocalcemia and tetany. PHP and PPHP are caused by different types of mutations in the *GNAS* gene, and presence of genetic imprinting may lead to quite diverse clinical phenotypes.<sup>32,34</sup> Specifically, maternal inactivating mutations result in PHP-Ia, whereas paternal inactivating mutations result in PPHP and the disorder progressive osseous heteroplasia (POH), a disease of

**Figure 23-4** Osteoma cutis. These rock-hard papulonodules revealed ectopic ossification microscopically.

severe heterotopic ossifications of the subcutaneous tissues, skeletal muscles, and deep connective tissues (see Chapter 9).<sup>35</sup>

Patients with PHP have hypocalcemia, hyperphosphatemia, and elevated serum levels of PTH. Hypothyroidism secondary to TSH resistance may be seen in PHP-Ia. Ectopic calcification is common, and intracranial lesions usually involve the basal ganglia and occasionally other regions. Calcinosis cutis may occur and presents with multiple small papules, plaques, or nodules with a predilection for the scalp, hands and feet, periarticular regions, and chest wall.<sup>35</sup> Soft-tissue ossification (osteoma cutis) may be present at birth or develop during infancy or childhood (Fig. 23-4) and is often a presenting feature of the disease, along with hypothyroidism.<sup>36</sup> The subcutaneous calcifications or ossifications may occasionally present very early in life (even by 2 weeks of age) and in those patients may be vital to early recognition and diagnosis of PHP.<sup>37</sup> Dermal or subcutaneous hypoplasia may occasionally be noted in areas of cutaneous calcification.<sup>38</sup>

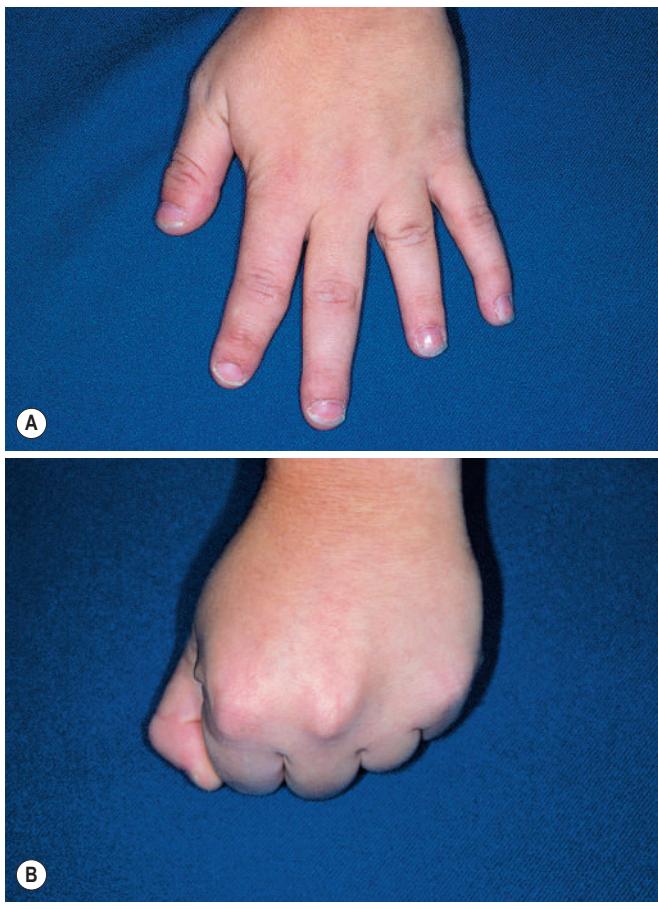

The characteristic features of AHO include short stature, obesity, and characteristic facial features, including round face, flat nasal bridge, and a short neck. Brachymetaphalangism refers to shortening of the fourth and fifth metacarpals and may be recognized by knuckle dimples when the patient makes a clenched fist.<sup>35</sup> In addition, the fourth and fifth fingers and toes may appear shortened (Fig. 23-5).<sup>39</sup> Plain radiography may confirm this feature when the clinical findings are subtle. Mental retardation may be present and may be less common with aggressive and early treatment for the hypocalcemia.

## Disorders of the Adrenal Glands

Adrenal gland dysfunction may result in a variety of systemic effects with various cutaneous manifestations. Those of particular interest to the pediatrician, dermatologist, and pediatric dermatologist are Addison disease, Cushing syndrome (CS), and the adrenogenital syndrome (discussed under Disorders of Androgen Excess).

### ADDISON DISEASE

Addison disease (primary adrenal insufficiency) is caused by the absence of glucocorticoids and mineralocorticoids despite an increased concentration of adrenocorticotrophic hormone (ACTH), and characterized by weakness, anorexia, weight loss, hypotension, decreased serum sodium and chloride, increased serum potassium, hypoglycemia, and hyperpigmentation of the skin and mucous membranes. Sporadic and recurrent "flu-like" episodes may provide a clinical clue to the diagnosis, especially in the setting of pigmentary alterations.<sup>40</sup> Hyperpigmentation in Addison disease is the result of increased production of proopiomelanocortin, which is cleaved to form MSH and ACTH.<sup>41</sup> This overproduction in the pituitary gland occurs as a compensatory phenomenon associated with decreased cortisol production by the adrenal glands. The hyperpigmentation of Addison disease occurs in the setting of primary adrenocortical failure as opposed to

**Figure 23-5** (A) Brachymetaphalangism in a girl with pseudohypoparathyroidism, with shortened fourth and fifth metacarpals. (B) The “knuckle, knuckle, dimple, dimple” sign when she makes a fist. (Reprinted with permission from Schachner LA, Hansen RC, editors. Pediatric dermatology. 3rd ed. Edinburgh: Mosby; 2003.)

secondary adrenal insufficiency, in which case ACTH levels are low and mineralocorticoid production remains relatively intact.<sup>42</sup>

The pigmentation of Addison disease is most intense in the flexures, at sites of pressure and friction, in the creases of the palms and soles (Fig. 23-6), in the nails, in sun-exposed areas, and in normally hyperpigmented areas such as the genitalia and areolae. Pigmentation of the conjunctivae and vaginal mucous membranes is common, and pigmentary changes of the oral mucosae (Fig. 23-7) include spotty or streaked blue-black to brown hyperpigmentation of the gingivae, tongue, hard palate, and buccal mucosa. In addition, increased pigmentation may be noted in existing nevi.<sup>43</sup> The pigmentation may in some children be quite diffuse.<sup>40</sup> Labial pigmentation and longitudinal pigmentary streaks of the fingernails similar to those in Laugier-Hunziker syndrome have been observed.<sup>44</sup> Because the pigmentation may in some cases be subtle, comparison of the patient to other family members may be useful in highlighting the clinical findings.<sup>42</sup> In one series of 18 pediatric patients with primary adrenal insufficiency at one institution, 12 (67%) exhibited cutaneous hyperpigmentation.<sup>45</sup> Primary adrenal insufficiency without hyperpigmentation has been reported and may result in a delay in the diagnosis of Addison disease.<sup>46</sup> Loss of body hair may be another cutaneous finding in this disorder.

The diagnosis of chronic adrenocortical insufficiency is suggested by the clinical features and confirmed by serum electrolyte studies and cortisol level determinations after stimulation by ACTH (the ACTH-stimulation test). A morning serum-cortisol (“AM cortisol”) level is a convenient and simple test but may be insensitive as a screening tool.<sup>42</sup> There are multiple potential causes of Addison disease, including adrenal dysgenesis (which may be related to a variety of

**Figure 23-6** Hyperpigmentation of Addison disease. Increased pigmentation of the palmar creases in this male with Addison disease. (Courtesy of Anne Lucky, MD.)

**Figure 23-7** Oral mucosa pigmentation of Addison disease. Note hyperpigmentation of the tongue and buccal mucosa in this patient with Addison disease.

gene mutations), diseases resulting in adrenal destruction, or impaired steroidogenesis (disorders of cholesterol or steroid biosynthesis, including several forms of congenital adrenal hypoplasia). Although the majority of cases of Addison disease in the past century were attributed to tuberculosis, autoimmune disease currently accounts for most cases presenting outside of the newborn period.<sup>47</sup> APS (autoimmune polyendocrinopathy syndrome) types 1 and 2 may both present with this disorder as one component. Other nonautoimmune causes include infection, metabolic and infiltrative or metastatic diseases, and drug-induced damage.<sup>48</sup> The incidence of Addison disease is elevated in vitiligo probands and their first-degree relatives.<sup>49</sup> When these two disorders occur concurrently, patients may have a striking presentation of hypopigmentation and hyperpigmentation.

## CUSHING SYNDROME

Cushing syndrome (CS) is a rare disorder caused by long-term glucocorticoid excess, which may be caused by a variety of different etiologies. It is divided into ACTH-dependent types (including pituitary-dependent Cushing disease, ectopic ACTH syndrome, and adrenal hyperplasia) and non-ACTH-dependent types (including adrenal adenoma, adrenal carcinoma, and adrenal hyperplasia).<sup>50</sup> The most common form is pituitary-dependent bilateral adrenal

#### Box 23-4 Cutaneous Features of Cushing Syndrome

- Facial plethora and telangiectasias
- Hirsutism, fine lanugo hair growth
- Violaceous striae (especially over the abdomen, flanks, and upper arms)
- Acne
- Bruising
- Poor wound healing
- Skin atrophy
- Thin, translucent skin
- Hyperpigmentation (seen only in ACTH-dependent form)
- Acanthosis nigricans
- Frequent fungal infections (i.e., tinea corporis, pityriasis versicolor, candidiasis)
- Male-pattern alopecia (in females)

ACTH, Adrenocorticotrophic hormone.

hyperplasia, termed *Cushing disease*. Endogenous CS is fairly uncommon in children, and the lack of classic features of hypercortisolism in pediatric patients may delay diagnosis and treatment. In all patients with CS, there is loss of diurnal variation of ACTH and cortisol secretion, which leads to sustained hypercortisolism.<sup>51</sup> Growth retardation to complete linear growth arrest is the hallmark of the disease in children and growing adolescents.<sup>52</sup> CS may also result from the systemic administration of exogenous glucocorticoids (including oral, parenteral or rarely, topical) or ACTH, and should be suspected by the findings of suppressed ACTH and cortisol with no response to corticotropin-releasing hormone (CRH) or ACTH, respectively.<sup>50</sup> CS has occurred after intralesional corticosteroid injections for keloids in a child.<sup>53</sup> The authors have observed CS in a few children after topical application of ultrapotent corticosteroids for extensive alopecia areata/totalis and severe atopic dermatitis.

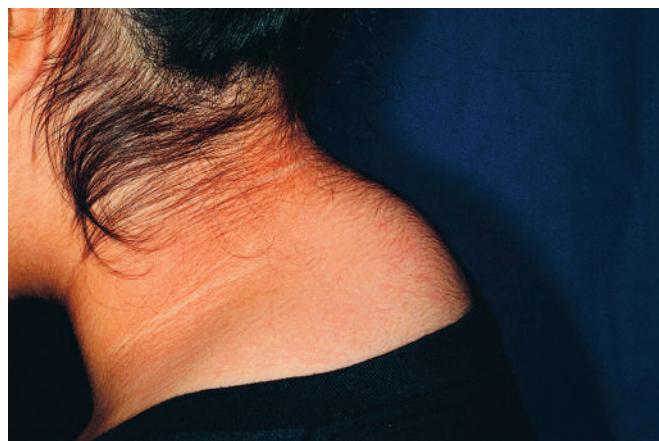

The clinical findings in CS are multiple and usually suggest the presence of hypercortisolism. Noncutaneous signs and symptoms include truncal obesity, marked diminution of the linear growth rate, diabetes mellitus or glucose intolerance, gonadal dysfunction, hypertension, muscle weakness, fatigue, mood disorders, sleep disturbances, menstrual irregularities, osteoporosis, delayed or accelerated bone age, edema, polydipsia, polyuria, and fungal infections.<sup>50,54</sup> The typical growth chart in a child with CS reveals a severely diminished linear growth curve, with continued weight gain across percentiles. This is in distinction to the growth chart in a child with exogenous obesity, which reveals increasing linear growth.<sup>55,56</sup>

The cutaneous features of CS are listed in Box 23-4. Addison disease-like pigmentation (particularly on the face and neck) has been noted in 6% to 10% of patients and is seen primarily in the ACTH-dependent forms of the disease. Other skin findings include a characteristic plethoric “moon” facies with telangiectasias over the cheeks; increased fine lanugo hair on the face and extremities; purplish striae (stretch marks, see below) at points of tension such as the lower abdomen, flanks, thighs, buttocks, upper arms, and breasts; fragility of dermal blood vessels with an increased tendency toward bruising at sites of minimal trauma; poor wound healing; and steroid acne. The latter usually presents as red papules or small pustules distributed primarily on the upper trunk (Fig. 23-8), arms, neck, and to a lesser degree, the face. There is a tendency to develop cutaneous fungal infections (i.e., tinea corporis, onychomycosis, candidiasis, pityriasis versicolor), and disseminated mycobacterial infection has been reported.<sup>57</sup> Patients with CS classically have fatty deposits over the back of the neck, termed the *buffalo hump* (Fig. 23-9).

CS is diagnosed based on suspicious clinical findings and the results of laboratory testing. A 24-hour urinary free-cortisol test is a widely used assay for diagnosing hypercortisolism and has a very high specificity and sensitivity.<sup>50,51</sup> Other diagnostic studies include plasma-cortisol measurement (limited by diurnal variation), low-dose dexamethasone suppression test (excellent sensitivity but requires overnight hospitalization), high-dose dexamethasone suppression test, ACTH measurement (useful for discriminating between ACTH-dependent and ACTH-independent forms), late night salivary cortisol measurement, inferior petrosal sinus sampling, and the CRH stimulation test.<sup>51,58,59</sup> Radiographic imaging may be useful for

**Figure 23-8** Steroid acne. Erythematous papules and papulopustules on the chest and upper arms.

**Figure 23-9** Buffalo hump. This finding consisting of fatty deposits over the posterior neck and upper back may be associated with either endogenous or exogenous Cushing syndrome.

assessing for pituitary or adrenal tumors. The treatment options for CS depend on the etiology and may include transsphenoidal pituitary surgery, external pituitary radiotherapy, excisional surgery (adrenal tumors), and mitotane (an adrenocytolytic agent). With the exception of striae, the cutaneous effects of CS most often completely heal after successful therapy.<sup>60</sup> After treatment, glucocorticoid replacement and stress dosing of cortisol are often required.

Striae distensae (stretch marks), mentioned earlier, are linear depressions of the skin that are initially pink (Fig. 23-10) or purple and later become more flesh-colored, translucent, and atrophic (Fig. 23-11). They are most commonly seen in areas subject to stretching such as the lower back, buttocks, thighs, breasts, abdomen, and shoulders. Striae may develop physiologically in up to 35% of girls and 15% of boys between the ages of 9 and 16 years. Causes of striae include stretching exercises, rapid growth, obesity, adolescence, pregnancy, CS, and prolonged use of systemic or potent topical corticosteroids. They may be seen in patients with anorexia nervosa, mainly the restrictive (vs. the bulimic) form.<sup>61</sup> They can occasionally be mistaken for nonaccidental injury or physical abuse.<sup>62</sup> Although the precise cause of striae is unknown, their formation appears to be related to stress-induced rupture of connective tissue, alteration of collagen and elastin, and dermal scarring in which glucocorticoids suppress fibroblastic activity and newly synthesized collagen fills the gaps between ruptured collagen fibers.<sup>63</sup> Elastic fibers are fine in early lesions and thickened in older lesions of striae.<sup>64</sup> Treatment of striae is challenging, and most therapies are generally unsatisfactory. Many of the lesions that occur during adolescence tend to become less noticeable with time. It has been suggested that topical tretinoin cream may be

**Figure 23-10** Striae distensae. These early lesions appear as pink, linear depressions in the skin.

**Figure 23-11** Striae distensae. These older lesions appear as flesh-colored, linear, atrophic bands.

helpful for some patients, although the results are mixed. Other topical agents reportedly effective in some patients include glycolic and trichloroacetic acid peels and topical hyaluronic acid preparations.<sup>65</sup> The flashlamp-pumped pulsed-dye laser has also been used for treating these lesions, but data suggest that this modality should be reserved for patients with the more fair skin phenotypes (types II to IV).<sup>66-68</sup> Other treatment modalities that have been reported for striae include intense pulsed light, excimer laser, copper-bromide laser, fractional photothermolysis, and microdermabrasion.<sup>65,69,70</sup>

## Disorders of Androgen Excess

Patients with androgen excess may initially present with a variety of skin-related conditions, including hirsutism, acne, and alopecia. Hyperandrogenism may be related to benign or malignant ovarian, testicular, or adrenal tumors; functional overproduction of androgens by the adrenal glands or ovaries; or exogenous androgens. The clinical findings of hyperandrogenism may vary depending upon the pubertal

### Box 23-5 Clinical Features of Hyperandrogenism

Prepubertal
Precocious sexual development:

Other virilizing signs (deep voice, increased muscle mass, male habitus)
Early cardiovascular disease

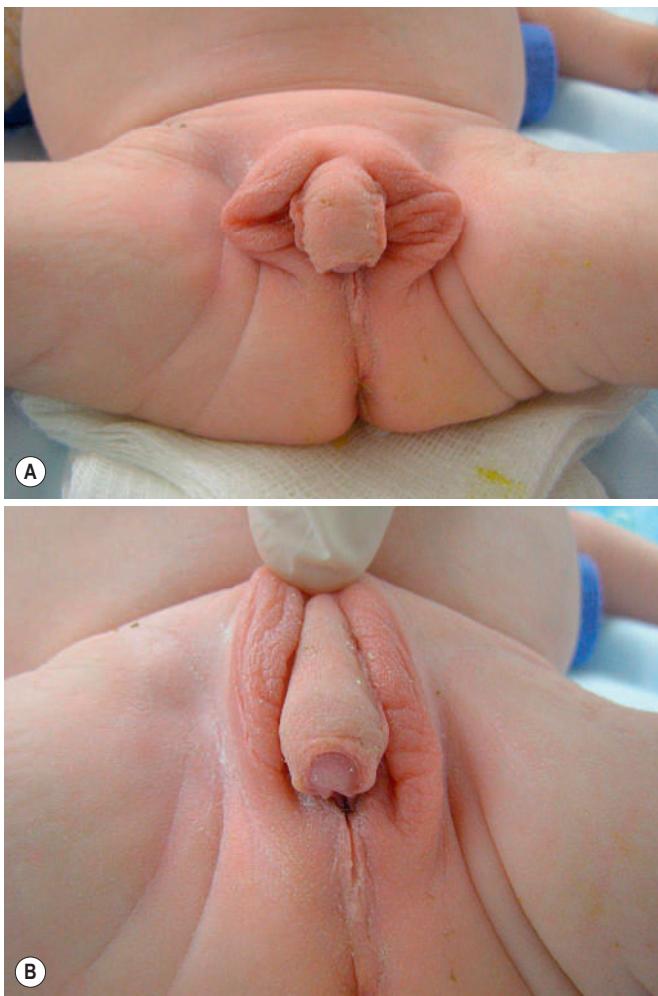

development of the child, and these are summarized in **Box 23-5**. The two disorders to be discussed in this section are congenital adrenal hyperplasia (CAH) and polycystic ovary syndrome (PCOS).

A brief mention of exogenous androgen excess is in order, in light of the expanding US market for testosterone-replacement therapies. These products are the standard of care for androgen deficiency and are available as depot injectables, subcutaneously implanted pellets, transdermal patches, topical gels, and buccal tablets.<sup>71</sup> Inadvertent drug transfer to spouses and/or children (secondary exposure) may occur in association with use of the topical agents and may present with precocious puberty in young children or virilization in exposed adult females.<sup>71-73</sup> Although skin-to-skin contact is presumed to be the primary mode of transfer, spread via shared linens may also be possible. These reports highlight the importance of adequate education in contact precautions when topical androgens are prescribed, as well as vigilance on the part of pediatric practitioners, with recognition of this potential cause for precocious puberty. The United States Food and Drug Administration (FDA) added a box warning about the risks of secondary transfer to topical testosterone product labels in 2009.<sup>74</sup>

## CONGENITAL ADRENAL HYPERPLASIA

*Congenital adrenal hyperplasia (CAH; also known as adrenogenital syndrome)* is a term used to describe a constellation of diseases characterized by impaired steroid metabolism in the adrenal cortex. The most common cause of CAH is 21-hydroxylase deficiency, and other enzymes that may be defective include 11 β-hydroxylase and 3 β-hydroxysteroid dehydrogenase.<sup>75</sup> 21-Hydroxylase deficiency occurs in about one in 10,000 to one in 15,000 live births worldwide.<sup>76</sup> It is inherited in an autosomal recessive fashion, and the gene (*CYP21A2*) is located in the HLA class III region on the short arm of chromosome 6p.<sup>77,78</sup> Owing to the defect in cortisol synthesis, the adrenal cortex in these disorders is stimulated by corticotropin, and overproduction of cortisol precursors occurs, some of which are diverted toward synthesis of sex hormones. This androgen excess leads to clinical signs of hyperandrogenism, and concomitant aldosterone deficiency may result in salt-wasting, failure to thrive, hypovolemia, and in some cases, shock.<sup>79</sup>

One of the most classic presenting features of female children with CAH (21-hydroxylase deficiency) is ambiguous genitalia (Fig. 23-12). Because of exposure to high systemic levels of adrenal androgens during gestation, affected girls are born with a large clitoris, rugated and partially fused labia majora, and a common urogenital sinus in place of a separate urethra and vagina.<sup>79</sup> The degree of virilization is variable and may range from simple clitoromegaly to the appearance of a penile urethra. In severe forms, important features in distinguishing the virilized female genitalia from true male genitalia include the absence of testicles and the presence of normal internal sex organs.<sup>80</sup> Affected boys generally have no obvious physical signs

**Figure 23-12** Congenital adrenal hyperplasia. This newborn has ambiguous genitalia. Note the marked clitoral enlargement (resembling a penis), the rugated and partially fused labia majorae (**A**) and the common opening between the vagina and the urethra (urogenital sinus) (**B**). (Courtesy of Marleta Reynolds, MD.)

of the disorder, although subtle hyperpigmentation and/or penile enlargement may be present. Some forms of CAH, such as 17 $\alpha$ -hydroxylase/17,20-lyase deficiency, may result in ambiguous or female-appearing external genitalia in males, identical to the androgen insensitivity syndrome.<sup>81</sup>

In patients who are not treated or in whom therapy is inadequate, long-term exposure to these androgens results in rapid somatic growth, advanced skeletal age, and premature development of secondary sexual characteristics, including development of pubic and axillary hair, clitoral growth, and penile growth in males. Although linear growth may be accelerated during childhood, these patients often ultimately have short stature because of premature epiphyseal closure. Centrally mediated precocious puberty may occur. Hirsutism is a common feature in patients with nonclassic (partial) 21-hydroxylase deficiency, and when menstrual irregularity and acne also occur, the presentation may simulate that of PCOS (see below). Patients with nonclassic CAH do not have ambiguous genitalia at birth and usually have premature adrenarche and advanced skeletal maturation.<sup>82</sup>

Abnormalities of reproductive function are common in CAH, and infertility is often present. Affected males have fewer problems with reproductive function. Salt-wasting is seen in up to 75% of patients with classic 21-hydroxylase deficiency, owing to decreased synthesis of aldosterone. These patients are prone to hyponatremia, hyperkalemia, hypovolemia, dehydration, and shock. Hyperpigmentation, most notably of skin creases and the genitalia, may occur as an early

sign of adrenal insufficiency. Classic 21-hydroxylase deficiency is diagnosed by the finding of markedly elevated levels of serum 17-hydroxyprogesterone, the main substrate for the enzyme; this is the measurement utilized in newborn-screening protocols. The cosyntropin (corticotropin)-stimulation test is useful for differentiating this disorder from other steroidogenic enzyme defects. Molecular-based genetic testing is available for CAH, and prenatal diagnosis is possible using chorionic villus and amniotic fluid cells for deoxyribonucleic acid (DNA) analysis.<sup>83</sup> Fetal DNA harvested from maternal plasma has also been investigated as a noninvasive approach to prenatal diagnosis. Management for CAH consists of glucocorticoid and mineralocorticoid replacement, supplemental sodium chloride, and surgical management of ambiguous genitalia, which is generally recommended between 2 and 6 months of life.<sup>79</sup> When the diagnosis is known, dexamethasone administered to the mother before the ninth week of gestation may prevent the development of genital ambiguity.<sup>84</sup>

## POLYCYSTIC OVARY SYNDROME

Poly cystic ovary syndrome (PCOS; also called Stein–Leventhal syndrome) is the most common androgen disorder of ovarian function<sup>85</sup> and among the most common endocrine disorders in women.<sup>86</sup> It is estimated to affect between 6% and 15% of women, depending on the diagnostic criteria utilized.<sup>87</sup> Patients with PCOS have increased androgen production and disordered gonadotropin secretion, resulting in amenorrhea or severe oligomenorrhea, increased testosterone levels, and enlarged polycystic ovaries on ultrasound examination. Women with PCOS also have metabolic derangements related to insulin resistance and an increased risk of type 2 diabetes mellitus. The hormonal dysregulation seen in PCOS usually begins during adolescence.<sup>88</sup> The pathophysiology of PCOS is multifactorial, and it has been found to cluster in families with a history of PCOS, non-insulin-dependent diabetes mellitus (NIDDM), cardiovascular disease, and breast cancer.<sup>89</sup>

Three sets of diagnostic criteria have been utilized for adult women, including the 1990 National Institutes of Health criteria (which requires chronic oligoovulation plus clinical or biochemical signs of hyperandrogenism), the 2003 Rotterdam criteria (which requires two of three criteria: chronic oligoovulation or anovulation, clinical or biochemical signs of hyperandrogenism, and polycystic ovaries), and the criteria of the Androgen Excess Society (which defines PCOS as hyperandrogenism manifested as hirsutism and hyperandrogenemia, and ovarian dysfunction based on chronic oligoovulation or anovulation and polycystic ovaries).<sup>87,90,91</sup> There are no formal diagnostic criteria in adolescents, and this may present a challenge given the potential clinical overlap between features of normal puberty and PCOS.

Hirsutism and acne vulgaris are the most common manifestations of PCOS and in fact, the leading cause of hirsutism in adolescence is PCOS (see Chapter 7).<sup>92</sup> Hair growth occurs in androgen-dependent areas including the face, neck (Fig. 23-13), chest, back, and lower abdomen. It may be less noticeable in adolescents (given their shorter duration of hyperandrogenism) and is less common in some ethnic backgrounds such as Asians.<sup>88</sup> Acne is a common finding, and in one study of 119 women with acne but without menstrual disorders, obesity, or hirsutism, PCOS was found on ultrasound in 45%.<sup>93</sup> These findings suggest that PCOS is common in women with acne even in the absence of other suggestive clinical findings.

Acanthosis nigricans (AN) (see below in Acanthosis Nigricans section) is another common cutaneous finding in patients with PCOS. It presents with hyperpigmented, velvety plaques of the neck folds, axillae, and other intertriginous areas. AN is a marker for insulin resistance, although the latter appears to be only one factor leading to its development.<sup>94</sup> Other important components of PCOS include menstrual irregularity and obesity. Anovulation or oligoovulation commonly occur, although women with PCOS can ovulate spontaneously. Secondary amenorrhea, oligomenorrhea, and dysfunctional uterine bleeding may all occur, and delayed menarche may be seen in girls.<sup>95</sup> Adolescent females with oligomenorrhea secondary to PCOS may be difficult to distinguish from those with physiologic anovulation. Obesity is often present, with a centripetal weight distribution and

**Figure 23-13 Hirsutism.** The hair growth in this adolescent female with polycystic ovary syndrome occurs in androgen-dependent areas and is accompanied by acne.

increased waist-to-hip ratio of greater than 0.85.<sup>95</sup> Some patients with PCOS display a metabolic pattern of atherogenic lipid profile, glucose intolerance, and increased fasting insulin level, with an increased incidence of type 2 diabetes mellitus and cardiovascular disease.<sup>85</sup> Studies of adult women with type 2 diabetes mellitus show a prevalence of PCOS higher than that reported in the general population.<sup>96</sup>

The clinical presentation of PCOS and its associated features have overlap with other entities described in the literature. The association of hyperandrogenism, insulin resistance, and AN has been called *HAIR-AN syndrome*. Although the potential causes of hyperandrogenism in this syndrome are multiple, PCOS may be present in many patients. It is possible that the etiology of insulin resistance (and resultant hyperinsulinemia) could produce both polycystic ovaries and hyperandrogenism.<sup>97</sup> *Syndrome X* is a term that has been used to describe a systemic disease notable for hyperinsulinemia and hyperandrogenism. More recently, *metabolic syndrome* has been the terminology used to describe patients with abdominal obesity, dyslipidemia, glucose intolerance, and often, PCOS.<sup>98</sup> These patients are also prone to hypertension, hyperuricemia, fatty liver disease, chronic inflammation, endothelial dysfunction, and coagulopathy.<sup>98</sup> Importantly, there is a threefold increase in the risk of coronary heart disease and stroke. Sleep disorders such as obstructive sleep apnea and excessive daytime sleepiness have been increasingly recognized in patients with PCOS.

The diagnosis of PCOS is suggested by the clinical features of hyperandrogenism and prolonged menstrual irregularity and confirmed by finding elevated serum androgens and excluding other potential causes. The ultrasound finding of polycystic changes is common, but such changes may also be seen in normally menstruating adolescents or in other conditions, and so this must be kept in appropriate context during the evaluation. In addition, some adolescents with PCOS may not have polycystic ovaries. Screening for glucose intolerance and diabetes mellitus should be performed in all patients with PCOS, as should fasting lipid levels. **Box 23-6** lists the recommended diagnostic testing for adolescents suspected of having PCOS.<sup>99</sup>

Treatments for the condition are primarily directed at symptoms and lifestyle modifications, and include hormonal regulation, weight reduction via nutritional changes and physical exercise, and treatment for hirsutism and acne. A serious attempt at weight loss and increased physical activity should be first-line therapy; weight loss itself has been associated with decreased testosterone, increased sex-hormone binding globulin, normalization of menses, and improved fertility in females with PCOS.<sup>100</sup> Combined estrogen-progestin contraceptives provide regular withdrawal bleeds, contraception, and improvement in hirsutism and acne. Antiandrogen medications such as spironolactone may also be of benefit. The use of insulin-sensitizing drugs such as metformin may be effective for anovulation and may benefit the associated metabolic derangements.<sup>101</sup> Other options for treatment of hirsutism include mechanical hair removal (i.e., plucking, waxing, shaving, chemical depilatories, and laser therapy), topical

### Box 23-6 Recommended Testing for Adolescents Suspected of Having Polycystic Ovary Syndrome

#### Laboratory

- Human chorionic gonadotropin (HCG) (urine or serum)
- Follicle-stimulating hormone (FSH)
- Luteinizing hormone (LH)
- Estradiol
- Thyroid-stimulating hormone (TSH)
- Prolactin
- Testosterone (total and free)
- Dehydroepiandrosterone sulfate (DHEA-S)
- Androstenedione
- 17-hydroxyprogesterone

#### Radiologic

- Pelvic ultrasonography (transabdominal if virginal, or transvaginal)

#### If PCOS Confirmed:

- Fasting glucose and insulin
- 2-hour oral glucose tolerance test
- Fasting lipid panel

PCOS, Polycystic ovary syndrome.

inhibitors of ornithine decarboxylase (eflornithine), and gonadotropin-releasing hormone agonists.

## Gonadal Dysgenesis/Turner Syndrome

Gonadal dysgenesis, or Turner syndrome (TS), is a condition characterized by short stature and ovarian dysgenesis. Patients are females with either a missing X chromosome (45, X) or an abnormality of one of the X chromosomes. It occurs in 1 in 2000 to 1 in 5000 female live births.<sup>102</sup> Genomic imprinting, whereby allelic genes or chromosomes are expressed differently depending on the parent of origin, has been implicated in TS in which up to 80% of patients have retained the maternal X chromosome.<sup>103</sup> The rate of spontaneous fetal loss for 45, X fetuses is high; TS may occur in up to 3% of all fetuses and may cause up to 10% of all spontaneous fetal loss (the majority terminating during the first and second trimesters).<sup>104</sup>

In addition to short stature and ovarian failure, patients with TS may have lymphatic abnormalities, skeletal abnormalities (micrognathia, broad “shield” chest, kyphoscoliosis, Madelung deformity), hearing and cardiac defects, renal abnormalities, and endocrinopathies (most notably involving the thyroid and glucose metabolism). Congenital cardiovascular disease is present in approximately 50% of girls with TS, the most common being bicuspid aortic valve; aortic coarctation (10%) and hypertension (25% of adolescents and 50% of adults) may also occur.<sup>105</sup> Characteristic physical findings also include a low posterior hairline, cubitus valgus, unusual rotation of the ears, downward displacement of the lateral canthus, epicanthal folds, inverted or hypoplastic nipples, and shortened fourth and fifth metacarpals and metatarsals. Learning deficits occur in the majority of patients with TS, and psychiatric conditions may be more common.

Abnormalities of the lymphatic system include cystic hygroma (macrocystic lymphatic malformation), which when occurring *in utero*, may result in neck webbing or pterygium colli (Fig. 23-14). Transient lymphedema of the distal extremities, mainly the hands and the feet, may occur, and nail dysplasia may be seen as a result of intrauterine peripheral lymphedema.<sup>106</sup> This lymphedema usually resolves by 2 years of age. Deep furrows of the scalp, similar to what has been termed *cutis verticis gyrata*, may also be the result of preceding lymphedema.<sup>107</sup>

The nails in patients with TS are characteristic, revealing hypoplasia and hyperconvexity (Fig. 23-15).<sup>39</sup> Increased numbers of melanocytic nevi are commonly noted, although clinical atypia is not necessarily more prominent.<sup>108</sup> Despite the increased numbers of melanocytic

**Figure 23-14** Pterygium colli in Turner syndrome. This neck webbing is likely the result of *in utero* cystic hygroma.

**Figure 23-16** Cutis verticis gyrata. This coarse furrowing of the skin on the scalp may be associated with hyperpituitarism or as part of a disorder called *pachydermoperiostosis*.

**Figure 23-15** Nail changes in Turner syndrome. Note the hypoplastic, hyperconvex toenails and hypoplasia of the fourth and fifth metatarsals in this girl with gonadal dysgenesis. (Reprinted with permission from Schachner LA, Hansen RC, editors. *Pediatric dermatology*. 3rd ed. Edinburgh: Mosby; 2003.)

nevi, there appears to be a lower-than-expected incidence of malignant melanoma in patients with TS, possibly reflecting the relationship between sex hormones and melanoma development.<sup>109,110</sup> Multiple pilomatricomas, including giant lesions, have been reported in girls with TS.<sup>111,112</sup>

## Pituitary Disorders

### HYPERPITUITARISM

The pituitary gland, an endocrine organ located in a bony cavity (the sella turcica) at the brain base, is divided into anterior and posterior portions. Both portions secrete a variety of hormones under the influence of the hypothalamus. These hormones include growth hormone (GH), TSH, ACTH, luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin, antidiuretic hormone (ADH, vasopressin), and oxytocin. Skin manifestations of hyperpituitarism include those related to excess GH, glucocorticoids (see Cushing Syndrome section), and prolactin (not discussed here). Most GH-secreting pituitary tumors are eosinophilic adenomas. Excessive secretion of GH by pituitary-gland tumors produces gigantism in children whose epiphyses have not yet closed and acromegaly in individuals whose normal bone growth has ceased. Acromegaly is rare in children, but transitional acromegalic features at times may be seen in affected adolescents. Soft-tissue overgrowth of the hands, feet, face, and nasal tip occur. Patients may have a large furrowed tongue, thick lips,

lantern jaw, broad spade-like hands with squat fingers, hypertrichosis, and hyperpigmentation in a pattern similar to that observed in patients with Addison disease. Although the cause of the hypertrichosis is not well understood, the hyperpigmentation is related to increased secretion of MSH. Other cutaneous manifestations of acromegaly include excessive sweating, oily skin, acrochordons (skin tags), heel-pad thickening, eyelid swelling, and AN.<sup>113</sup> Early noncutaneous complaints in patients with acromegaly may include headache, visual disturbances, weakness, and paresthesias, and impaired glucose tolerance may be present.<sup>114</sup>

Cutis verticis gyrata (coarse furrowing of the skin on the posterior aspect of the neck and the vertex of the scalp; Fig. 23-16) is caused by an increase in dermal collagen; as a result, excessive skin buckles and forms furrows and ridges that resemble gyri of the cerebral cortex (hence the terminology). In addition to being an occasional manifestation of hyperpituitarism, cutis verticis gyrata may occasionally occur as a primary disorder without other associated abnormalities. It has been reported in association with TS (see earlier) and Noonan syndrome.<sup>115-118</sup> It may also be seen as part of a disorder called *pachydermoperiostosis*, which is manifested by thickening of the skin of the face and scalp, clubbing of the fingers, and periostosis of the long bones. Severe progressive arthritis has rarely been reported in association with this syndrome.<sup>119</sup>

### HYPOPITUITARISM

*Pituitary insufficiency (hypopituitarism)* refers to a group of disorders resulting from a deficiency in secretion of one or more hormones derived from the pituitary gland. These include idiopathic hypopituitarism (panhypopituitarism, Simmonds disease), Sheehan syndrome (pituitary deficiency usually arising as a result of hemorrhage or infarct), pituitary tumors (especially craniopharyngioma, Langerhans cell histiocytosis), autoimmune disorders, trauma, infections (i.e., tuberculosis), congenital abnormalities, or ablation of the pituitary gland by surgery or radiation used for the treatment of local tumors. Systemic manifestations of hypopituitarism may include those related to mineralocorticoid and glucocorticoid deficiencies (see Addison Disease section), hypothyroidism, GH and gonadotropin deficiency, and diabetes insipidus secondary to ADH deficiency.

The most obvious skin manifestations of pituitary insufficiency are pallor secondary to anemia and decreased cutaneous blood flow, and a predisposition toward sunburn with decreased ability to tan (because of a decrease in melanin pigmentation secondary to diminished or absent secretion of MSH). Other features (and proposed causes) include smooth, fine skin (GH deficiency) or myxedematous, coarse,

dry skin (hypothyroidism and GH deficiency). The face may be slightly puffy and pale or yellowish (secondary to carotenoderma from hypothyroidism). Hair is thin and sparse with alopecia (hypothyroidism and androgen deficiency), and the nails grow slowly. Adolescent males may have a smooth scrotum with absence of hair and rugae (androgen deficiency).<sup>120</sup> Gonadotropin deficiency may result in loss of axillary, pubic, and body hair and micropenis in males.

## Multiple Endocrine Neoplasia Syndromes

The multiple endocrine neoplasia (MEN) syndromes are familial disorders characterized by benign and malignant tumors of multiple endocrine glands. Cutaneous manifestations may also be found in these disorders. The clinical manifestations of MEN syndromes are inconsistent and reflect the variable involvement of hormone-producing tissues. These disorders are inherited in an autosomal dominant fashion. The endocrine and cutaneous manifestations of the MEN syndromes are summarized in Table 23-1.

MEN 1 (Werner syndrome) is characterized by tumors of the parathyroid glands, endocrine pancreas, and anterior pituitary. Thyroid and adrenal gland tumors may also be seen, as may foregut carcinoid tumors.<sup>121</sup> Clinical manifestations may be related to primary hyperparathyroidism, gastrinoma, tumors secreting neuroendocrine peptides and prolactinomas. There is an increased risk of malignant endocrine tumors, including parathyroid, thymic, bronchial (carcinoid), and enteropancreatic neuroendocrine tumors.<sup>122</sup> The gene for MEN 1 (*MEN1*) was initially mapped to chromosome 11q13, and genetic testing is available.<sup>122,123</sup> This gene encodes a protein called *menin*, which functions as a tumor suppressor protein and in whose absence cellular replication, hyperplasia, and tumorigenesis are increased.

Cutaneous manifestations of MEN 1 include lipomas, angiofibromas, collagenomas, confetti-like hypopigmented macules, and gingival papules.<sup>121</sup> Café-au-lait macules may also occur, although not in the high numbers usually associated with neurofibromatosis. The multiple facial angiofibromas (Fig. 23-17) are clinically and histologically indistinguishable from those that occur in the setting of tuberous sclerosis, although they tend to present later in life in MEN 1, usually during the third or fourth decade.<sup>121,124</sup> In addition, they may involve the upper lip and vermillion border. Nonetheless, facial angiofibromas, which were once felt to be pathognomonic for tuberous sclerosis (and traditionally referred to as *adenoma sebaceum*), can no longer be considered a specific marker for that disorder. In one series of patients with MEN 1, 88% had facial angiofibromas.<sup>121</sup> Collagenomas, which are hamartomas of connective tissue, tend to be more discrete and papular

**Figure 23-17** Facial angiofibromas. These pink to red, dome-shaped smooth papules occur most commonly on the cheeks, nasolabial folds, and chin and may be seen in the setting of MEN 1 or tuberous sclerosis. They may occasionally be confused with lesions of acne vulgaris.

in MEN 1 than the histologically similar lesions ("shagreen patch") seen in patients with tuberous sclerosis.<sup>121</sup> Protuberant collagenomas have been reported, with rapid growth after surgery to remove an endocrine tumor.<sup>125</sup> Melanoma may occur with increased incidence in patients with MEN 1.<sup>126</sup> Patients who have a cluster of tumors suggestive of the syndrome or with single proliferative disorders with a high correlation such as prolactinoma or multigland parathyroid hyperplasia, or with facial angiofibromas in the absence of stigmata of tuberous sclerosis, should be screened for MEN 1.<sup>127</sup>

MEN 2A (Sipple syndrome) is a rare autosomal dominant disorder caused by a point mutation in the *RET* protooncogene. Clinical findings include medullary thyroid carcinoma, pheochromocytoma, and parathyroid hyperplasia. Hirschsprung disease may also occur with increased incidence. Cutaneous manifestations are not a significant feature of MEN 2A. The one that has received the most attention is lichen amyloidosis, which presents as multiple infiltrated papules overlying a well-demarcated plaque on the upper back (especially the interscapular region) or extensor surfaces of the extremities.<sup>128,129</sup> These lesions often begin with intense pruritus, with the subsequent development of brown-colored papules on the skin<sup>130</sup> and the histologic finding of amorphous material in the papillary dermis that stains as amyloid.<sup>131,132</sup>

MEN 2B (MEN III, mucosal neuroma syndrome) is characterized by medullary thyroid carcinoma, pheochromocytoma, ganglioneuromatosis, a Marfanoid body habitus, and only very occasional parathyroid hyperplasia. Medullary thyroid carcinoma is the initial presentation in most patients with MEN 2B (as well as those with MEN 2A) and remains the major cause of morbidity.<sup>133</sup> This disorder is also caused by an activating mutation in the *RET* protooncogene.

Mucocutaneous manifestations of MEN 2B include multiple mucosal neuromas that are often present by the preschool years. These ganglioneuromas involve the anterolateral tongue and lips and may also be located on the conjunctiva and eyelids.<sup>134,135</sup> Lip involvement results in diffusely enlarged lips with a fleshy, bubbled appearance. The upper lip is usually more involved than the lower lip. The tongue lesions are usually limited to the anterior third of the surface and appear as pink-white, somewhat translucent papules and nodules (Fig. 23-18). They may be congenital or noted during the first few years of life and are an important feature, because they may be the initial marker of the syndrome. Although multiple mucosal neuromas are nearly pathognomonic for this disorder, they may rarely occur without other clinical, biochemical, or molecular evidence of MEN 2B.<sup>136</sup> Multiple lesions of lichen nitidus have also been observed.<sup>137</sup>

Ocular involvement may involve the limbus of the conjunctivae and the eyelids, in which case it results in thickening of the lid margin and distortion or displacement of the eyelashes (Fig. 23-19). Nasal, laryngeal, and gingival neuromas may also be present, and skin lesions are

**Figure 23-18** Mucosal neuromas in multiple endocrine neoplasia 2B. Characteristic lingual neuromas and protuberant fleshy lips are present in this 16-year-old male with mucosal neuroma syndrome.

**Figure 23-20** Oral candidiasis. White plaques of the lateral tongue (thrush) in a young female with chronic mucocutaneous candidiasis and diabetes mellitus.

**Figure 23-19** Eyelid changes in multiple endocrine neoplasia 2B. Neuromas of the eyelid margins result in thickening and displacement of the lashes.

**Figure 23-21** Perlèche (angular cheilitis). In this condition, which can occur as a component of chronic mucocutaneous candidiasis, candidal infection presents as erythema, fissures, and maceration at the mouth angles.

occasionally seen. Café-au-lait macules may also be a cutaneous component of the syndrome. Intestinal ganglioneuromatosis (distinct from Hirschsprung disease) is another feature of MEN 2B, presenting with intermittent intestinal obstruction, gas formation, diarrhea, and failure to thrive.<sup>134</sup> Musculoskeletal features of Marfan syndrome are common, including tall stature, elongated limbs, pes cavum, and pectus excavatum, but cardiac or ocular abnormalities typical of that disorder are absent.

Genetic testing for *RET* gene mutations should be performed early in life for individuals with a known family history of MEN 2A or 2B and can identify young carriers at an early stage, often before the development of cancer.<sup>129</sup> In primary relatives of patients affected by medullary thyroid carcinoma with no identified *RET* mutation, linkage analysis and biochemical testing for MEN should be performed. Total thyroidectomy is recommended for all patients at risk.<sup>134,138</sup>

## Autoimmune Polyglandular Syndromes

Autoimmune polyglandular syndromes (APSs) are a group of disorders in which multiple endocrine and nonendocrine defects occur together. The best characterized of these syndromes is APS1, also known as *APECED syndrome*. This autosomal recessive condition is defined by the presence of two of three conditions: adrenocortical failure (Addison disease), hypoparathyroidism, and mucocutaneous candidiasis.<sup>139</sup>

It occurs with increased incidence in Finnish, Iranian, Jewish, and Sardinian populations.<sup>140</sup> APS2, the most common APS, is characterized by Addison disease in conjunction with thyroiditis and/or diabetes mellitus. APS3 has been defined as autoimmune thyroid disease in conjunction with other autoimmune endocrinopathy excluding adrenal disease. More recently, immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome has been recognized as a rare disorder caused by mutations in the *FOXP3* gene and resulting in overwhelming autoimmunity and absence or dysfunction of regulatory T cells<sup>141</sup> (see Chapter 3). Children with this syndrome often die early in life without prompt diagnosis and bone marrow transplantation.

The symptoms of APS1 commonly begin in infancy, although studies of affected individuals reveal marked heterogeneity in clinical features and age of onset of manifestations.<sup>142</sup> In addition to hypoparathyroidism and adrenal failure, other associations may include insulin-dependent diabetes mellitus, gonadal failure, autoimmune thyroiditis, chronic active hepatitis, malabsorption, and parietal-cell atrophy.<sup>143,144</sup> Autoimmune hepatitis may occur and can be one of the presenting features.<sup>145</sup> Candidiasis is seen in nearly all patients, and in the majority of patients it appears first before the endocrinologic manifestations.<sup>146,147</sup> Oral candidiasis (thrush; Fig. 23-20) tends to be chronic and has a peak incidence during the first 2 years of life.<sup>148</sup> Candidal infection may also take the form of angular cheilitis (perlèche; Fig. 23-21), hyperplastic or atrophic oral candidiasis, candidal esophagitis, diaper or perianal candidiasis, scalp infection, intertrigo,

**Figure 23-22** *Candida* onychodystrophy. Nail thickening, subungual debris, and culture positivity for *Candida albicans* were present in this young girl with chronic mucocutaneous candidiasis and endocrinopathy.

or nail infection. These changes, taken together, are also referred to as *chronic mucocutaneous candidiasis* (see Chapter 17). When chronic candidal infection occurs in the esophagus or larynx, stricture formation may result. Nail involvement leads to thickening (Fig. 23-22), brittleness, and discoloration with associated inflammation of the periumgual areas (paronychia). Many postpubertal female patients may experience candidal vulvovaginitis.<sup>148</sup> Generalized candidiasis in these patients is rare, but serious lung infection may occasionally occur. Mucocutaneous candidal infections that are unresponsive to topical therapy should be considered an alerting sign for possible APS1.<sup>142</sup>

Alopecia areata occurs in around one-third of patients with APS1,<sup>144</sup> often presents in childhood, and may progress to alopecia universalis. It tends to begin around the peripubertal years. Vitiligo occurs in some patients and is quite variable in extent. The most consistent cutaneous features are those representing ectodermal dysplasia. APS1 patients often have enamel hypoplasia of permanent teeth, and nail dystrophy with pitting affects around half of the patients.<sup>148</sup> They are more prone to dental caries, abscesses, and tooth loss.<sup>149</sup>

The gene mutated in patients with APS1 is termed *AIRE*, for “autoimmunity regulator.” It is localized to the short arm of chromosome 21 and may act as a transcriptional regulator.<sup>140,143</sup> Mutations in *AIRE* result in loss of central tolerance to a number of self-antigens, with impaired clonal deletion of self-reactive thymocytes, which may subsequently attack a variety of host organs.<sup>141,150</sup> Treatments for APS1 include hormone replacement, aggressive treatment for mucocutaneous candidiasis, and close surveillance for the development of additional autoimmune conditions.

## McCune–Albright Syndrome

McCune–Albright syndrome (MAS) is defined clinically as the triad of fibrous dysplasia of bones (polyostotic fibrous dysplasia), patchy cutaneous pigmentation, and various endocrinopathies, most notably precocious puberty. Other associated endocrine disorders include pituitary adenomas (resulting in GH excess), hyperthyroid goiters, and adrenal hyperplasia.<sup>151</sup> Renal phosphate wasting with or without rickets/osteomalacia as well as hepatic and cardiac involvement have also been reported.<sup>152</sup> The endocrinopathies of MAS are all characterized by autonomous excessive hyperfunction of hormonally responsive cells, which respond to signals through activation of the adenylate cyclase system.<sup>153</sup> Activating mutations in the guanine nucleotide-binding (G) protein gene *GNAS*, which encodes a subunit of the G protein that stimulates adenylate cyclase, have been identified in patients with MAS.<sup>154</sup> A postzygotic somatic mutation leads to a mosaic distribution of cells bearing the defect.<sup>151</sup> As mentioned earlier in this chapter, germline inactivating mutations of this same gene are present in patients with AHO (PHP).

**Figure 23-23** Café-au-lait lesions in McCune–Albright syndrome. Well-demarcated tan patches with a ragged border involved the labia majora, thigh, leg, and foot in this 18-month-old female.

The pigmentary lesions of MAS, which are seen in approximately 50% of patients, present as one or more *café-au-lait* macules or patches with a distinct distribution pattern: they rarely extend beyond the midline, and the majority are on the same side of the body as the skeletal lesions.<sup>154</sup> The most common sites of involvement are the buttocks and lumbosacral regions, and lesions may follow the lines of Blaschko. These *café-au-lait* lesions have irregularly ragged or serrated borders (Fig. 23-23) that are described as resembling the “coast of Maine,” in contrast to the *café-au-lait* spots of neurofibromatosis, where the smooth borders are said to resemble the “coast of California.” They are usually present early in life and often are the first sign of this disorder. Bilateral involvement and lack of respect for the midline may occasionally be observed.<sup>155</sup> Diffuse scalp alopecia with histologic features of fibrous dysplasia has been reported.<sup>156</sup>

Fibrous dysplasia is a rare bone disorder that results in bone pain, fractures, bony deformity, and occasionally neurologic compression. It occurs most often as a bone-limited process, and fewer than 5% of patients have concomitant endocrine dysfunction.<sup>157</sup> Most patients with MAS have either solitary or multiple fibrous dysplasia lesions of bone, which tend to develop during the first decade. Although any bone can be involved, the proximal femurs, pelvis, and skull base are most common, and progressive deformity with fractures may occur. Radiographic studies reveal lytic lesions with scalloped borders and a “ground-glass” pattern. Computed tomographic imaging or bone biopsy may be required to confirm the diagnosis in questionable cases. Precocious puberty is a common initial manifestation in girls with MAS (much less common in boys) and is recognized by the development of secondary sexual characteristics before 9 years of age.<sup>154</sup> In males, testicular tumors associated with penile enlargement may be present, and Leydig- and/or Sertoli cell tumors or hyperplasia are common.<sup>152</sup>

## Disorders Associated with Diabetes Mellitus

Diabetes mellitus is a common, chronic disease, and up to 30% of patients with diabetes mellitus may have some form of cutaneous disorder. The exact influences of plasma-glucose homeostasis, insulin resistance, elevated body mass index (BMI), and/or components of

metabolic syndrome on these cutaneous findings are, in many instances, unclear. Some skin findings associated with diabetes mellitus include poor wound healing, necrobiosis lipoidica (NL), DD, diabetic bullae, acrochordons, AN, and the syndrome of limited joint mobility and waxy skin.<sup>158–160</sup> For some skin conditions, the exact association between the disorder and diabetes mellitus is uncertain, and for many, pathogenesis remains unproven. Box 23-7 lists some potential cutaneous associations with diabetes mellitus. A select number of these disorders will be discussed here. The glucagonoma syndrome, which may be associated with mild diabetes mellitus and cutaneous manifestations, is discussed separately in the next section.

### NECROBIOSIS LIPOIDICA DIABETICORUM

Necrobiosis lipoidica (NL; also known as *necrobiosis lipoidica diabetorum*) is a fairly distinct clinical entity that, although not the most common, is the best recognized cutaneous marker of diabetes mellitus.<sup>158</sup> It may be seen outside of the setting of diabetes mellitus, although up to three-quarters of patients with NL have or will have diabetes mellitus; among patients with diabetes mellitus, it occurs in fewer than 1% of patients.<sup>161,162</sup> NL is predominantly seen in females and has an average age of onset of 34 years.<sup>158,163</sup> However, it may occur in children, and its presence may suggest a higher risk for diabetic nephropathy and retinopathy.<sup>164</sup> In up to one-third of patients with NL, these cutaneous lesions may precede the diagnosis (by up to several years) or present simultaneously with diabetes mellitus. NL is most commonly seen in patients who are insulin dependent. The etiology is unclear but may relate to microangiopathy resulting from glycoprotein deposition in the vasculature.

Lesions of NL typically occur in the pretibial areas and are usually asymptomatic. They present as slowly enlarging, irregularly bordered, red to yellow-brown to violaceous plaques (Fig. 23-24). The center often becomes atrophic and more yellow, and there may be superficial telangiectasias, especially later in the course. Older lesions may be primarily brown in color. Multiple lesions are usually present, and ulceration may occur in up to one-third of patients with NL. Skin biopsy can be useful for diagnosis, revealing degeneration of collagen with inflammation and granuloma formation. However, it is preferable to avoid surgical procedures in this location in patients who have diabetes mellitus when possible. The diagnosis is usually strongly suggested in the presence of sharply demarcated, waxy plaques with a red

**Figure 23-24** Necrobiosis lipoidica diabetorum. Waxy, yellow-brown plaques (**A**) were present in this young girl with diabetes mellitus, with subtle atrophy present on closer inspection (**B**).

or violaceous border on the anterior tibial surfaces of a patient with diabetes mellitus. The cause of NL is unclear but may relate to microangiopathy, endarteritis, vasculitis, or delayed hypersensitivity.

The treatment of NL is challenging, and there is no established gold standard of care, because the clinical response to various treatments is quite variable. When there is no ulceration and lesions are relatively asymptomatic, watchful waiting and protection from injury is appropriate.<sup>169</sup> The influence of strict diabetic control on the lesions of NL is controversial. Many have suggested that glucose control has no effect on the appearance or clinical course of NL, whereas others support the opposite hypothesis.<sup>110,161,165</sup> Cosmetic cover-ups are useful for patients in whom the appearance of lesions is

bothersome. Active therapy of lesions has included topical and intralesional corticosteroids, aspirin, dipyridamole, pentoxifylline, clofazimine, cyclosporine, mycophenolate mofetil, systemic corticosteroids, chloroquine, topical tretinoin, hyperbaric oxygen, and topical psoralen plus ultraviolet A (PUVA) light therapy.<sup>163,166–171</sup> Local corticosteroid products should be used with caution, because they may contribute to further atrophy or ulceration. Antiplatelet therapy with aspirin is reportedly quite effective and well tolerated, although this observation has not been confirmed by randomized clinical trials.<sup>165</sup> Pulsed-dye laser has been used and may benefit the telangiectatic and erythematous components.<sup>172</sup> Ulcerated lesions of NL are treated with local wound care, semipermeable wound dressings, and topical or systemic antibiotics. Surgical excision with split-thickness skin grafting may be useful.<sup>173</sup>

### DIABETIC DERMOPATHY

Diabetic dermopathy (DD; also called spotted leg syndrome, shin spots) is the most common cutaneous marker for diabetes mellitus. It is considered by some to be a pathognomonic sign of diabetes mellitus.<sup>174</sup> DD is seen most often in older patients with diabetes mellitus and only occasionally in children. It presents as multiple, well-circumscribed, brown macules and patches with a tendency toward bilateral involvement of the pretibial surfaces. The lesions often become atrophic and take on the appearance of scars. They are occasionally scaly and measure from several millimeters up to 2 cm. Lesions of DD may occasionally occur on the scalp, forearms, or trunk, but the pretibial surfaces are the most common site of involvement in the majority of patients. The etiology of these lesions is unclear, but some have suggested that their presence may be a clinical sign of an increased likelihood of retinopathy, nephropathy, and neuropathy.<sup>175</sup> It may also be associated with large-vessel (i.e., coronary artery) disease.<sup>174</sup> In a histopathologic study of 14 skin biopsies from DD, taken at the time of autopsy in patients with diabetes mellitus, the most common findings were melanin and hemosiderin deposition with arterial or arteriolar wall thickening seen in a minority of specimens.<sup>176</sup>

Lesions of DD are in large part uninfluenced by treatment. Because the condition is asymptomatic, it requires no therapy aside from protection from trauma and supportive wound care should lesions become inflamed or infected. Although lesions may resolve spontaneously, others may appear individually or in asymmetric crops.<sup>153</sup>

### DIABETIC BULLAE

Diabetic bullae are an uncommon association with diabetes mellitus and present as spontaneously arising large blisters with a predilection for the distal extremities. Diabetic bullae are felt to be a distinct marker for diabetes mellitus. The most common location for these bullae is the dorsal and lateral surfaces of the lower legs and feet (Fig. 23-25). Occasionally, patients may have lesions on the hands or forearms.<sup>158</sup> They range in size from less than 1 cm to several centimeters. There is usually no history of trauma, and the lesions usually have no surrounding erythema. These lesions are generally asymptomatic, and healing occurs over several weeks with supportive wound care. They often heal without scarring, although in some patients, atrophy and scarring typical of dystrophic epidermolysis bullosa may result.<sup>163,177</sup>

### ACANTHOSIS NIGRICANS

Acanthosis nigricans (AN) is a symmetric cutaneous eruption consisting of brown, velvety plaques that involve primarily the skin folds. It may be associated with several different clinical settings, including obesity, insulin resistance, various syndromes, malignancy, and medications, as well as occurring as "benign" and mixed types.<sup>178</sup> Table 23-2 summarizes the various clinical associations with AN. The discussion here will focus primarily on AN associated with obesity, insulin resistance, and diabetes mellitus.

AN presents as dark brown, velvety thickening of the skin involving the axillae (Fig. 23-26) and the neck, especially the posterior and lateral neck folds (Fig. 23-27). The initial change is hyperpigmentation followed by eventual thickening with intensification of skin markings.<sup>179</sup> In addition to the characteristic areas of involvement,

**Figure 23-25** Diabetic bullae. These large, painless, tense bullae may occur in the setting of diabetes mellitus, often with no history of preceding trauma.

**Table 23-2** Clinical Associations with and Variants of Acanthosis Nigricans

Association	Comments
"Benign"	Form of epidermal nevus; may be autosomal dominant; associated with multiple nevi
Obesity	Most common type; insulin resistance common; increased incidence of type II diabetes mellitus
Malignancy	Usually adults, rarely observed in children; sudden onset and rapid spread; especially abdominal adenocarcinoma
Syndromes	Multiple syndrome associations, including Bloom, Crouzon, Prader-Willi, Lawrence-Seip, PCOS, Beare-Stevenson; also lupus erythematosus, dermatomyositis, scleroderma
Medications	Niacin, corticosteroids, oral contraceptives, diethylstilbestrol, others
Acral type	Dorsal hands, fingers, feet
Unilateral type	Unilateral distribution or "nevroid"; may persist unchanged or progress to bilateral involvement
Mixed type	Two of the above types occurring together

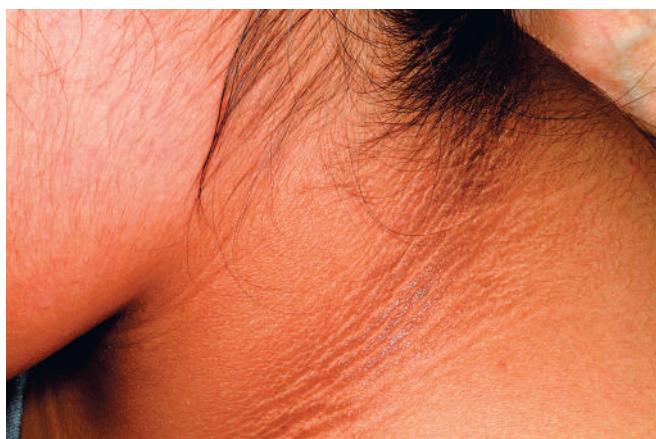

Modified from Schwartz RA. Acanthosis nigricans. J Am Acad Dermatol 1994;31(1):1–19.  
PCOS, Polycystic ovary syndrome.

**Figure 23-26** Acanthosis nigricans. Velvety hyperpigmentation involves the axillae in this patient.

**Figure 23-28** Acanthosis nigricans. Hyperpigmentation with verrucous changes may occasionally occur overlying the knuckles.

**Figure 23-27** Acanthosis nigricans. Velvety hyperpigmentation is present on the lateral and posterior neck folds of this obese teenaged female.

there may be verrucous hyperkeratosis of the knuckles (Fig. 23-28), genitalia, perineum, face, thighs, breasts, and flexural regions of the elbows and knees. Occasionally the eruption of AN may become generalized,<sup>180,181</sup> and mucosal involvement may occur, manifested as thickening and papillomatosis of eyelids, conjunctivae, lips, and oral mucosa. The differential diagnosis of AN may include epidermal nevi, lichen simplex chronicus, postinflammatory hyperpigmentation, erythrasma, and endocrine disorders with hyperpigmentation (Addison disease).

Hyperinsulinemia appears to predispose individuals to AN, and patients with inactivating insulin receptor mutations often have severe involvement.<sup>182</sup> Children with AN often have greater body weight and body fat mass, greater basal and glucose-stimulated insulin levels during oral-glucose tolerance testing, and lower insulin sensitivity. Importantly, after adjusting for body-fat mass and age, the differences in glucose metabolism and insulin studies were less significant in some studies, suggesting that increased BMI should still suggest the possibility of hyperinsulinemia whether or not AN is present.<sup>182</sup> However, other studies have disputed this finding, showing

that AN is associated with hyperinsulinemia and impaired glucose metabolism independent of BMI.<sup>183,184</sup> In a study of 149 overweight Caucasian children, those with AN had greater BMI, waist circumference, and total body fat, but after correcting for age and BMI, there was no evidence for increased abdominal fat.<sup>185</sup> Among African-Americans, AN is strongly associated with obesity and insulin resistance and identifies a subset with a much higher prevalence of NIDDM than is present in African-Americans in the general population.<sup>186</sup> AN is associated with obesity in every ethnic group but occurs with greatest incidence (within the obese population) in Native Americans, followed by African-Americans, Hispanics, and Caucasians.<sup>187</sup> It should be considered a clinical surrogate for laboratory-determined hyperinsulinemia and indicates a high risk for NIDDM.<sup>187,188</sup> As mentioned earlier in this chapter, AN and insulin resistance may also be associated with hyperandrogenism as part of the HAIR-AN syndrome, which may also have as a feature PCOS.

The pathogenesis of AN is unclear. In patients with hyperinsulinemia, insulin may bind to insulin-like growth factor receptors in the epidermis, resulting in papillomatosis (thickening with folding). There are no successful therapies for AN, and the primary focus should be on treatment for the underlying condition. In obesity-associated disease, weight reduction itself seems to reduce the findings of AN. Topical or oral retinoids may benefit some patients, and lactic acid-containing emollients (i.e., LactiCare, AmLactin, Lac-Hydrin) or other keratolytic agents (salicylic acid, urea) may also be useful.

#### Confluent and Reticulated Papillomatosis

Confluent and reticulated papillomatosis (CARP) of Gougerot and Carteaud is briefly discussed here because of its clinical overlap with AN. CARP is a rare disorder characterized by hyperpigmented papules confluent in the center and reticulated at the periphery. They have a characteristic distribution involving the intermammary region (Fig. 23-29) most commonly, as well as the epigastric area (Fig. 23-30) and upper back. Less commonly, the neck, face, and shoulders may be involved. The differential diagnosis may include AN and tinea versicolor. This disorder is seen primarily in adolescents and young adults, and females are involved twice as often as males.

The cause of CARP remains unknown, although there are several speculative theories. An association with insulin resistance has been hypothesized, and the condition has been reported in patients with concomitant AN, obesity, and hyperinsulinemia.<sup>189</sup> However, in most patients, no such association exists. An abnormal host immune response to *Pityrosporum orbiculare* (*Malassezia furfur*) has also been suggested given clinical resemblance to tinea versicolor and the occasional response of patients to treatment with topical or oral antifungal agents, although this association remains controversial.<sup>190,191</sup> Potassium hydroxide examinations on skin scrapings for fungal elements are negative in the majority of patients.<sup>192</sup> A hypopigmented variant of CARP has been described and may be challenging to differentiate clinically from tinea versicolor.<sup>193</sup>

**Figure 23-29** Confluent and reticulated papillomatosis. Hyperpigmented papules and plaques with a reticulate appearance around the periphery involving the intermammary region.

**Figure 23-30** Confluent and reticulated papillomatosis. Reticulate tan papules, patches, and plaques involving the epigastrium, inframammary areas, and sternum.

Treatment of CARP is often but not always successful. A significant proportion of patients seem to respond to minocycline or doxycycline,<sup>194-197</sup> although the mechanism of action is unclear. Minocycline in conjunction with a topical lactic acid-containing emollient is often useful. Other reported therapies of variable effectiveness include topical selenium sulfide shampoo, oral or topical retinoids, oral and topical antifungal agents, topical vitamin D analogues, topical salicylic acid, and topical urea.

## Scleredema Diabeticorum

Scleredema (see Chapter 22) is a rare disorder characterized by diffuse and symmetric induration of the skin. There are two forms: scleredema of Buschke (which tends to occur after upper respiratory infection, especially streptococcal) and the diabetes mellitus-associated form. Scleredema diabetorum occurs most often in middle aged, obese men, although it has been reported in childhood and even in a congenital form.<sup>198</sup> The most common sites are the neck and upper back, but eventual extension to other areas may occur, including the face, scalp, chest, and arms. The skin in affected areas is firm and indurated without pitting and cannot be wrinkled or pressed into folds.<sup>158</sup> The surface appears taut and shiny with loss of normal surface markings. Scleredema is painless but may be uncomfortable for patients given the textural changes and limitation of movement. Occasionally, involvement of the tongue, pharynx, and esophagus may result in dysarthria and dysphagia. Rare associations include pleural, pericardial, or peritoneal effusion, skeletal muscle dysfunction, and paraproteinemia. Histologic evaluation of biopsy tissue characteristically reveals collagen bundles separated by mucin deposits. The course of scleredema diabetorum is variable. It may improve

with control of the diabetes mellitus,<sup>199</sup> although this is inconsistent; in some patients it persists for many years. Therapy is challenging, and the results are often disappointing. Treatments reported include antibiotics, corticosteroids, steroid-sparing immunosuppressant agents, chemotherapy, radiation, light therapy, physiotherapy, and attention to glycemic control.<sup>200,201</sup>

## The Glucagonoma Syndrome

Patients with glucagon-secreting, pancreatic islet  $\alpha$ -cell tumors may have a distinctive dermatosis termed *necrolytic migratory erythema* (NME). The glucagonoma syndrome is characterized by the triad of this cutaneous eruption, a glucagon-secreting tumor, and diabetes mellitus.<sup>202</sup> Weight loss, anemia, and stomatitis are common. Patients with this syndrome are generally middle-aged to elderly, with only rare reports of affected adolescents or young adults.

The cutaneous findings of NME are a hallmark of this syndrome. These skin changes may be present for several years before the diagnosis of glucagonoma is made. Characteristic features include erythema that most often begins in the groin, perineum, and buttocks, with eventual extension to the extremities and perioral areas. The erythematous lesions develop into well-demarcated, annular plaques with scaling, vesicles, and bullae. Erosions and pustules may develop (the latter occasionally studding the periphery of the plaques), and crusting is common. Induration, psoriasisiform changes, lichenification, and bronze pigmentation may occur. The skin lesions of NME evolve sequentially from erythema to blistering to crusting to resolution and are characterized by a pattern of spontaneous remissions and exacerbations.<sup>202</sup> Secondary superinfection with *Staphylococcus aureus* or *Candida* (especially at perineal sites) is common. Patients often appear ill and may have venous thromboses and alopecia. The average 5-year survival rate is less than 50%.<sup>203</sup> The differential diagnosis of NME may include several nutritional deficiency-related dermatoses, staphylococcal scalded-skin syndrome, psoriasis, and toxic epidermal necrolysis.

The diagnosis of NME is suggested by the histologic finding of necrosis of the upper layers of the epidermis. The diagnosis of glucagonoma syndrome is confirmed by finding an elevated serum glucagon level or identifying the neuroendocrine tumor radiographically or histologically. Complete surgical resection of the tumor, when feasible, is the treatment of choice and is usually associated with complete to near-complete resolution of the cutaneous eruption.

The inborn disorders of metabolism are a group of primarily autosomal recessive hereditary disorders that result in metabolic and clinical defects. (More comprehensive discussion of some of these topics is covered elsewhere: disorders of tyrosine metabolism [Richner–Hanhart syndrome], Gaucher syndrome, and multiple sulfatase deficiency are mentioned in Chapter 5; Menkes syndrome in Chapter 7; alkaptonuria in Chapter 11; Fabry disease and fucosidosis in Chapter 12; and Hartnup disease in Chapter 19.) Most developed countries have instituted comprehensive screening programs during the first week of life that allow detection of many of these defects, among them biotinidase deficiency, aminoacidopathies, urea cycle defects, and organic acid disorders.<sup>1</sup>

### **Phenylketonuria**

Phenylketonuria (PKU; phenylpyruvic oligophrenia) is an autosomal recessive disorder of amino acid metabolism characterized by mental retardation, diffuse hypopigmentation, seizures, dermatitis, and photosensitivity (Table 24-1).<sup>2-4</sup> The classic form is caused by a deficiency of phenylalanine hydroxylase or its cofactor, tetrahydrobiopterin. Its incidence has been estimated to be 1 in 10,000 births. Because of mandatory screening in the neonatal period, the disorder is detected early in developed countries, and the clinical features do not appear if early dietary control is achieved. Screening is achieved by a variety of different tests ranging from a semiquantitative bacterial inhibition assay (Guthrie test) to mass spectrometry assays. If missed in the neonatal period by screening, the diagnosis depends on the demonstration of elevated serum levels of phenylalanine (20 mg/dL or higher, 10 to 50 times that of normal), normal or elevated levels of plasma tyrosine (normal is approximately 1 mg/dL), or elevated urinary levels of phenylpyruvic acid. The latter can be detected by a characteristic green or blue color that results when a few drops of urine are added to a 10% solution of ferric chloride. The normal phenylalanine/tyrosine ratio is 1 : 1; in PKU it is greater than 3 : 1. The observed pigmentary dilution is thought to result from the inhibitory effect of phenylalanine on tyrosinase.

Most commonly seen in individuals of northern European ancestry, 90% of affected individuals are blond, blue-eyed, and fair-skinned, given the important role of phenylalanine and its derivative tyrosine in pigment formation. A peculiar musty odor, attributable to decomposition products (phenylacetic acid or phenylacetalddehyde) in the urine and sweat, and early intractable vomiting are characteristic. Infants appear to be normal at birth and if untreated, develop manifestations of delayed intellectual development sometime between 4 and 24 months of age. Seizures, attention-deficit/hyperactivity disorder, hypertonicity, hyperreflexia, a peculiar gait, speech delay, and self-destructive behavior have been described. Skeletal changes include microcephaly, short stature, pes planus, and syndactyly. The dermatitis appears in 10% to 50% of untreated patients and resembles atopic dermatitis; sclerodermoid changes of the proximal extremities, sparing the hands and feet, may present during the first 2 years of life.<sup>5,6</sup> These changes regress with appropriate treatment.

Management consists of a diet low in phenylalanine content, starting at as early an age as possible. This can be initiated by the use of formula from which most of the phenylalanine has been removed or a synthetic amino acid preparation devoid of phenylalanine. Restriction of phenylalanine leads to reversal of the seizures, dermatitis, and pigmentary dilution, but the effect on intellectual function depends on the age at which therapy is initiated. Little benefit for intellectual function can be achieved if therapy is initiated after 2.5 years of age, and optimal benefit is achieved if it is initiated by 2 months of age. It should

be remembered that phenylalanine is high in many foods and is a metabolite of the sweetener aspartame. Children and adolescents with PKU who achieve dietary control early in life are well adjusted and have an excellent quality of life.<sup>7</sup> Sapropterin dihydrochloride may reduce phenylalanine levels in patients who do not adequately adhere to the prescribed diet<sup>8</sup> and has been shown to significantly improve within 4 weeks the attention-deficit hyperactivity disorder and executive function of patients.<sup>9</sup>

Although there is some controversy about continuation of phenylalanine restriction in later childhood and adults, lack of dietary control during the 1st trimester of pregnancy of affected mothers (>600 µM or 10 mg/dL phenylalanine) has led to cardiac defects in 15% of offspring, particularly coarctation of the aorta and hypoplastic left heart.<sup>10</sup> Optimal levels during pregnancy of 120 to 360 µM/L are recommended. Some patients maintain low levels of phenylalanine as adults without dietary manipulation.

### **Disorders of Tyrosine Metabolism**

Clinical disorders of tyrosine metabolism include neonatal tyrosinemia, tyrosinemia I, and tyrosinemia II (Richner–Hanhart syndrome). Of these, only Richner–Hanhart syndrome exhibits cutaneous manifestations and is described in Chapter 5. These include palmoplantar keratoderma with painful erosions and photophobia with corneal erosions.

### **Cobalamin Deficiency**

In a single patient, a metabolic disorder of vitamin B<sub>12</sub> (cobalamin), called *cbfJ*, resulted from biallelic mutations in *ABCD4*, which encodes an ABC transporter involved in the intracellular processing of cobalamin.<sup>11</sup> Features were prominent, diffuse progressive skin hyperpigmentation, but hair lightening, with macrocytic anemia and cobalamin deficiency. Treatment with oral cobalamin (3 mg daily for this 12-year-old) led to metabolic correction and some reduction in the skin hyperpigmentation.

### **Homocystinuria**

Homocystinuria is an autosomal recessive disorder of methionine metabolism that results from an absence or deficiency of cystathione β-synthase, the pyridoxine-dependent hepatic enzyme that catalyzes the formation of cystathione from homocysteine and serine.<sup>12</sup> Based on biochemical testing, the disorder is most common in Ireland (1 in 65,000 births) and has a worldwide incidence of 1 in 344,000.<sup>13</sup> However, a study in Norway using genotyping showed an estimated birth prevalence of 1 in 6400.<sup>14</sup>

The disorder affects predominantly the eyes, central nervous system, blood vessels, and bones (see Table 24-1). Subluxation of the ocular lenses (ectopia lentis) occurs in 82% of patients by 15 years of age<sup>15</sup> and is usually present by 10 years of age. Developmental delay is evident during infancy and most untreated patients develop seizures and significant retardation. Bony abnormalities include a body habitus similar to that seen in Marfan syndrome (see Chapter 6), and generalized osteoporosis, which is seen radiographically in 50% of affected individuals by 15 years of age. Platyspondylia (congenital flattening of the vertebral bodies) and hollowing out of the vertebral bodies by pressure of the vertebral disks are also seen radiographically, and kyphoscoliosis, pectus carinatum, and genu valgum are common.

**Table 24-1** Errors of Protein Metabolism

<b>Disorder</b>	<b>Inheritance</b>	<b>Defect</b>	<b>Clinical Features</b>	<b>Diagnosis</b>	<b>Treatment</b>
Phenylketonuria	AR	Phenylalanine hydroxylase	90% are blond, blue-eyed, and fair-skinned; musty odor; sclerodermatosus plaques; eczematous dermatitis; photosensitivity; retardation; microcephaly; short stature	Guthrie test, ferric chloride test	Low phenylalanine diet; sapropterin dihydrochloride
Homocystinuria	AR	Cystathione synthetase	Ectopia lentis, myopia, arachnodactyly, seizures, mental retardation, cerebrovascular accidents, sparse light or blond easily friable hair, malar flush, wide-pored facies, livedoid rash, "Charlie Chaplin-like" gait and "rocker-bottom" feet	Cyanide nitroprusside test	Low methionine diet with pyridoxine (vitamin B <sub>6</sub> )
Alkaptonuria (ochronosis)	AR	Homogentisic acid oxidase	Dark urine; blue to brownish-black pigment on nose, malar region, sclerae, ears, axillae, genitalia; staining of clothing ("beads of ink" perspiration); arthritis; contractures; rupture of Achilles tendon; mitral and aortic valvulitis and/or calcific aortic stenosis	Ferric cyanide reduction	Nitisinone
Trimethylaminuria	AR	Flavin mono-oxygenase type 3	Odor of rotting fish	Trimethylamine in urine	Dietary avoidance of choline
Wilson disease (hepatolenticular degeneration)	AR	ATP7B; ceruloplasmin metabolism	Kayser–Fleischer rings, hyperpigmentation, azure lunulae, neurologic and liver dysfunction	Aminoaciduria, decreased ceruloplasmin	Chelating agents (BAL, versenate, or D-penicillamine; trientine has fewer side effects, but is weaker and more expensive); zinc to sequester copper
Lesch–Nyhan syndrome	X-LR	HPRT deficiency	Mental retardation, spastic cerebral palsy, choreoathetosis, self-mutilation	Increased uric acid, orange uric acid crystals in diaper	Allopurinol

AR, Autosomal recessive; BAL, British antilewisite or dimercaprol; HPRT, hypoxanthine-guanine phosphoribosyl transferase; X-LR, X-linked recessive.

Some patients have rocker-bottom feet and most have a shuffling toe-out "Charlie Chaplin-like" gait. Megaloblastic anemia has also been described.<sup>16</sup>

The vascular complications can be life-threatening; the chance of a vascular event during childhood is 25% to 30% and increases to 50% by 30 years of age. These include pulmonary embolism, myocardial infarction, transient ischemic attacks, cerebrovascular accidents, abdominal aortic aneurysm, and venous thromboses. Cutaneous features include sparse, light or blond, coarse hair that can darken and become softer with treatment; a malar flush; coarse, wide pores on facial skin; and a reticulated livedoid vasculopathy (*cutis reticulata*) on the face and extremities.

The presence of homocystinuria is suggested by the clinical features and can be confirmed by a urinary cyanide or sodium nitroprusside testing (turns a beet-red color) and by amino acid chromatography of the serum and urine. The presence of homocystine in the urine establishes the diagnosis. In the blood, homocysteine and methionine are elevated, whereas cysteine levels are decreased. Unfortunately, there are no neonatal manifestations of homocystinuria, and not all newborns with this disorder have increased blood methionine levels.

In at least 50% of patients, the disease is responsive to pyridoxine and can be controlled with the combination of pyridoxine (vitamin B<sub>6</sub>; 150 mg/day for an infant to 500 mg/day for an adolescent), folic acid, and vitamin B<sub>12</sub> (cobalamin). For those who do not respond to vitamins alone, a methionine-restricted, cystine-supplemented diet is required as well.<sup>17</sup> Betaine, a methyl donor that remethylates homocysteine to methionine, has been used as an adjunct to treatment, especially in patients who do not respond to vitamin therapy. As with PKU, early institution of therapy dramatically reduces the risk of complications.

## Trimethylaminuria

Trimethylaminuria (the fish odor syndrome) is a metabolic disorder in which accumulation of trimethylamine in the sweat and urine gives rise to an unpleasant "rotting fish" odor to the skin, sweat, and urine. There are no visible cutaneous changes, but one-third of patients with an unexplained intermittent malodor were shown to be positive for the disorder using a standard choline challenge.<sup>18</sup>

The disorder results from mutations in the flavin-containing monooxygenase type 3 (*FM03*) gene.<sup>19</sup> The liver is unable to convert the trimethylamine generated in the intestinal tract by bacterial degradation of choline- and lecithin-containing foods such as saltwater fish and seafood, egg yolk, liver, kidney, soy beans, meat, broccoli, cauliflower, cabbage, Brussels sprouts, wheat germ, milk (from wheated cows), and yeast to the nonodorous oxide metabolite.<sup>20</sup> The psychosocial effects of the condition can be devastating, including disruption of schooling, clinical depression, and attempted suicide. Treatment is best accomplished by avoidance and limitation of choline-containing foods,<sup>17,21</sup> although administration of metronidazole has also led to a clinical and biochemical response.<sup>22</sup>

## Wilson Disease (Hepatolenticular Degeneration)

Wilson disease is an autosomal recessive disorder that results from mutations in *ATP7B*, which encodes a copper-transporting adenosinetriphosphatase (ATPase).<sup>23</sup> Deficiency leads to an inability to

synthesize normal amounts of ceruloplasmin.<sup>24,25</sup> Patients show abnormal hepatic excretion of copper and toxic accumulations of copper in the liver, brain, and other organs. The clinical triad that results consists of progressive neurologic dysfunction, hepatic cirrhosis, and pathognomonic pigmentation of the corneal margins (Kayser–Fleischer ring) (see Table 24-1).

The disorder can be detected as early as 4 years of age but usually manifests during adolescence. The clinical signs at presentation can be quite varied. Although initial signs of the disorder are often neurologic (intention tremors, dysarthria, ataxia, incoordination, personality changes, psychiatric problems, and worsening school performance and handwriting), signs of liver insufficiency (jaundice, ascites, hepatomegaly, hematemesis, and cutaneous spider angiomas) are present at onset in 40% to 50% of affected individuals.<sup>26</sup>

Hyperpigmentation of the anterior lower legs, genital region, or even in a generalized distribution<sup>27</sup> may be the presenting sign and may be misinterpreted as Addison disease. In addition, patients may manifest a vague greenish discoloration on the skin of the face, neck, and genitalia. Increased melanin deposition, but not copper or iron, is seen in cutaneous biopsy specimens. Blue or azure lunulae of the nails have been reported in individuals with this disorder, but also have been observed in normal individuals as a complication of phenolphthalein or quinacrine ingestion, and in argyria. White discoloration of the nails has also been noted.<sup>28</sup> Xerosis has been described in 45.7% of affected children.<sup>28</sup>

Kayser–Fleischer rings are seen as dense golden brown or greenish brown pigmentation localized near the limbus of the cornea. Occurring in about 95% of patients with this disorder and best visualized by side lighting and slit-lamp examination, this discoloration is produced by the deposition of copper in the Descemet membrane at the periphery of the cornea. Kayser–Fleischer rings may also be seen in other copper overload states such as primary cirrhosis, intrahepatic cholestasis of childhood (Byler syndrome), and chronic active hepatitis.

Hepatolenticular degeneration is a progressive disease, and if untreated, is inevitably fatal. Death usually results from infection, hepatic disease, or liver failure. Treatment depends on removal of accumulated copper deposits in the body. Chelating agents such as D-penicillamine or trientine (triethylene tetramine dihydrochloride)<sup>29</sup> and elemental zinc (1 to 3 mg/kg per day divided three times daily) are helpful. Because discontinuation of therapy can result in rapid deterioration, treatment is life long. Penicillamine can produce allergic or toxic reactions, fever, cutaneous rashes, leukopenia, thrombocytopenia, elastosis perforans serpiginosa<sup>30</sup> (see Chapter 6; Fig. 6-13), other dermal disorders,<sup>31</sup> and immunobullous skin disease.<sup>32</sup> Because penicillamine inhibits pyridoxine-dependent enzymes, patients should also be given daily supplements of pyridoxine (12.5 to 50 mg/day). In an effort to minimize copper deposition, patients should be encouraged to limit their ingestion of copper-rich foods such as liver, nuts, chocolate, cocoa, mushrooms, brain, shellfish, dried foods, and broccoli. Liver transplantation can be life saving for patients with hepatic failure.<sup>33,34</sup>

## Lesch–Nyhan Syndrome

Lesch–Nyhan syndrome, an X-linked recessive disorder of purine metabolism, is characterized by mental retardation, choreoathetoid movements, and self-mutilation.<sup>35</sup> The condition is caused by a deficiency of hypoxanthine-guanine phosphoribosyl transferase (HPRT),<sup>36</sup> which leads to an overproduction of uric acid and the clinical features associated with this disorder (Table 24-1). Patients appear normal at birth and may develop normally for 6 to 8 months. The first recognizable sign of the disease is often orange uric acid crystals (resembling grains of sand) in the diaper or as hematuria during the early months of life.

The onset of cerebral manifestations may be subtle, with difficulty in sitting or standing without help, involuntary movements, dystonia, spasticity, and increased deep tendon reflexes. Although mental retardation may vary in degree, it usually is severe, and abnormal behavior remains a striking characteristic of the disease. The main clinical feature of this disorder is a loss of tissue about the mouth or fingers that occurs, not because of an inability to feel pain, but as a result of

the child's habit of compulsive self-destructive biting of these areas. In time, without adequate restraints, all of the lower lip accessible to the teeth may be chewed away. The face, fingers, and wrists may also be mutilated, and because young children commonly bite others, caution should be exercised when handling children with this disorder. Other destructive behaviors include head banging, extension of arms when being wheeled through doorways, tipping of wheelchairs, eye-poking, fingers in wheelchair spokes, and rubbing behaviors. Other manifestations of hyperuricemia, such as tophaceous deposits, nephropathy, and gouty arthritis, occur later. Reticulated pigment changes in a variant form have been described.<sup>37</sup>

Not to be confused with familial dysautonomia (Riley–Day syndrome) and congenital insensitivity to pain with anhidrosis (see Chapter 8), other conditions characterized by biting and self-mutilating behavior, Lesch–Nyhan syndrome can be confirmed by the clinical presentation and laboratory demonstration of increased levels of uric acid in the blood and urine.<sup>38</sup> Heterozygous females are asymptomatic. Management includes the use of allopurinol (in dosages of 10 mg/kg per day or, if >10 years of age, 600 to 800 mg/day divided twice daily) in an effort to control uric acid levels. Physical restraints (hand bandages and elbow splints) may be used to help control the self-mutilating behavior of patients.<sup>35</sup> Lip biting may require extraction of deciduous teeth, but permanent teeth should be spared, because lip biting usually diminishes with age.

## Dermatitis From Nutritional Abnormalities

### ACRODERMATITIS ENTEROPATHICA

Acrodermatitis enteropathica is an autosomal recessive disorder that generally appears in early infancy and is characterized by a triad of acral and periorificial skin lesions (vesiculobullous, pustular, and eczematous), diarrhea, and alopecia (Table 24-2).<sup>39-41</sup> The condition first becomes manifest days to weeks after birth if an infant is bottle-fed and shortly after weaning if breastfed. The disorder results from mutations in *SLC39A*, which encodes an intestinal zinc transporter ZIP4.<sup>42</sup>

The basic cutaneous lesion of acrodermatitis enteropathica is an erythematous, scaling, crusted, psoriasiform, eczematous, or vesiculobullous eruption (see Fig. 2-29). Lesions tend to be localized around the body orifices (mouth, nose, ears, eyes, and perineum; Fig. 24-1) and symmetrically located on the buttocks (Fig. 24-2) and extensor surface of major joints (elbows, knees, hands, and feet), the scalp, and the fingers and toes (hence the term *acrodermatitis*). On the face, the eroded and crusted peribuccal plaques may appear impetiginized, and

**Figure 24-1** Acrodermatitis enteropathica. Moist, sharply marginated psoriasiform plaques around the mouth, nose, and eyes of an infant.

**Table 24-2** Genetic and Acquired Nutritional Disorders

Disorder	Cause	Features	Evaluation	Therapy
Zinc deficiency	Acrodermatitis enteropathica Decreased zinc in breast milk Malabsorption Zinc-poor IV hyperalimentation	Periorificial dermatitis, stomatitis, glossitis, alopecia, irritability, diarrhea, failure to thrive, candidal infection, photophobia	Zinc levels, serum alkaline phosphatase; zinc levels in maternal breast milk	Zinc supplementation
Biotin deficiency	Holocarboxylase deficiency Biotinidase deficiency Malabsorption Ingestion of egg whites Biotin-poor IV hyperalimentation	Periorificial dermatitis, conjunctivitis, blepharitis, alopecia, candidal infections, metabolic acidosis, vomiting, lethargy, developmental delay, seizures, ataxia, optic atrophy, hearing loss	Urinary organic acids, plasma ammonia and lactate, serum biotin, specific enzyme activity	Biotin supplementation
Deficiency of vitamin B <sub>12</sub> or isoleucine from restrictive diets	Organic acidurias Citrullinemia Maple syrup urine disease Methylmalonic acidemia Propionic acidemia	Periorificial dermatitis, alopecia, candidal infections, metabolic acidosis, vomiting, failure to thrive, lethargy, developmental delay, hypotonia, pancytopenia	Urinary organic acids; plasma ammonia and glycine levels, plasma isoleucine levels	Dietary manipulation (results from effects of low-protein diet; some respond to vitamin B <sub>12</sub> supplementation)
Cystic fibrosis	Deficiency of CFTR	Periorificial and truncal dermatitis, occasionally alopecia, failure to thrive, diarrhea, irritability, edema	Sweat test, serum albumin, gene analysis, mutational analysis of <i>CFTR</i> gene	Pancreatic enzymes, vitamin and zinc supplementation
Essential fatty acid deficiency	Inadequate dietary intake	Generalized scaling with underlying erythema, intertriginous erosions, alopecia, decreased pigmentation of hair, failure to thrive, thrombocytopenia, and anemia	Plasma linoleic, linolenic, arachidonic and icosatrienoic acid levels; check for other deficiencies	Supplementation of essential fatty acids
Kwashiorkor	Inadequate protein; often infants taken off milk protein for allergies or dietary fads without adequate replacement	Superficial desquamation with erosion (flaky paint), edema with moon faces and pallor, hyperpigmentation and hypopigmentation, ecchymoses, sparse, dry lusterless hair with decreased pigmentation and "flag sign", cheilitis, dry mucosae, irritability and failure to thrive, irritability and apathy, secondary skin infections, diarrhea, hepatomegaly	Serum albumin, good dietary history	Slow supplementation with protein, correction of electrolyte imbalances

*CFTR*, Cystic fibrosis transmembrane conductance regulator; *IV*, intravenous.

**Figure 24-2** Acrodermatitis enteropathica. Sharply marginated psoriasis-like plaques of the perianal area and buttock.

secondary infection with *Candida albicans* is common. When the fingers and toes are involved, there is marked erythema and swelling of the paronychial tissues, often with subsequent nail deformity. If unrecognized or untreated, acrodermatitis enteropathica follows an intermittent but relentlessly progressive course, and as a consequence of general disability, infection, or both, commonly ends in death.

Typically, infants with acrodermatitis enteropathica are listless, anorexic, and apathetic. Many infants show frequent crying, irritability, and restlessness. Tissue wasting is present with an associated failure to thrive. During periods of exacerbation, frothy, bulky, foul-smelling diarrheal stools are present. Other findings include conjunctivitis, photophobia, stomatitis, perlèche, nail dystrophy, recurring candidal or bacterial infection, and alopecia of the scalp, eyelashes, and/or eyebrows.<sup>43</sup> Children suffering from this disorder exhibit a striking uniformity of appearance, mainly because of the alopecia and periorificial lesions.

In addition to the classic inherited disease, zinc deficiency with signs mimicking acrodermatitis enteropathica may also occur in babies who are breastfed by mothers with inadequate secretion of zinc in the maternal milk.<sup>44</sup> Maternal mutations in *SLC30A2* (*ZnT-2*), which

encodes a protein required for zinc secretion, have been found.<sup>45</sup> Zinc deficiency with clinical manifestations may also be seen in individuals receiving long-term parenteral nutrition with inadequate zinc supplementation, patients who have had intestinal bypass procedures, premature infants with low zinc storage (particularly those fed exclusively with human milk), in patients with Crohn disease,<sup>46</sup> in infants with human immunodeficiency virus (HIV) infection and diarrhea (causing inadequate absorption of zinc), in patients with cystic fibrosis with poor zinc absorption,<sup>47,48</sup> patients with celiac disease,<sup>49</sup> chronic alcoholics or patients with anorexia nervosa,<sup>50</sup> in individuals on zinc-deficient vegetarian diets, and in patients with low pancreatic enzyme levels resulting in poor intestinal absorption of zinc.<sup>41,51</sup> In babies with cystic fibrosis, the manifestations of zinc deficiency typically are noted at 3 to 5 months of age, before any evidence of pulmonary disease. The low serum albumin level and abnormal sweat test can confirm the diagnosis. An acrodermatitis enteropathica-like eruption can be seen with biotin deficiency and kwashiorkor.

The diagnosis of acrodermatitis enteropathica is based on the clinical features and low serum zinc levels (50 mcg/dL or lower). It should be noted, however, that zinc contamination of glass tubes and rubber stoppers often occurs; blood samples should be collected in acid-washed sterile plastic tubes with the use of acid-washed plastic syringes. Low serum alkaline phosphatase levels (even when the serum zinc level is normal), low serum lipid levels, and defective chemotaxis may be found. Skin biopsy is not diagnostic but may be useful in some patients. Zinc levels can also be measured in maternal milk.

Zinc sulfate supplementation is provided at 5 to 10 mg/kg per day, which usually provides approximately 1 to 2 mg/kg per day elemental zinc, although the dosage may differ to provide sufficient elemental zinc if other formulations are used. When given in divided doses two or three times a day, improvement in temperament and decrease in irritability can generally be noted within 1 or 2 days; the appetite improves in a few days, and diarrhea and skin lesions begin to respond within 2 or 3 days after the initiation of therapy. Hair growth begins after 2 to 3 weeks of therapy, and increase in the growth of the infant generally occurs within approximately 2 weeks. After the patient's condition appears to be stabilized, zinc levels should be monitored at periodic (6-month) intervals, followed by the adjustment of supplemental zinc to the lowest effective dosage schedule. Because foods may have an effect on the absorption of zinc, zinc supplementation should be administered 1 or 2 hours before meals. Zinc supplementation can cause gastrointestinal upset (nausea, vomiting, gastric hemorrhage); zinc gluconate tends to cause fewer gastrointestinal problems. Less zinc supplementation may be required for acquired or dietary zinc deficiency. In infants who have zinc deficiency as a result of defective maternal mammary zinc secretion, zinc supplementation can be discontinued after weaning.

## Disorders That Resemble Acrodermatitis Enteropathica

### BIOTIN DEFICIENCY/ORGANIC ACID DISORDERS

A dermatitis resembling acrodermatitis enteropathica, often in association with alopecia and changes in hair texture, has been described in patients with biotin deficiency and in certain organic acid disorders.<sup>52,53</sup> The cutaneous features resembling acrodermatitis enteropathica have been described in methylmalonic aciduria,<sup>54</sup> propionic acidemia,<sup>54</sup> glutaric aciduria type I,<sup>55</sup> maple syrup urine disease,<sup>56</sup> ornithine transcarbamylase deficiency,<sup>57</sup> and citrullinemia,<sup>58</sup> because of dietary restriction and deficiency of amino acids, especially isoleucine (Fig. 24-3).<sup>59,60</sup> Acrodermatitis enteropathica-like eruptions have also been reported in children with Hartnup disease (see Chapter 19).<sup>61,62</sup>

Biotin, part of the vitamin B complex, is required for the function of four carboxylase enzymes<sup>51</sup>:

1. 3-Methyl crotonyl-CoA carboxylase, essential for the catabolism of leucine
2. Propionyl CoA carboxylase, essential for the catabolism of isoleucine, threonine, valine, and methionine

**Figure 24-3** Methylmalonic aciduria. **(A)** This patient developed the typical erosive and desquamative eruption while on a restricted diet. **(B)** Isoleucine deficiency was discovered, and the eruption cleared within a week when isoleucine was added to the diet.

3. Pyruvic acid carboxylase, required for the gluconeogenesis and regulation of carbohydrate metabolism
4. Acetyl CoA carboxylase, an enzyme of long-chain fatty acid synthesis that contains biotin.

Biotin deficiency may be induced by a biotin-deficient diet; that is, a diet in which patients ingest large quantities of raw egg white (which contains the protein avidin that binds to biotin, thus preventing its absorption in the intestine) and/or prolonged parenteral nutrition to which biotin has not been added (see Table 24-2). The resulting deficiency is manifested by anorexia, lassitude, a pale tongue, grayish pallor of the skin, atrophy of the lingual papillae, hair loss, anemia, muscle pains, dryness of the skin, and a scaly dermatitis, all of which disappear after biotin administration or by cooking, boiling, or steaming of egg white (which causes avidin to lose its biotin-binding capacity). Decreased biotin levels have also been noted in patients who have been administered antiepileptics (phenytoin, carbamazepine), and may result in seborrheic dermatitis and alopecia.<sup>63,64</sup>

Several autosomal recessive disorders may manifest as an acrodermatitis enteropathica-like eruption, because they require biotin as a cofactor. Cheilitis and diffuse erythema with erosions and desquamation are features of methylmalonic aciduria before therapeutic amino acid restriction.<sup>65</sup> Inherited biotin deficiency also occurs in two forms of multiple carboxylase deficiency, one of which presents acutely during the neonatal period (neonatal form), and the other that

**Figure 24-4** Biotin deficiency. Scaly, periorificial dermatitis in a child with biotin-responsive carboxylase deficiency.<sup>67</sup>

**Figure 24-5** Kwashiorkor. Sharply marginated raised edge of reddish-brown scaling (flaky paint dermatosis) on the arm of an infant with severe hypoalbuminemia from dietary deficiency.

presents during early infancy (juvenile form).<sup>66</sup> These disorders occur in up to 1 : 40,000 births. Both forms usually show a sharply marginated, brightly erythematous scaling eruption of the periorificial areas, scalp, eyebrows, and eyelashes (Fig. 24-4).<sup>67</sup> Alopecia can manifest as hair thinning or total alopecia. Secondary candidiasis is not uncommon.<sup>68</sup> The neonatal form, which results from deficiency of holocarboxylase synthetase, appears in the first few weeks of life with metabolic acidosis, ketosis, and rarely, cutaneous manifestations. Patients show feeding and breathing difficulties, seizures, hypotonia, and lethargy; without early diagnosis and treatment, they usually die. The juvenile form of the disorder, which first manifests at 2 months of age or older, is the result of deficiency of biotinidase, which is required for recycling of endogenous biotin. Patients have low levels of biotin in the blood and urine and impaired biotin absorption and/or transport. In addition to the cutaneous features, the juvenile form is characterized by seizures (especially myoclonic spasms that respond partially to antiepileptics), hyperventilation or apnea, recurrent infections (including candidal skin infections), keratoconjunctivitis, ataxia, hypotonia, glossitis, and life-threatening acidosis and massive ketosis. More than 50% of patients whose disease is not recognized early have hearing loss that does not improve with biotin therapy.

The diagnosis of biotin deficiency can be established by a decreased concentration of plasma biotin. Deficiencies of biotinidase or holocarboxylase synthetase also show an increase in the urinary metabolites 3-hydroxyisovaleric acid, 3-methylcrotonyl-glycine, 3-hydroxypropionic acid, methylcitric acid, and lactic acid. Biotin deficiency can be treated by intravenous multivitamins containing 60 mcg of biotin or by the oral administration of 5 to 10 mg of biotin daily. Higher concentrations of biotin may be required for holocarboxylase synthetase deficiency.<sup>69</sup> Skin and neurologic signs tend to improve within a few weeks, although neurologic dysfunction can be permanent if treatment is delayed.

## KWASHIORKOR

Kwashiorkor is a severe form of protein deficiency in which edema, hypoalbuminemia, and dermatosis predominate.<sup>70</sup> Seen primarily in underdeveloped countries, several cases of kwashiorkor have been described in developed countries as well.<sup>71,72</sup> Cases in developed countries have been described because of nutritional ignorance, food allergen avoidance, food fads, and child abuse.<sup>73</sup> Particularly common is the substitution of rice "milk," which has only a minuscule content of protein and is not a milk substitute.<sup>74</sup> In children with chronic protein and caloric malnutrition, particularly from Africa, signs usually present during the second or third year of life with the onset of

**Figure 24-6** Kwashiorkor. Note the brown, peeling, "flaky paint" appearance of the posterior aspect of the upper thighs.

weaning from breastfeeding. In contrast, patients in developed countries most commonly show features during the first year of life with a rapid onset of edema. Kwashiorkor has also been described with malabsorption disorders, including infantile Crohn disease<sup>75</sup> and cystic fibrosis.<sup>76</sup>

The clinical picture consists of a blanching erythema with an overlying reddish-brown scale that shows a sharply marginated raised edge. This edge resembles paint that is lifting up and about to peel off, leading to the term *flaky paint dermatosis* (Figs. 24-5 and 24-6). In contrast to lesions of pellagra, the dermatosis seldom appears on areas exposed to sunlight and tends to spare the feet and dorsal areas of the hands. Photosensitivity, purpura, and excessive bruising may also be present. Other associated features include changes in mental behavior, anorexia, apathy, irritability, growth retardation, and fatty infiltration of the liver with hypoproteinemia. As a result of the hypoalbuminemia, affected children show edema of the face (moon facies) (Fig. 24-7), feet, and abdomen (potbelly appearance).

In mild cases the cutaneous eruption is associated with a superficial desquamation; in severe cases there are large areas of erosion that have been mistaken for Stevens-Johnson syndrome and/or toxic epidermal necrolysis.<sup>77</sup> As the disease progresses, the entire cutaneous surface develops a reddish or coffee-colored hue. Other associated

**Figure 24-7** Kwashiorkor. Moon facies and generalized dermatosis.

**Figure 24-8** Kwashiorkor. The hair often loses its coloration and may become gray or straw-colored.

features include circumoral pallor, loss of pigmentation (especially after minor trauma), and depigmentation of the hair. In darker haired children, the hair color can change to a reddish-brown hue or even gray or straw color (Fig. 24-8). The dyschromia with hypopigmentation has been attributed to deficiency of tyrosine, which is critical for melanin synthesis. When periods of malnutrition alternate with intervals of adequate dietary intake, alternating bands of light and dark color (the flag sign) are produced in the hair.

The condition may be difficult to distinguish from acrodermatitis enteropathica, and in fact, children may have concomitant zinc deficiency as well. The hypoalbuminemia and edema are helpful signs to distinguish kwashiorkor from acrodermatitis enteropathica and other disorders of nutritional deficiency. Children with marasmus have both protein and caloric deficiency. They appear emaciated (vs. the edematous appearance of children with kwashiorkor), have dry, scaling skin that may show follicular hyperkeratosis, and often have thin, sparse hair.

Children afflicted with kwashiorkor are extremely ill, and if they are not treated, the mortality rate can be 30% or more, primarily resulting from infection (impairment of immunity) and electrolyte imbalance

with diarrhea. In underdeveloped countries where the disorder is common, breastfeeding should be continued for as long as possible to prevent the protein malnutrition. Treatment of affected individuals with gradual administration of a high-protein diet, vitamin supplementation, and correction of dehydration and electrolyte imbalance leads to resolution of the clinical abnormalities.

### ESSENTIAL FATTY ACID DEFICIENCY

Essential fatty acid deficiency (EFA) can also be manifested by periorificial dermatitis and a generalized xerotic or eczematous dermatitis (see Table 24-2).<sup>78</sup> Failure to thrive, alopecia with lightly colored hair, and thrombocytopenia are other signs that may occur. The condition usually occurs in patients receiving parenteral nutrition without lipid supplementation, in association with severe fat malabsorption from gastrointestinal disorders, or with surgery of the gastrointestinal tract. EFA has also been described in patients with cystic fibrosis, anorexia nervosa, and acrodermatitis enteropathica. Decreased plasma levels of linoleic, linolenic, arachidonic, and icosatrienoic acid, as well as an icosatrienoic/arachidonic acid ratio of greater than 0.4 confirms the diagnosis. The treatment consists of oral or parenteral fat emulsions. If these cannot be administered, topical application of 2 to 3 mg/kg soybean or safflower oil may be sufficient to restore plasma levels of linoleic acids but may not maintain stores in the liver or other tissues.<sup>79</sup>

## The Hyperlipidemias

The hyperlipidemias (hyperlipoproteinemias) represent a group of metabolic diseases characterized by persistent elevation of plasma cholesterol levels, triglyceride levels, or both. Because plasma lipids circulate in the form of high molecular-weight complexes bound to protein, the term *hyperlipidemia* also indicates an elevation of lipoproteins, hence justification for the term *hyperlipoproteinemia* for this group of disorders. The dermatologic manifestation is the xanthoma, which may also be seen in metabolic disorders with normal levels of lipids (sitosterolemia and cerebrotendinous xanthomatosis) and disorders with deficiencies in high-density lipoproteins. Xanthomas can provide a clue that a child has a serious lipid abnormality and is at risk for other abnormalities, particularly vascular disease.

Lipid levels can be assayed in blood samples taken after a 12-hour fast. Plasma lipoproteins differ significantly in electrostatic charges, thus permitting their separation by electrophoretic mobility techniques into four major fractions: chylomicrons and  $\beta$ -, pre- $\beta$ -, and  $\alpha$ -lipoproteins. By means of ultracentrifugation it is also possible to separate the plasma lipoproteins into four major groups: chylomicrons and very low-density lipoproteins (VLDL; including the pre- $\beta$ -mobility lipoproteins), low-density lipoproteins (LDL, the  $\beta$ -mobility lipoprotein), and high-density lipoprotein (HDL; the  $\alpha$ -mobility lipoprotein), which correlate well with those separated by electrophoresis. Triglycerides are the major core lipids of chylomicrons and VLDLs. Cholesterol esters predominate in the core of LDLs. HDLs, remnants of VLDLs (also known as *intermediate-density lipoproteins* or *IDLs*), and chylomicrons. Apolipoproteins mediate the binding of lipoproteins to their receptors in target organs and activate enzymes that metabolize lipoproteins (Table 24-3). The levels of lipoproteins allow classification of the familial hyperlipidemias into five groups, designated as hyperlipoproteinemias I through V (World Health Organization [WHO]/Frederickson classification system), each with its own specific clinicopathologic, prognostic, and therapeutic features (Tables 24-4 and 24-5). Of these, types I and II most commonly present during childhood.

Lipoproteins can be synthesized from dietary intake or made endogenously in the liver. Dietary triglycerides are degraded by pancreatic lipase and bile acids to fatty acids and monoglycerides, but they are repackaged after intestinal absorption with cholesterol esters to form the central core of a chylomicron. This core is surrounded by free cholesterol, phospholipids, and apolipoproteins (see Table 24-3). In the circulation, this triglyceride core is hydrolyzed by lipoprotein lipase (LPL), leaving a chylomicron remnant of predominantly cholesterol ester and releasing fatty acids to peripheral tissues; LPL is activated by apolipoprotein C-II and requires hormones such as insulin. The

**Table 24-3** Apolipoproteins and Their Function

Apolipoprotein	Association with Lipoprotein	Function
ApoA1	HDL, chylomicrons	Main protein of HDL; activates lecithin/cholesterol acyltransferase
ApoA3	VLDL, HDL, chylomicrons	Interacts with LDL receptor and affects lipoprotein metabolism
ApoB48	Chylomicrons	Only in chylomicrons; ApoB100 without LDL receptor-binding domain
ApoB100	LDL, VLDL	Main protein of LDL; binds to LDL receptor
ApoC2	HDL, VLDL, chylomicrons	Activates lipoprotein lipase
ApoC3	VLDL	Inhibits lipoprotein lipase and hepatic lipase to delay catabolism of triglyceride-rich particles
ApoE2, E3, E4	HDL, VLDL, chylomicron remnants	Binds to LDL receptor

HDL, High-density lipoprotein; LDL, low-density lipoprotein, VLDL, very low-density lipoprotein.

endogenous pathway of lipid synthesis begins in the liver with the formation of VLDLs from hepatic triglycerides and circulating free fatty acids.

Xanthomas are lipid-containing papules, plaques, nodules, or tumors that may be found anywhere on the skin and mucous membranes.<sup>80,81</sup> Although the mechanism of their formation is not completely understood, it appears that serum lipids infiltrate the tissues where they are phagocytized by macrophages to form lipid-laden foam cells. They are then deposited, particularly in areas subjected to stress and pressure. Depending on their morphology, anatomic location, and mode of development, xanthomas can be categorized as *plane*, *eruptive* or *papuloeruptive*, *tendinous*, or *tuberous*. Recognition of these types of lesions, in addition to biochemical testing and physical examination, provides clues to possible metabolic abnormalities and diagnosis of specific metabolic diseases. Of note, juvenile xanthogranuloma (JXG; see Chapter 10), the most common xanthomatous skin lesion seen in children, does not have an association with systemic hyperlipidemias or other metabolic abnormalities.

### PLANE (PLANAR) XANTHOMAS

Plane (planar) xanthomas range from soft, yellow-orange, and brown-yellow macules to slightly elevated plaques (Fig. 24-9). They are generally seen on the face, sides of the neck, upper trunk, buttocks, elbows, and knees, but they may occur anywhere on the body and have a marked predilection for surgical or acne scars and the palmar creases.<sup>82</sup> Commonly seen plane xanthomas are xanthelasmas, which occur on or near the eyelids and are rarely seen in children or adolescents. Xanthelasmas in pediatric patients, in contrast with those in adults, are almost always associated with an underlying lipid abnormality. Intertriginous plane xanthomas, as in the antecubital fossae or the web spaces of the fingers, are usually associated with homozygous familial hypercholesterolemia.<sup>67</sup> Plane xanthomas of the palmar creases (xanthoma striatum palmarum) suggest the diagnosis of dysbetalipoproteinemia, especially when the child also has tuberous xanthomas. Plane xanthomas also occur in children with cholestasis from biliary atresia or primary biliary cirrhosis (Box 24-1), because of the accumulation of circulating unesterified cholesterol, and in patients with an underlying monoclonal gammopathy, such as in Castleman disease.

**Figure 24-9** Plane xanthomas in a girl with homozygous type II hyperlipoproteinemia.

**Figure 24-10** Xanthomas in hyperlipidemia. Eruptive xanthomas in a boy with nephritic syndrome. More commonly, eruptive xanthomas are grouped. Biopsy confirmed the diagnosis of xanthoma.

### ERUPTIVE (PAPULOERUPTIVE) XANTHOMAS

Eruptive (papuloeruptive) xanthomas appear in crops of multiple 1- to 4-mm, red to yellow-orange papules (Fig. 24-10) and are often surrounded by an erythematous base. Although they may involve the trunk and oral mucosa, they have a predilection for sites subjected to pressure or trauma, particularly the extensor surfaces of the arms, legs, and buttocks. Papuloeruptive xanthomas are almost always associated with hypertriglyceridemia (often to levels of >3000 mg/dL).<sup>83,84</sup> They can result from deficiency of LPL activity, as in patients with LPL deficiency (type I hyperlipoproteinemia), dysfunctional apolipoprotein C-II, (impaired insulin activity); or from overproduction by the liver of triglyceride-rich lipoproteins (as in endogenous familial hypertriglyceridemia [type IV hyperlipoproteinemia] or the elevations of both chylomicrons and VLDLs of type V hyperlipoproteinemia). Environmental factors and underlying diseases can also significantly elevate triglyceride levels. Among these are obesity, alcohol abuse, diabetes mellitus, nephrotic syndrome, and therapy with estrogens or

retinoids (see Box 24-1). The mechanism for retinoid-induced hypertriglyceridemia is by elevation of hepatic VLDL production.

### TENDINOUS XANTHOMAS

Tendinous xanthomas are skin-colored or yellowish, smooth, freely movable subcutaneous nodules and tumors.<sup>85</sup> They have a predilection for the extensor tendons of the elbows, knees, heels (Fig. 24-11), hands, and feet. These nontender, firm nodules measure 1 cm or more in diameter. They usually are seen or palpated on the Achilles tendon and the tendons on the dorsal aspect of the hands. They are most commonly seen in either heterozygotes or homozygotes with familial hypercholesterolemia (type II hyperlipidemia), but may also be seen in individuals with familial defective apolipoprotein B-100, cerebrotendinous xanthomatosis, and sitosterolemia.

### TUBEROUS (TUBEROERUPTIVE) XANTHOMAS

Tuberous (tuberoeruptive) xanthomas are large, firm, nodular, sessile or pedunculated, flesh-colored or yellowish to red xanthomas (Fig. 24-12). They occur on the palms and extensor surfaces subject to stress or trauma, particularly the elbows, knees, hands, and buttocks. Located in the dermis and subcutaneous layers, they can enlarge to 5 cm or more in diameter, and in contrast to tendon xanthomas, are not attached to underlying structures. These lesions are found in patients with hypercholesterolemia, particularly with familial hypercholesterolemia (type II hyperlipoproteinemia)<sup>86</sup>; hepatic cholestasis; or dysbetalipoproteinemia (type III hyperlipoproteinemia). Some 80% of individuals with dysbetalipoproteinemia have tuberous xanthomas. Tuberous xanthomas are also found in sitosterolemia.<sup>87</sup>

### OTHER XANTHOMAS

Other xanthomas, not part of the hyperlipoproteinemia spectrum, include *xanthoma disseminatum*, an uncommon clinical entity charac-

**Figure 24-11** Xanthomas in hyperlipidemia. Tendinous xanthomas in adolescent with type II hyperlipoproteinemia.

**Figure 24-12** Xanthomas in hyperlipidemia. Tuberous xanthomas in a boy with Alagille syndrome.

terized by red-yellow or mahogany-colored papular and nodular lesions with a predilection for the flexural creases (see Chapter 10), and *verruciform xanthomas*, a rare disorder manifested by solitary, 0.2- to 2-cm, verrucous papillary or flat to lichenoid, gray to reddish-pink, sessile, occasionally pedunculated lesions most commonly seen on the oral mucosa and lips and occasionally on the penis, scrotum, vulva, groin, digits, nostrils, and areas of epidermal hyperplasia such as in congenital hemidysplasia with ichthyosiform nevus and limb defects (CHILD syndrome; see Chapter 5), lymphedema,<sup>88</sup> or epidermolysis bullosa (see Chapter 13).

The five major types of hyperlipoproteinemas are summarized in Tables 24-4 and 24-5. Type I hyperlipoproteinemia (Bürger-Grütz disease, familial LPL deficiency, and familial hyperchylomicronemia syndrome) is usually discovered accidentally because of lactescence

(manifested by a creamy or chocolate appearance of whole blood)<sup>89</sup> in an infant or child with bouts of abdominal pain, which may be caused by lipid accumulations in the liver and spleen, splenic infarct, or pancreatitis. The risk of atherosclerosis is not increased in this form. About two-thirds of children with type I disease have eruptive xanthomas, primarily localized to the buttocks, shoulders, and extensor surfaces of the extremities.<sup>90</sup> Eruptive xanthomas occur when the serum triglyceride level exceeds approximately 2000 mg/dL. The disorder results from LPL or apolipoprotein C-II deficiency, or is a result of the presence of an LPL inhibitor. Increased levels of chylomicrons can also be found in familial hypertriglyceridemia or in patients with diabetes or hypothyroidism, or in those undergoing therapy with retinoids, glucocorticoids or estrogens.

Type II hyperlipoproteinemia (familial hypercholesterolemia) is the most common and best understood disorder of the lipoprotein disorders in pediatric patients.<sup>91,92</sup> Heterozygotes (1 in 500 individuals) have plasma concentrations of total cholesterol and LDL cholesterol that are increased by twofold to threefold.<sup>93</sup> Homozygotes have levels five to six times normal values from birth to early childhood. Children with homozygous disease may have planar xanthomas at birth or by the first decade (including intertriginous xanthomas), and tendon and tuberous xanthomas by 15 years of age.<sup>94–97</sup> Rarely, tuberous xanthomas are the first manifestation.<sup>98</sup> Arcus cornea (lipid deposits around the edge of the cornea), angina pectoris, and myocardial infarction often present during the second decade. Carotid plaque has been noted as early as 4 years of age,<sup>99</sup> and coronary artery bypass or aortic valve replacement may be required during childhood.<sup>100–102</sup> Ten percent to 15% of heterozygous individuals develop tendon xanthomas during the second decade of life, particularly involving the Achilles tendon and the extensor tendons of the hands, but only rarely show angina pectoris during late teenage years. Approximately 5% of families have a mutation in *ApoB100* (see Table 24-3), and lack tendon xanthomas.

Type III hyperlipoproteinemia (also known as *dysbetalipoproteinemia* or *broad β disease*) is usually first diagnosed in adulthood, but sometimes first manifests during childhood.<sup>103</sup> Most affected individuals are homozygotes for the *ApoE2* allele, which is seen in 1 in 100 individuals; clinical expression is thought to be triggered by environmental factors, such as hormonal abnormalities, obesity, or medications, because only 1 in 2000 individuals are known to have the disorder. Some 75% of patients have plane xanthomas of the palms and/or tuberous xanthomas. Type IV disease (endogenous familial hypertriglyceridemia) is usually not seen before the age of 20 years, although it may appear in children with renal disease or in patients with diabetes who have become ketotic. Type V disease (seen in familial hyperchylomicronemia with hyperprebetalipoproteinemia or occasionally *ApoC2* deficiency) occasionally presents in preadolescent children. Patients are usually obese and have acute abdominal pain. Eruptive xanthomas are most common. Diabetes, glycogen storage disease, ingestion of contraceptives, and alcohol abuse may trigger manifestations.

Treatment of hyperlipidemias is type-specific but may include dietary modification, statins (hydroxymethylglutaryl [HMG]-CoA reductase inhibitors, which also decrease LDL levels by increasing LDL receptor expression and thus hepatic reuptake of LDL), cholesterol lowering agents (fibrates, which act on *PPARα* to decrease free fatty acid production; cholestyramine, which is a bile acid sequestrant; and niacin), and/or ezetimibe (selectively inhibits the absorption of cholesterol).<sup>104–106</sup> Apheresis<sup>107</sup> and even liver transplantation<sup>108</sup> have been used for recalcitrant cases of homozygous hypercholesterolemia. Successful therapy can lead to dramatic shrinkage or clearance of xanthomas.

## ALAGILLE DISEASE

Hyperlipidemia with hypercholesterolemia and xanthomas is also a feature of Alagille syndrome (arteriohepatic dysplasia, Watson-Alagille syndrome),<sup>109,110</sup> an autosomal dominant disorder caused by mutations in *JAG1*, which encodes a ligand for the Notch receptor and is critical for determination of cell fates in early development.<sup>111</sup> The most characteristic feature is congenital intrahepatic biliary hypoplasia with cholestasis and pruritus. Most patients show an unusual facies with a prominent forehead, hypertelorism, eyes deeply

set in orbits, atrophy of the iris, a pointed, bulbous, or saddle-shaped nose, and a sharply pointed chin, even in relatives without other features.<sup>112</sup> Other features may include vertebral anomalies, cardiovascular disease (generally pulmonic stenosis or aneurysms), renal abnormalities, hypogonadism, and physical and mental retardation.<sup>113</sup> The xanthomas have been described in approximately 30% of affected children, may appear as early as the first year of life, and are associated with high cholesterol levels.<sup>110</sup> The xanthomas are most often tuberous (see Fig. 24-12) and are often widespread, especially over extensor surfaces and fold areas. They may form confluent plaques, especially on the elbows and knees. Secondary eczematization is not uncommon, given the intense pruritus from cholestasis. Early photosensitivity with sunburn and residual facial scars resembling erythropoietic protoporphyria have rarely been described.<sup>114,115</sup> Death before 5 years of age as a result of cardiac failure, renal failure, or both has occurred, but the prognosis of children with Alagille syndrome is generally better than that of patients with congenital biliary atresia, in whom survival to 2 years of age is unusual. Transplantation and other means to lower cholesterol result in clearance of the xanthomas.<sup>110</sup>

## SITOSTEROLEMIA

Individuals with this autosomal recessive disorder have 30- to 100-fold elevations in plasma levels of plant sterols<sup>116</sup> and often have increased cholesterol levels owing to mutations in two adjacent sterol adenosine triphosphate (ATP)-binding cassette transporters, ABCG5 (encoding sterolin-1) or ABCG8 (encoding sterolin-2).<sup>117</sup> These proteins are thought to prevent dietary noncholesterol sterols from being retained by the body and for cholesterol excretion into bile. Affected children show tuberous and tendinous xanthomas during the first decade of life, as well as arthritis, premature vascular disease with a high risk of fatal cardiac events during teenage years, and sometimes hemolysis and thrombocytopenia.<sup>87,118,119</sup> Treatment with ezetimibe, which inhibits cholesterol absorption, reduces the plasma concentrations of plant sterols in patients.<sup>120</sup> The combination of ezetimibe and cholestyramine has also been used successfully to clear the xanthomas.<sup>119,121,122</sup>

## CEREBROTENDINOUS XANTHOMATOSIS

Cerebrotendinous xanthomatosis is an autosomal recessive disorder caused by mutations in *CYP27A1* (sterol 27-hydroxylase).<sup>123,124</sup> As a result, large amounts of cholestanol, the 5-α-dihydro derivative of cholesterol, accumulate in virtually every tissue, leading to tendinous xanthomas, juvenile cataracts, diarrhea, and atherosclerosis.<sup>125</sup> Patients may develop cataracts, and neurologic signs include dementia, psychiatric disturbances, seizures, progressive paresthesias, mental retardation, and cerebellar problems.<sup>126</sup> Replacement therapy with chenodeoxycholic acid (750 mg/day) reduces cholestanol synthesis and concentrations. If started early enough (the neurologic manifestations can be seen during infancy), therapy improves neurologic function and clears the xanthomas.<sup>123</sup>

## DEFICIENCIES IN HIGH-DENSITY LIPOPROTEIN

Low levels of HDL cholesterol are most commonly seen in disorders of triglyceride metabolism, but may occur in the presence of otherwise normal levels of lipids and be associated with xanthomas. These disorders are Tangier disease, apolipoprotein A-I and C-III deficiency, and HDL deficiency with planar xanthomas (with decreased levels of *ApoC3*).

## TANGIER DISEASE

Tangier disease (familial HDL deficiency) is an autosomal recessive disorder characterized by hypcholesterolemia (50 to 125 mg/dL), an almost complete absence of plasma HDL, and massive deposition of cholesterol esters in tissues. The disorder results from homozygous mutations in the ATP-binding cassette (ABCA1) transport protein, which mediates the efflux of cellular cholesterol to the HDL particle in plasma for transport to the liver.<sup>127,128</sup> Triglyceride levels may be normal or slightly elevated (150 to 250 mg/dL), and plasma ApoA1

**Table 24-6** The Mucopolysaccharidoses

Disorder	Inheritance	Enzyme	Storage	Clinical Features
MPS I-H Hurler	AR	$\alpha$ -Iduronidase	DS, HS	Severe retardation, corneal clouding, hepatosplenomegaly, chondrodstrophic dwarfism, generalized mongolian spots; early death
MPS I-S Scheie	AR			Bone and joint involvement, retinopathy, corneal clouding, sometimes cardiac abnormalities; normal intelligence
MPS II Hunter	X-LR	Iduronate 2-sulfatase	DS, HS	Cutaneous papules and nodules on scapula, posterior axillae, thigh, buttocks, atypical retinitis pigmentosa; normal cornea
MPS III Sanfilippo	AR	Several subtypes*	HS	Aggressive behavior, severe neurologic involvement, mild somatic changes
MPS IV Morquio	AR	A: Galactose-6-sulfatase B: $\beta$ -galactosidase	KS	Striking dwarfism but not dysmorphic, corneal opacity, severe osteoporosis, extreme short stature; atlantoaxial dislocation leads to chronic cervical myelopathy and progressive paresis; restrictive respiratory disease usually leads to death; normal intelligence
MPS VI Maroteaux-Lamy	AR	Galactosamine-4-sulfatase	DS	Dwarfism, severe corneal, and bony lesions; cardiac involvement, respiratory obstruction; normal intelligence
MPS VII Sly	AR	$\beta$ -glucuronidase	HS, DS	Often born with hydrops fetalis, severe Hurler-like phenotype if survive
MPS IX	AR	Hyaluronidase	HA	One patient; short stature, periaricular soft-tissue masses

AR, Autosomal recessive; DS, dermatan sulfate; HA, hyaluronic acid; HS, heparan sulfate; KS, keratan sulfate; MPS, mucopolysaccharidosis; X-LR, X-linked recessive.

\*A: heparan N-sulfatase; B: N-acetylglucosaminidase; C: acetyl-CoA: glucosamine N-acetyltransferase; D: N-acetylglucosamine-6-sulfatase.

levels are less than 3% of normal. The disorder commonly manifests during childhood. The tonsils are enlarged and show distinctive alternating bands of red, orange, or yellowish white striations overlying the normal red mucosa.<sup>129</sup> Lipid deposits in the skin and other organs may be accompanied by a persistent maculopapular eruption over the trunk and abdomen, hepatosplenomegaly, lymph node enlargement, infiltration of the cornea in adults, and alterations in the intestinal and rectal mucosa. Several patients have had recurrent peripheral neuropathy.

## The Mucopolysaccharidoses

The mucopolysaccharidoses (MPSs) are inherited disorders of lysosomal hydrolases that catabolize glycosaminoglycan (GAG), a sulfated component of connective tissue.<sup>130</sup> As a result, dermatan sulfate, heparin sulfate, and/or keratan sulfate accumulate within cells and are excreted in excess amounts in the urine. First described by Hunter in 1917 (and labeled *gargoylism* in 1936), these disorders can now be divided into at least seven subtypes that share clinical features, mode of inheritance, and nature of the accumulated mucopolysaccharide. Affected individuals are normal in appearance at birth but, as with all lysosomal storage disorders, progressively show features with advancing age, beginning during infancy. Patients with any of the MPSs can show hypertrichosis, especially over the back and extremities, and thickened, roughened, taut inelastic skin, especially over the fingers because of the accumulation of GAG. Only individuals with Hunter syndrome (MPS type II, iduronate-2-sulfatase deficiency) have specific cutaneous features (papulonodules), although extensive, persistent Mongolian spots have rarely been described in children with Hunter<sup>131</sup> and Hurler<sup>132,133</sup> syndromes.

The disorders tend to present because of dysmorphic features or psychologic and learning difficulties, or as severe bony dysplasia. Considerable heterogeneity within subgroups has been described. Urinary screening tests for GAG should be followed by specific enzyme assays. Hunter syndrome (MPS II) is an X-linked recessive disorder; all others are autosomal recessive. Hurler syndrome, or MPS I, is presented as the prototype MPS; Hunter syndrome is also discussed in detail because it is the one form of MPS that shows a distinctive cutaneous feature: dermal papules and nodules. Table 24-6 summarizes the clinical and biochemical features of all of the MPSs.

## HURLER SYNDROME

Hurler syndrome (MPS I-H, MPS I in McKusick's original classification) is the most common of this group of disorders.<sup>134,135,136</sup> Seen in approximately 1 in 100,000 births, it appears in the first year of life. MPS I is a particularly grave disorder, with death occurring in almost all cases before the age of 10 years, usually from cardiac failure or respiratory infection.

Patients are usually diagnosed toward the end of the first year of life because of their coarse facial features (Fig. 24-13). Many have umbilical and inguinal hernias at presentation and recurrent respiratory infections before diagnosis. Other cardinal features of the Hurler syndrome include coarse hair; macrocephaly with frontal bulging; premature closure of the sutures with hyperostosis, commonly leading to a scaphocephalic skull; flattened nasal bridge with a saddle-shaped appearance; hypertelorism; protuberant tongue; short neck; protuberant abdomen because of hepatic and splenic enlargement; deformity of the chest; shortness of the spine; laxity of the abdominal wall with inguinal and umbilical hernias; broad hands with stubby fingers; a claw hand due to stiffening of the phalangeal joints (Fig. 24-14); limitation of extensibility of the joints; severe, progressive mental retardation; and marked retardation of growth. Although most affected infants are normal or above normal in length during the first year of life, the growth rate starts to decrease by 2 years of age. By age 3, almost all patients are below the third percentile for stature. Clouding of the cornea develops in all patients with Hurler syndrome and is best seen by side-lighting of the cornea; if severe visual loss occurs, however, it is usually related to retinal involvement. Deafness is almost always a feature, and cardiac involvement may range from severe early life-threatening cardiomyopathy to progressive valve disease. Approximately 40% of affected individuals have hydrocephalus, and a large head circumference, even without hydrocephalus, is often noted. Dysplasia of the odontoid process increases the risk of atlantoaxial subluxation and acute spinal cord damage. Upper respiratory tract obstruction and sleep apnea related to the large tongue and midfacial hypoplasia may require corrective surgery.<sup>137</sup> MPS I is the most common metabolic disorder associated with generalized mongolian spots during the first decade of life.<sup>132,138</sup>

There is a wide range of heterogeneity in severity and manifestations of Hurler syndrome. At the other end of the spectrum is Scheie syndrome (MPS I-S, formerly MPS V), which also results from mutations in the gene encoding ( $\alpha$ )-L-iduronidase. Patients with Scheie

**Figure 24-13** Hurler syndrome. Coarse facial features, macrocephaly, scaphocephalic skull, flattened nasal bridge, hypertelorism, short neck, chest deformity, and protuberant abdomen in a girl with Hurler syndrome (MPS I).

**Figure 24-14** Hurler syndrome. Broad hands with stubby fingers and limited joint extension. Note the hypertrichosis.

syndrome have normal intelligence and may have a normal lifespan, with predominantly bone and joint problems. Carpal tunnel syndrome occurs commonly, and corneal transplantation may be considered for corneal clouding (assuming lack of concurrent retinopathy as a cause of visual loss). Cardiac valvular insufficiency may develop and require surgery.

### HUNTER SYNDROME

Hunter syndrome (MPS II) is distinguished from Hurler syndrome by an X-linked recessive inheritance, longer survival, lack of corneal clouding, and the different biochemical defect with deficiency of the lysosomal enzyme iduronate-2-sulfatase.<sup>139,140</sup> As with Hurler syndrome, patients show coarse, straight scalp hair. Some patients develop papules and nodules on the upper back and sides of the upper arms, which are pathognomonic. Mental retardation progresses at a slower rate, and humping of the lumbar area (gibbus) does not occur.

**Figure 24-15** Hunter syndrome. Distinctive, firm, flesh-colored papules and nodules on the buttocks (a cutaneous marker of Hunter syndrome, or MPS II).

Progressive deafness is a feature of 50% of patients and can impair speech development. A mild form of MPS II (type IIB) may show only mild skeletal abnormalities, and skin lesions may be the presenting feature.<sup>141</sup>

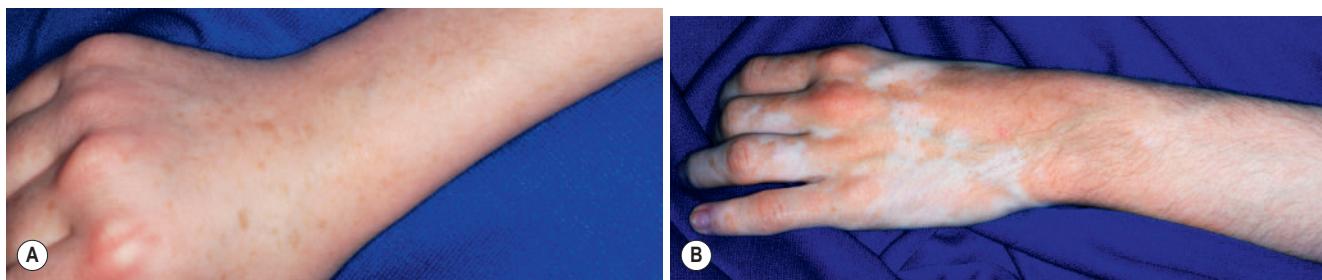

The distinctive cutaneous changes are found in the minority of affected boys. They consist of firm flesh-colored to ivory-white papules and nodules that often coalesce to form ridges or a reticular pattern in symmetric areas between the angles of the scapulae and posterior axillary lines, the pectoral ridges, the nape of the neck, buttocks (Fig. 24-15), and/or the lateral aspects of the upper arms and thighs. They appear before age 10 years and can spontaneously disappear.

### THERAPY FOR MUCOPOLYSACCHARIDOSES

Palliative therapy for the hydrocephalus and joint stiffness and pain are appropriate, but surgical correction of the skeletal or cardiac abnormalities is not, given the limited life expectancy. Hematopoietic stem cell transplantation is standard treatment and can stabilize cognitive improvement when performed before 9 to 24 months of age.<sup>142,143</sup> Other effects are unpredictable but can include softening of coarse hair and facial features, and improvement in corneal clouding, hepatomegaly, upper airway obstruction, and cardiomyopathy (but not the constellation of bony defects [dysostosis multiplex] or cervical instability). Enzyme replacement therapy with  $\alpha$ -L-iduronidase (iduronidase) can also reduce GAGs and improve respiratory and cardiac function, as well as the hepatomegaly and joint mobility in patients with MPS I.<sup>134,144,145</sup> Enzyme replacement therapy (ERT) with idurafuse, recombinant lysosomal iduronate-2-sulfatase, has been noted to improve the skin texture, as well as the hepatosplenomegaly, bronchitis, and physical activity of Hunter syndrome.<sup>146,147</sup> However, ERT cannot pass the blood-brain barrier to improve neurocognitive function.<sup>144,148–150</sup> The combination of ERT and transplantation may benefit patients with more severe manifestations.<sup>134</sup>

### Other Storage Disorders

Several other storage disorders may show cutaneous features, particularly angiokeratomas and pigmentary changes. Among these are the mucolipidoses (sialidosis II or mucolipidosis I and mucolipidosis II), the sphingolipidoses (Fabry disease, Farber lipogranulomatosis, Gaucher disease, GM1 gangliosidosis, salt and pepper syndrome/GM3 synthase deficiency (Fig. 24-16),<sup>151–153</sup> and multiple sulfatase deficiency) and other storage disorders of carbohydrate metabolism (aspartylglycosaminuria, fucosidosis, galactosialidosis,  $\alpha$ -mannosidosis, Salla disease, and Schindler disease).<sup>154–160</sup> The features of these storage disorders, their cutaneous manifestations, and their underlying causes are summarized in Table 24-7. (Fabry disease and fucosidosis are discussed in

**Figure 24-16** Dyspigmentation with GM3 synthase deficiency. **(A)** Hyperpigmented macules, especially acrally, begin late in childhood and give GM3 synthase deficiency the name *salt and pepper syndrome*. **(B)** Vitiliginous lesions tend to appear in late adolescence and can become extensive.

**Table 24-7** Other Storage Disorders with Cutaneous Manifestations during Childhood

Disorder	Inheritance	Enzyme	Cutaneous Features	Clinical Features
Aspartylglycosaminuria	AR	Aspartylglycosaminidase	Angiokeratomas	Speech delay, otitis media, behavioral change resembling MPS III
Fabry	X-LR	$\alpha$ -Galactosidase	Angiokeratomas, hypohidrosis	Acroparesthesias, progressive renal disease (see Chapter 12)
Farber lipogranulomatosis	AR	Ceramidase	Painful subcutaneous nodules, especially over joints	Hydrops fetalis, chronic pulmonary disease with granulomatous infiltration of the lungs, hepatosplenomegaly, neurodegeneration; granulomatous infiltration of the mucosae with hoarse cry, recurrent vomiting, dysphagia
Fucosidosis	AR	$\alpha$ -Fucosidase	Angiokeratomas, sweating abnormalities, purple nail bands	Neurodegeneration, dysostosis, respiratory infections, hepatosplenomegaly, growth retardation, resembles MPS (see Chapter 12)
Galactosialidosis	AR	Defective protective protein/cathepsin A; proteolysis of both $\beta$ -galactosidase and neuraminidase	Angiokeratomas	Hydrops fetalis, skeletal abnormalities, myoclonus, cherry-red macular spots, ataxia, mild mental retardation
Gaucher, type II	AR	$\beta$ -Glucocerebrosidase	Collodion baby	Severe neurologic involvement, marked hepatosplenomegaly (see Chapter 5)
GM1 gangliosidosis	AR	$\beta$ -Galactosidase	Angiokeratomas, extensive mongolian spots	Dysostosis multiplex, hepatosplenomegaly, early neurologic degeneration, corneal clouding
Mannosidosis	AR	$\alpha$ -Mannosidase	Angiokeratomas	Middle ear and respiratory infections; may have mild learning difficulties to severe MPS I-like phenotype and seizures
Multiple sulfatase deficiency	AR	Posttranslational processing of multiple sulfatases	Ichthyosis (recessive X-linked)	Hepatosplenomegaly, dysostosis, progressive neurologic deterioration (see Chapter 5)
Mucolipidosis I (sialidosis type II)	AR	Neuraminidase I	Angiokeratomas	MPS I phenotype; dysostoses multiplex, progressive retardation
Mucolipidosis II (I-cell disease)	AR	N-acetylglucosaminyl-1-phosphotransferase	Malar telangiectasia, puffy eyelids, prominent periorbital veins; thick, rigid skin	MPS I phenotype; gingival hypertrophy, dysostosis multiplex, stiff joints, respiratory tract infections, cardiac failure
Salla disease (infantile sialic acid storage)	AR	Sialic acid transporter	Hypopigmentation	Hydrops fetalis, recurrent infections, failure to thrive, dysostosis multiplex, cardiac disease, coarse facies, learning disabilities
Salt and pepper syndrome	AR	GM3 synthase	Small acral pigmented macules; vitiliginous lesions	Severe intellectual disability, seizures, choreoathetosis, spasticity, scoliosis, dysmorphic facies
Schindler	AR	$\alpha$ -N-acetylgalactosaminidase	Angiokeratomas	Variable; may have myoclonus, spasticity, progressive dementia

AR, autosomal recessive; X-LR, X-linked recessive; MPS, mucopolysaccharidosis.

more detail in Chapter 12.) The neonatal form of Gaucher disease, type II, may present as a collodion baby, whereas multiple sulfatase deficiency (mucosulfatidosis) is phenotypically identical to recessive X-linked ichthyosis (see Chapter 5). All of these conditions are inherited in an autosomal recessive fashion, except for Fabry disease, which is X-linked recessive.

 The complete list of 160 references for this chapter is available online at <http://expertconsult.inkling.com>.

## Primary Immunodeficiency Disorders

Recurrent infections, including those involving the skin, raise the possibility that a child has an immune deficiency. The most common cause of immunodeficiency in children is acquired immunodeficiency resulting from human immunodeficiency virus (HIV) infection (see Chapter 15). Less commonly, children with evidence of an immunodeficiency have an inherited disorder.<sup>1–6</sup> Genetic immunodeficiency disorders may show a variety of cutaneous abnormalities, some of which are unique and characteristic of the disorder, and others, such as dermatitis, that are shared by other immunodeficiencies and other disorders.

Some of these immunodeficiencies are discussed elsewhere because of their manifestations. Wiskott–Aldrich syndrome and hyperimmunoglobulinemia E (Hyper-IgE) syndrome are discussed in Chapter 3, owing to the common presence of dermatitis. Chediak–Higashi and Griscelli syndromes, the silvery hair syndromes associated with immunodeficiency, are reviewed in Chapter 11 with the disorders of pigmentation. The telangiectasias that allow ataxia-telangiectasia to be distinguished from other forms of ataxia are described in Chapter 12. Complement deficiencies are mentioned in Chapter 14 because individuals with a deficiency of a late complement component have an increased risk of nosocomial infection, in Chapter 20 because hereditary angioedema (HAE) can be confused with angioedema, and in Chapter 22 because deficiency of the early components of complement may lead to a lupus-like disorder. Given its characteristic recurrent and recalcitrant candidal infections, chronic mucocutaneous candidiasis is reviewed in Chapter 17.

Signs that should raise the suspicion of acquired or hereditary immunodeficiency are listed in **Box 25-1**. Screening laboratory tests for a patient with recurrent cutaneous infections suspected of having an immunodeficiency are suggested in **Table 25-1**.

### IMMUNOGLOBULIN DEFICIENCIES

Children with deficiencies of immunoglobulins (Igs) primarily manifest with bacterial infections beginning at 3 to 6 months of age, at a time when transplacentally derived maternal Igs wane.<sup>7,8</sup> In general, the treatment of hypogammaglobulinemia is antibody replacement by intravenous infusions of immune serum globulin and vigorous antibiotic therapy.<sup>9</sup>

The most common Ig deficiency is selective IgA deficiency, found in 1 in 500 individuals, of which 10% to 15% show clinical manifestations. About 5% of patients with IgA deficiency have mutations in TACI, which encodes a tumor necrosis factor (TNF) receptor family member. B cells in individuals with TACI mutations have impaired isotype switching and do not produce IgA and often IgG in response to TACI ligand. The most common features are sinopulmonary bacterial infections and *Giardia* gastroenteritis. Approximately one-third of patients with clinical manifestations develop immune-mediated disorders, some of which involve the skin. These include an atopic-like dermatitis, lupus erythematosus with selective IgA deficiency (recently linked to mutations in *IFIH1*),<sup>10</sup> vitiligo, recurrent candidal infections, lipodystrophy, and idiopathic thrombocytopenic purpura. Two percent of individuals with celiac disease have full or partial selective IgA deficiency; this subgroup of patients has more concomitant autoimmune disorders and may have persistent elevation of IgG serologies, even with disease improvement.<sup>11</sup> The risk of allergy is also increased with selective IgA deficiency, including asthma, cow's milk allergy, and allergic rhinoconjunctivitis.

In addition to their decreased levels of IgA, 30% to 50% of affected individuals have serum anti-IgA IgG antibodies, leading to a risk of fatal anaphylactic reactions upon administration of blood products with IgA-bearing lymphocytes; if intravenous immunoglobulin (IVIG) is necessary, only IVIG with low IgA content should be administered.<sup>12</sup>

IgA deficiency may transition into (and is seen with increased incidence in families with) combined variable immunodeficiency (CVID),<sup>13</sup> a heterogeneous group of disorders with decreased Ig levels (IgG, IgA, and sometimes IgM) and variable functional T-cell abnormalities.<sup>14–17</sup> Patients with CVID most commonly show pyoderma, extensive warts, widespread dermatophyte infections, and dermatitis. They are predisposed to pyogenic infections of the upper and lower respiratory tract, as well as gastrointestinal infections, particularly those caused by *Giardia*. Noncaseating granulomas of the lungs, liver, spleen, and/or skin have been described and are not associated with microorganisms. Individuals with CVID also have an increased risk of autoimmune diseases, including vitiligo (Fig. 25-1), alopecia areata, and vasculitis. The incidence of lymphoma is increased 400-fold, and that of cancer overall 8- to 13-fold. CVID is primarily a disorder of adults, with the mean age of onset 23 to 33 years<sup>18</sup>; however, 25% of cases are diagnosed before 21 years of age, with a peak incidence in children aged 5 to 10 years and a minimum age of 4 years used to exclude patients with other primary immunodeficiency disorders.<sup>19</sup> Death in patients with CVID usually results from lymphoma, hepatitis, respiratory insufficiency, or gastrointestinal disease.

Most cases of panhypogammaglobulinemia in children represent X-linked hypogammaglobulinemia (also called *X-linked agammaglobulinemia*), a disorder caused by mutations in *BTK*, which encodes a tyrosine kinase that regulates the conversion of pre-B cells to B cells able to differentiate and produce Igs.<sup>20</sup> Less commonly, pediatric patients may have a transient form during infancy with early failure to thrive, protracted diarrhea, sinopulmonary infections, pyoderma, and cutaneous abscesses, but with reversal when Ig is produced at 18 to 30 months of age. Approximately 10% have an autosomal recessive form of panhypogammaglobulinemia.

Boys with X-linked hypogammaglobulinemia develop recurrent bacterial infections in the first year of life and have an increased susceptibility to hepatitis B and enteroviral infections. Furuncles and cellulitis are the most common infections. An atopic-like dermatitis is common, and noninfectious cutaneous granulomas have been described. There is an increased predisposition to the development of pyoderma gangrenosum, which has been recently linked to Warthin–Starry-positive *Helicobacter bilis* infection; although difficult to grow, the *Helicobacter* organisms are detectable by polymerase chain reaction (PCR) and electrospray ionization time-of-flight mass spectrometry.<sup>21</sup> A small percentage of patients develop a dermatomyositis-like disorder with slowly progressive neurologic involvement, usually related to echoviral meningoencephalitis. Up to 6% of patients develop lymphomas.

Patients with X-linked hypogammaglobulinemia with hyper-IgM (HIM) tend to have deficiencies of IgA, IgE, and IgG with neutropenia, but increased levels of IgM and isohemagglutinins.<sup>22</sup> Rather than a primary B-cell defect, affected individuals have a primary T-cell defect. Cross-linking of CD40 on B cells induces switching of Ig classes from IgM to IgG, IgA, or IgE. Mutations in X-linked HIM lead to a dysfunction of the ligand for CD40 (CD40L). B cells from patients with HIM express functional CD40, but the T cells express the defective CD40 ligand and cannot bind CD40.<sup>23,24</sup> Three other forms of HIM are autosomal recessive; these result from deficiency of CD40

### Box 25-1 Signs of Immunodeficiency

#### History of infections

- Increased frequency, severity, and duration
- Unusual manifestations
- Unusual infecting agents
- Chronic infections, incomplete clearing
- Poor response to appropriate agents
- Severe viral infections
- Recurrent osteomyelitis

#### Failure to thrive

Diarrhea, vomiting, malabsorption

#### Clues to specific types of immunodeficiency

- Hematologic abnormalities (e.g., Wiskott–Aldrich syndrome)
- Arthritis (e.g., Wiskott–Aldrich syndrome or early complement deficiency)
- Paucity of lymph nodes (e.g., SCID) or lymphadenopathy (e.g., CGD)
- Hepatosplenomegaly (e.g., CGD, Omenn syndrome, or Wiskott–Aldrich syndrome)
- Poor wound healing (e.g., leukocyte adhesion deficiency)
- Silvery hair (e.g., Chediak–Higashi or Griscelli syndromes)

*CGD*, Chronic granulomatous disease; *SCID*, severe combined immunodeficiency.

**Table 25-1** Screening Laboratory Testing for the Child with Recurrent Infections

Test	Primary Immunodeficiency
Complete blood count with differential, platelet count and examination of smear	Giant leukocyte granules (Chédiak–Higashi syndrome) Thrombocytopenia (Wiskott–Aldrich syndrome) Leukocytosis (chronic granulomatous disease and leukocyte adhesion deficiency)
Quantitative immunoglobulins	Selective IgA deficiency Transient hypogammaglobulinemia X-linked hypogammaglobulinemia Hypogammaglobulinemia with hyper-IgM Common variable immunodeficiency Wiskott–Aldrich syndrome Hyperimmunoglobulin E
Flow cytometry (T and B cells)	Severe combined immunodeficiency Leukocyte adhesion defect (CD18 deficiency) Chronic granulomatous disease

*IgA*, Immunoglobulin A; *IgM*, immunoglobulin M.

**Figure 25-1** Common variable immunodeficiency (CVID). Individuals with CVID or IgA deficiency have an increased incidence of autoimmune disorders, as evidenced in this adolescent with CVID and vitiligo.

**Figure 25-2** Hyperimmunoglobulinemia syndrome. Extensive warts are a commonly observed cutaneous manifestation of boys with this form of immunodeficiency.

itself,<sup>25</sup> activation-induced cytidine deaminase (AICD), or uracil-N-glycosylase (UNG),<sup>26</sup> the latter two being signaling components downstream of the CD40 receptor that are critical to B-cell differentiation and class switching. A rare form of X-linked immunodeficiency, sometimes associated with HIM, is associated with hypohidrotic ectodermal dysplasia (see Chapter 7), and has been linked to mutations in the *NEMO* gene, the same gene that is mutated in incontinentia pigmenti (see Chapter 11). Patients with HIM often seek treatment during infancy with bacterial and sometimes fungal or opportunistic sinopulmonary infections (most common feature), pyoderma, and gastrointestinal infections (especially with opportunistic infections such as *Cryptosporidium*), hepatosplenomegaly, cervical adenitis, autoimmune disorders (especially thyroiditis, and hemolytic anemia),<sup>27</sup> and an increased risk of lymphoma.<sup>25,28</sup> Numerous, widespread warts (Fig. 25-2), oral and perianal area ulcerations, and sclerosing cholangitis are additional features.<sup>29</sup> Extensive warts are also a feature of warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome, which results from mutations in the chemokine receptor CXCR4<sup>30</sup>; EVER1 and EVER2 deficiency; DOC8 deficiency (see Hyperimmunoglobulinemia E section in Chapter 3); Netherton syndrome (Chapter 5); GATA2 deficiency<sup>31</sup>; and STK4 deficiency.<sup>32,33</sup>

X-linked lymphoproliferative disease (XLP) is characterized by an abnormal response to Epstein–Barr virus infection because of mutations in either *SH2D1A*, which encodes signaling lymphocytic activation molecule (SLAM)-associated protein (SAP) (XLP-1), or *XIAP* (XLP-2), critical proteins for cytotoxic T-cell function.<sup>34–36</sup> Affected boys are healthy until they first develop infectious mononucleosis during childhood or adolescence. Fever, pharyngitis, maculopapular rash, lymphadenopathy, hepatosplenomegaly, purpura, jaundice, and hemorrhagic colitis, and often hypogammaglobulinemia are typical features. The virus stimulates a rapidly progressive B-cell lymphoma, often with superimposed bacterial sepsis, which leads to death in 70% of affected boys, especially with hemophagocytic lymphohistiocytosis and without transplantation.<sup>37</sup>

## CHRONIC GRANULOMATOUS DISEASE

Chronic granulomatous disease (CGD) is a group of disorders characterized by severe recurrent infections resulting from an inability of phagocytic leukocytes to generate oxidative metabolites and activate neutrophil granule elastase and cathepsin G, thus blocking the killing of intracellular bacteria and fungi.<sup>38,39</sup> In all forms of CGD the function of the nicotinamide dinucleotide phosphate (NADPH) oxidase complex is reduced. The disorder usually presents with recurrent pneumonias, hepatosplenomegaly, and lymphadenopathy. Patients develop granulomas, primarily of the lungs, liver, skin, and

genitourinary and gastrointestinal tracts, as an abnormal immune response.<sup>40–43</sup>

The most common form of CGD is X-linked recessive and results from mutations in the membrane-bound component of NADPH oxidase gp91<sup>phox</sup> (*phox* is short for *phagocyte oxidase*), and 90% of affected individuals are male. Autosomal recessive forms (30% of patients) are due to mutations in other components of phagocyte NADPH oxidase, p22<sup>phox</sup> and the cytoplasmic components p47<sup>phox</sup> and p67<sup>phox</sup>.

The skin, lungs, and perianal area are most often the sites of infection. Early lesions are usually cutaneous staphylococcal pyoderma and abscesses of the face and perianal area, not uncommonly associated with purulent dermatitis and regional lymphadenopathy. Seborrheic dermatitis, Sweet syndrome, scalp folliculitis, perioral and intraoral ulcerations that resemble aphthous stomatitis. Female carriers of gp91<sup>phox</sup> mutations may show aphthous stomatitis and lupus-like eruptions,<sup>44,45</sup> but rarely these have been described in affected patients with recessive form or administered Voriconazole.

The organisms associated with CGD are usually *Staphylococcus aureus* and opportunistic Gram-negative bacteria, including *Serratia*,<sup>46</sup> *Klebsiella*, *Pseudomonas*, and *Escherichia coli*. These organisms all require oxidative metabolism for intracellular killing. Other organisms that may cause infection in patients with CGD with increased incidence are *Aspergillus*, *Candida*, *Cryptococcus*, *Fusarium*, and *Nocardia*.<sup>47</sup> Bronchopneumonia and suppurative lymphadenitis are the most prevalent noncutaneous infections, and respond to appropriate antibacterial therapy and, in some cases, surgical drainage. The extracutaneous organs most commonly involved in CGD are the lymph nodes, lungs, liver, spleen, and gastrointestinal tract (Box 25-2). CGD has been misdiagnosed as Crohn disease because of the overlap in features (failure to thrive, diarrhea, colitis, bowel obstruction, perianal ulcerations and fistulas, anemia, and hypoalbuminemia),<sup>48</sup> and as hyper-IgE syndrome because of associated elevation of IgE levels in a case with selective IgA deficiency.<sup>49</sup>

Patients with CGD commonly show leukocytosis, anemia, elevated erythrocyte sedimentation rate (ESR), and hypergammaglobulinemia. Skin tests for delayed hypersensitivity, phagocytosis, and chemotaxis are normal. Carrier and affected patients are often detected by quantitative dihydrorhodamine flow cytometry,<sup>50</sup> and the nitroblue tetrazolium (NBT) screening assay is now rarely performed (in which the oxidized yellow form of NBT is reduced to a blue formazan precipitate). Ferricytochrome C reduction assay is a quantitative assay that shows absence of the respiratory burst. Immunoblots can detect the selective loss of membrane phagocyte oxidase components. However, mutations that lead to deficiency of gp91<sup>phox</sup> or p22<sup>phox</sup> cannot be differentiated by immunoblotting, because both are components of cytochrome b<sub>558</sub>, and the entire cytochrome is absent if one is deficient; gene sequencing is required to confirm the mutation in gp91<sup>phox</sup> or p22<sup>phox</sup>.

#### Box 25-2 Signs and Symptoms in Patients with Chronic Granulomatous Disease

Seen in more than 50% of patients

- Lymphadenopathy, lymphadenitis
- Hepatosplenomegaly
- Bronchopneumonia
- Failure to thrive

Seen in 25% of patients or less

- Persistent diarrhea
- Pleuritis or empyema
- Septicemia or meningitis
- Hepatic or perihepatic abscess
- Osteomyelitis

Seen in fewer than 25% of patients

- Perianal abscess
- Periorificial dermatitis
- Aphthous stomatitis
- Conjunctivitis
- Lung abscess
- Peritonitis
- Obstructive granulomas

Antibiotic treatment of infection with surgical intervention as needed, and prophylactic trimethoprim-sulfamethoxazole and itraconazole therapy<sup>51</sup> have been used in most affected individuals.<sup>52</sup> Short courses of systemic corticosteroids have been helpful for patients with obstructive visceral granulomas. Stem-cell therapy has led to reversal of the immunodeficiency in severe cases with fewer infections and better linear growth, but management of CGD without transplantation similarly prolongs survival during childhood.<sup>53–55</sup>

#### LEUKOCYTE ADHESION DEFICIENCIES

The leukocyte adhesion deficiencies (LADs) are a group of three autosomal recessive disorders that affect the ability of neutrophils, cytolytic T lymphocytes, and monocytes to be mobilized into extravascular sites of inflammation.<sup>56</sup> In most affected individuals (LAD1), mutations in CD18 occur, leading to deficiency or dysfunction of the β<sub>2</sub> subunit of integrins. The principal ligand for these integrins is ICAM1, which participates actively in neutrophil and monocyte chemotaxis and phagocytosis. More than 75% of patients with severe disease die by 5 years of age; more than half of the patients with moderate deficiency die between the ages of 10 and 30 years.

Patients with LAD have frequent skin infections (especially facial cellulitis and perianal infection), mucositis, and otitis, with a 5- to 20-fold increase in peripheral blood leukocytes. Poor wound healing is characteristic and leads to paper-thin or dysplastic cutaneous scars. Minor skin wounds may become large ulcerations that resemble pyoderma gangrenosum (Fig. 25-3), especially if secondarily infected. Periodontitis is a typical feature, and if severe, may lead to loss of teeth. Bacterial and fungal infections may be life-threatening. Delayed separation of the umbilical cord is a common historic clue to the diagnosis. Psoriasis has been described in affected individuals with mild disease.<sup>57</sup>

A second form of LAD (LAD2) is an autosomal recessive disorder caused by mutations in FUCT1. FUCT1 encodes a GFP-fucose transporter that is required for formation of sialyl-Lewis X, a ligand for selectins on the surface of neutrophils.<sup>58</sup> In addition to their elevated leukocyte counts and recurrent bacterial infections, patients have short stature, a distinctive facies, and developmental delay. A third type of LAD, which features a bleeding tendency, is caused by a mutation in FERMT3, which encodes kindlin-3 and prevents activation of β1, β2, and β3 integrins.<sup>59</sup> Dermal hematopoiesis, leading to the “blueberry muffin” presentation, has been described in affected infants and children.<sup>60</sup>

Therapy of the soft-tissue infections includes antimicrobial agents and, as appropriate, debridement of wounds. Scrupulous dental

**Figure 25-3** Leukocyte adhesion deficiency. Small wounds can lead to large ulcerations that may resemble pyoderma gangrenosum. The ulceration on this boy's leg, initiated by a scratch from his sister, eventually extended to several centimeters in diameter and required a graft. (Reprinted with permission from Schachner LA, Hansen R, editors. Pediatric dermatology. London: Churchill Livingstone; 1995.)

**Table 25-2** Classification of Severe Combined Immunodeficiency

Disorder	Gene Location	Gene	Diagnostic Tests	Cells
ADA deficiency*	20q12-13	ADA	Red cell ADA levels and metabolites	T-/B-/NK-
Artemis deficiency	10p13	Artemis	Defects in V(D)J recombination; increased sensitivity to radiation	TB-/NK <sup>+</sup>
CD45 deficiency	1q31-32	CD45	CD45 expression	T-/B <sup>+</sup> /NK
IL-7 receptor deficiency	5p13	IL-7 receptor $\alpha$	IL-7 receptor $\alpha$ expression	T-/B <sup>+</sup> /NK <sup>+</sup>
JAK3 deficiency	19p13	JAK3	JAK3 expression/signaling	T-L/B <sup>+</sup> /NK
MHC class II deficiency	16p13 1q21 13q13	CIITA RFX5 RFXAP	HLA-DR expression	T <sup>+</sup> /B <sup>+</sup> /NK <sup>+</sup>
PNP deficiency	14q11	PNP	Red cell PNP levels and metabolites	T-/B-/NK-
RAG deficiency, Omenn syndrome	11p13	RAG1 and RAG2	Defects in V(D)J recombination; T- and B-cell clonal analysis	T-/B-/NK <sup>+</sup>
T-cell receptor deficiency	11q23	CD3g	CD3 expression	T-/B <sup>+</sup> /NK <sup>+</sup>
X-linked SCID <sup>†</sup>	Xq13	Common $\gamma$ chain	$\gamma_c$ expression by FACS	T-/B <sup>+</sup> /NK-
ZAP70 deficiency	2q12	ZAP-70	ZAP-70 expression	T-/B <sup>+</sup> /NK <sup>+</sup>

ADA, Adenosine deaminase; IL, interleukin; HLA-DR, human leukocyte antigen DR; MHC, major histocompatibility complex; PNP, purine nucleoside phosphorylase; RAG, recombinase activating gene; SCID, severe combined immunodeficiency; V(D)J, variable (diversity) joining.

\*Most common autosomal recessive form.

<sup>†</sup>Most common X-linked recessive form (46% overall).

hygiene reduces the severity of the periodontitis. Death usually occurs by 2 years of age in patients with severe LAD unless successful bone marrow transplantation or cord blood transplantation is performed.<sup>61</sup> Oral fucose has been helpful for some patients with LAD2.

### SEVERE COMBINED IMMUNODEFICIENCY

Severe combined immunodeficiency (SCID) is a group of disorders with similar clinical manifestations and immune dysfunction, but different biochemical, cellular, and molecular features (Table 25-2).<sup>62-65</sup> Overall, 75% of affected patients are boys. The majority of cases are autosomal recessive. Approximately 46% have the X-linked recessive form resulting from mutations in gene that encodes  $\gamma_c$ , which leads to an absence of T and natural killer (NK) cells but normal B-cell numbers.<sup>66</sup> This  $\gamma_c$  chain is a component of several interleukin receptors and is critical for T- and NK-cell function. Mutations in adenosine deaminase (ADA) lead to the second most common form of SCID. Accumulation of adenosine when its deaminase is missing is toxic to lymphocytes. Omenn syndrome usually results from deficiency of recombination activating gene (RAG) proteins, which mediate the deoxyribonucleic acid (DNA) double strand breaks that allow variable (diversity) joining (V[D]J) recombination and Ig diversity.<sup>67-69</sup>

Infants may present have a generalized seborrheic-like dermatosis, a morbilliform eruption, or exfoliative erythroderma with alopecia. Extensive cutaneous inflammation is a characteristic of 98% of infants with Omenn syndrome, a subset of SCID with reticuloendothelial cell proliferation. Patients with Omenn syndrome typically show hepatosplenomegaly (88%), lymphadenopathy (80%), alopecia (57%), eosinophilia, and a high serum IgE level.<sup>67</sup> Oral and genital ulcers are characteristic of defects in patients with an *Artemis* mutation, especially in Athabaskan-speaking American Indian children.<sup>70</sup> Multicentric dermatofibrosarcoma protuberans<sup>71</sup> and pulmonary alveolar proteinosis<sup>72</sup> have recently been described in association with ADA deficiency.

Acute graft-versus-host disease (GVHD) from maternal cell engraftment or nonirradiated transfusions should also be considered in an infant with an extensive cutaneous eruption.<sup>73</sup> Biopsy will allow differentiation. A more chronic form of GVHD (often with the acute form *in utero*) may also present as lesions that resemble lichen planus, lamellar ichthyosis, or scleroderma.

Recurrent infections, diarrhea, and failure to thrive are apparent by 3 to 6 months of age. The most common early infections are candidal infections and pneumonia caused by bacteria, viruses, or *Pneumocystis jiroveci*. Patients with SCID usually lack tonsillar buds, thymus, and

palpable lymphoid tissue, despite recurrent infections. Nearly all patients with SCID have a profound deficiency of T lymphocytes and a low absolute lymphocyte count. Patients are further classified by the results of fluorescent activated cell sorter (FACS) analysis into those with B lymphocytes (T-/B<sup>+</sup> SCID) and those without B lymphocytes (T-/B- SCID). Further subclassification can be made according to the presence or absence of NK cells (see Table 25-2). The specific diagnosis is confirmed primarily by direct gene analysis and flow cytometric analysis of peripheral blood mononuclear cells with antibodies directed against specific proteins missing from the cell surface, such as JAK3 or  $\gamma_c$ . The natural outcome for SCID is poor, and most patients die by 2 years of age without intervention. Hematopoietic stem-cell transplantation in infants is the treatment of choice<sup>74</sup> and leads to survival of 95% of infants if performed in the first 3 months of life. Bone marrow-derived CD34+ cells transduced with the SIN- $\gamma_c$  modified  $\gamma$ -retrovirus vector without preparative conditioning led to T-cell recovery without evidence of leukemia development after 12.1 to 38.7 months of follow-up study in nine boys with X-linked SCID.<sup>75</sup> Early diagnosis of SCID is critical, preferably before the administration of live vaccines, nonirradiated blood products and, in countries where applicable, bacille Calmette-Guérin (BCG). Patients with SCID have a high risk of BCG-associated complications (34% disseminated and 17% localized) and subsequent death, especially if they are given the vaccination at 1 month of age or younger and with T-cell numbers of 250/mcL or less at diagnosis.<sup>76</sup> In a United Kingdom-based study, diagnosis at birth because of a positive family history significantly improved outcome with survival of greater than 90% related to reduced rate of infection and improved transplantation outcome, suggesting that neonatal screening for SCID will also improve outcome.<sup>77</sup> Perinatal screening is now mandatory in several states.<sup>78-80</sup>

### Graft-Versus-Host Disease

The *host-versus-graft reaction* occurs when a graft or transplant (skin, heart, or kidney) is placed in a normal individual and the host's circulating immune cells react against the foreign tissue, causing graft or transplanted tissue destruction. In GVHD, the reverse happens.<sup>81</sup> The inflammation from conditioning regimens is thought to activate host antigen-presenting cells and chemokines that recruit donor leukocytes into host target organs.<sup>82</sup> Activated donor T cells stimulate dendritic cells, leading to further T-cell stimulation and expansion and culminating in target organ apoptosis and dysfunction. GVHD most commonly occurs in children with malignancy suppressed by

radiation and chemotherapy, who receive hematopoietic stem-cell transplantation, or in immunodeficient children who receive nonirradiated blood products. The risk of both acute GVHD (aGVHD) and chronic GVHD (cGVHD) is greater in males who receive female donor cells because of responses to H-Y minor histocompatibility antigens.<sup>83</sup> It has been estimated that moderate to severe GVHD occurs in 10% to 50% of patients given an allogeneic transplant from a human leukocyte antigen (HLA)-identical donor and much more commonly in patients given a transplant from a partially matched family donor or an unrelated volunteer.<sup>84</sup> *In utero* GVHD may occur in immunodeficient babies exposed to maternal antigens.<sup>73</sup> GVHD can occur in recipients of solid-organ transplants, especially multiorgan transplants, and reflects donor T-cell chimerism.<sup>85–87</sup>

The response to the host can be early (acute) or late (chronic). aGVHD classically develops during the first 100 days (usually 2 to 4 weeks) but can be persistent, recurrent or late onset, and usually involves the skin, gastrointestinal tract, and liver (in that order of incidence).<sup>88</sup> Patients who receive autologous transplants may have a mild cutaneous form of aGVHD that occurs 1 to 3 weeks after transplantation and resolves spontaneously. Reactions to transfusions often occur 7 to 10 days after the transfusion.<sup>89</sup> The most common cutaneous manifestation of aGVHD is erythematous macules and maculopapules that often begin on the ears, face, neck, palms, and soles and then become generalized (Figs. 25-4 and 25-5). The cutaneous eruption may become confluent and desquamate. Mild to moderate aGVHD most often presents with a nonspecific cutaneous eruption and thus can be confused with infection (especially viral), drug reaction,<sup>90</sup> and

reactions related to the transplant (e.g., the self-limited eruption of lymphocyte recovery, engraftment syndrome (which is characterized by associated fever and vascular leak with weight gain, edema, ascites, pulmonary infiltrates and hypotension),<sup>91</sup> and toxic erythema of chemotherapy (which is painful and usually localized to the palms, soles and intertriginous areas. Severe aGVHD may resemble exfoliative erythroderma or toxic epidermal necrolysis. Patients with aGVHD may complain of nausea or crampy abdominal pain and have watery or bloody diarrhea, hepatomegaly, and hepatic function abnormalities. Many patients are anorexic and have fever.

Milder forms of aGVHD may be difficult to distinguish from an infection (especially viral) or drug reaction. Abnormalities seen in biopsy specimens reflect the clinical severity of the cutaneous manifestations and range from nonspecific changes to basal keratinocyte vacuolization with scattered necrotic keratinocytes surrounded by lymphocytes (the characteristic "satellite cell necrosis") to severe epidermal necrosis. As such, biopsies are not helpful for patients with milder disease and do not tend to affect treatment decisions.<sup>92</sup> Laboratory tests may show eosinophilia and elevation of bilirubin and hepatic transaminase levels.

GVHD occurs in 6% (matched sibling cord blood) to 65% (matched unrelated donor peripheral blood stem-cell transplants) of pediatric patients. It typically presents 6 to 18 months after allogeneic stem-cell transplantation. Patients may have previous aGVHD that resolves or progresses directly into cGVHD, or may have no history of preceding aGVHD. cGVHD is now defined based on clinical and histopathologic signs of presentation, rather than time of onset since transplantation (formerly ≥100 days) and can be subclassified as *mild*, *moderate*, or *severe* based on number of sites, disability, and lung involvement.<sup>93,94</sup> An overlap syndrome with features of both aGVHD and cGVHD has been described. cGVHD often resembles autoimmune disorders and in contrast to aGVHD, can affect virtually any organ, leading to significant morbidity with decreased quality of life and overall survival.<sup>95</sup> Decreased survival of patients with cGVHD has been associated with thrombocytopenia, progressive onset, extensive cutaneous involvement, gastrointestinal involvement and a low Karnofsky performance status at diagnosis.<sup>92</sup>

cGVHD often manifests with generalized cutaneous involvement<sup>92</sup> (Table 25-3). Early lesions may resemble lichen planus with flat-topped violaceous papules and plaques (including mucosal changes of lichen planus) (Figs. 25-6 and 25-7) (see Chapter 4). Lichenoid lesions may be localized to Blaschko lines or to the site of previous herpes zoster infection.<sup>96</sup> Some patients with cGVHD manifest acquired ichthyosis that resembles ichthyosis vulgaris (Fig. 25-8) or lichen sclerosus (Fig. 25-9). Later changes of cGVHD include generalized xerosis, patchy dyspigmentation (Fig. 25-10), progressive poikiloderma, sclerodermatous changes<sup>97,98</sup> with joint contracture and ulcerations<sup>99</sup> (Figs. 25-10 through 25-13), cicatricial alopecia (Fig. 25-14), and nail dystrophy resembling that of dyskeratosis congenita (see Chapter 7, Fig. 7-63).<sup>100</sup> Disseminated porokeratosis has also been described after stem-cell transplantation and may respond to acitretin administration.<sup>101</sup>

**Figure 25-4** Acute graft-versus-host disease. Involvement of the scalp, ears, palms, and soles is common.

**Figure 25-5** Acute graft-versus-host disease. Almost confluent eruption of erythematous macules and papules in an immunodeficient neonate treated with extracorporeal membrane oxygenation (ECMO) and transfusion of nonirradiated blood.

**Figure 25-6** Chronic graft-versus-host disease (GVHD), lichenoid. After bone marrow transplantation, this boy had acute GVHD and subsequently developed cutaneous scaling papules and plaques typical of lichen planus.

**Figure 25-7** Chronic graft-versus-host disease (GVHD), lichenoid. Note the white coloration on the lips and tongue of this girl with early chronic GVHD.

**Figure 25-8** Chronic graft-versus-host disease (GVHD), ichthyotic. The ichthyotic changes of chronic GVHD resemble those of ichthyosis vulgaris.

**Figure 25-9** Chronic graft-versus-host disease (GVHD). The changes of chronic GVHD can resemble those of other autoimmune skin disorders. In this case, the cutaneous plaques resembled those of morphea/lichen sclerosus et atrophicus.

<b>Table 25-3</b> Features of Chronic Graft-Versus-Host Disease		
Location	Characteristic Features	Other Features
Skin	Lichen planus-like Sclerotic (or lichen sclerosus-like) Poikilodermatous Ichthyotic Vaginal scarring, stenosis	Depigmentation Genital erosions, ulcers, fissures
Hair		Alopecia, nonscarring, or cicatricial
Nails		Ridging, onycholysis, loss, pterygium
Oral	Lichen planus-like Keratotic plaques Sclerosis with restricted opening	Mucosal atrophy Xerostomia Ulceration Mucocele
Eyes		Dry eyes Cicatricial conjunctivitis Keratoconjunctivitis sicca Punctate keratopathy
Joints/ muscle	Contracture from sclerosis Fasciitis, arthritis	Myositis
GI	Chronic diarrhea Upper esophageal strictures, stenosis, webbing Hepatomegaly	
Lungs	Bronchiolitis obliterans Interstitial fibrosis	

Affected individuals may have dry eyes (as in Sjögren syndrome; see Chapter 22) and desquamative esophagitis with stricture formation. Weight loss can result from dysphagia and mucositis. Other manifestations are chronic diarrhea, hepatomegaly, lymphadenopathy, myositis, arthritis, pleural and pericardial effusions, and pulmonary fibrosis.

Patients with cGVHD show evidence of immune dysfunction and have recurrent infections. The majority of patients with cGVHD have eosinophilia and hypergammaglobulinemia. Many have thrombocytopenia and increased titers of a wide variety of autoimmune

**Figure 25-10** Chronic graft-versus-host disease. Hypopigmented and hyperpigmented scaling, indurated plaques in a generalized distribution, is seen here on her back.

antibodies, especially antinuclear antibodies (ANAs).<sup>92</sup> Liver function testing may show evidence of cholestasis. Pulmonary function tests are abnormal in approximately 50% of patients, and chest radiographs may reveal interstitial fibrosis. Biopsies of skin lesions show changes consistent with the clinical picture. For example, patients

**Figure 25-11** Chronic graft-versus-host disease. Sclerodactyly and subtle telangiectasia overlying knuckles, as seen in patients with systemic scleroderma and juvenile dermatomyositis.

**Figure 25-14** Chronic graft-versus-host disease. Note the extensive alopecia of the scalp with dyschromia and numerous sclerodermatosus plaques of the scalp and back.

**Figure 25-12** Chronic graft-versus-host disease. Note the cutaneous atrophy and nail dystrophy, including onycholysis and pterygium formation resembling the nails of lichen planus.

**Figure 25-13** Chronic graft-versus-host disease (GVHD). Sclerodactyly and generalized scaling were noted at birth in this girl with immunodeficiency and *in utero* GVHD. Her skin softened considerably with high dosages of thalidomide.

with lichenoid lesions have the histologic changes of lichen planus (see Chapter 4), often with satellite cell necrosis. Patients with sclerosis tend to show band-like inflammation at the dermal–epidermal junction and dermal sclerosis with obliteration of adnexae. Direct immunofluorescence analysis of skin specimens often shows the linear deposition of immunoreactants at the dermal–epidermal junction.

The mortality rate of GVHD ranges from 12% for mild aGVHD to 55% for severe aGVHD, usually because of infection.<sup>102</sup> The mortality of cGVHD is 25%, usually from infection, hepatic failure, and malnutrition. Having aGVHD is a major risk factor for development of cGVHD (11-fold increased risk), emphasizing the importance of preventing aGVHD. Other risk factors are an unrelated or mismatched donor, use of peripheral blood stem cells, older age of donor or recipient, use of total body irradiation, male recipient with a female donor, and malignant disease.<sup>103</sup> For patients with myeloablation (full-intensity conditioning, which eliminates all malignant and marrow hematopoietic cells), prophylaxis usually involves 2 to 12 months of tacrolimus (or cyclosporine), with or without a short course (about 1 month) of methotrexate. With reduced intensity conditioning before transplant, which does not fully eradicate malignant and hematopoietic cells and instead relies on immunologic antihost and antitumor effects, a calcineurin inhibitor and mycophenolate mofetil (MMF) (or, instead, corticosteroid) are generally used prophylactically. In both situations, anti-T-cell serotherapy with either antithymocyte globulin or alemtuzumab (Campath) is usually added for unrelated donor transplants and also reduces graft rejection; for haploididentical donors, T-cell depletion or CD34 selection is often performed. Environmental isolation, bowel rest through hyperalimentation, irradiation of blood products, and prevention of infection are other protective measures.

If grade II through IV aGVHD develops, the first-line therapy is continuing prophylactic immunosuppression (optimizing calcineurin inhibitor levels) and adding methylprednisolone 1 to 2 mg/kg per day.<sup>94</sup> For skin GVHD, topical steroid and/or tacrolimus may be added, with oral administration of budesonide for gastrointestinal GVHD. Patients who fail to respond to corticosteroid alone after 5 to 7 days can be treated with salvage therapy, such as MMF,<sup>104–106</sup> anti-TNF antibodies (e.g., infliximab), mammalian target of rapamycin (mTOR) inhibitors (e.g., sirolimus/ rapamycin),<sup>107–109</sup> anti-interleukin

**Figure 25-15** Orofacial granulomatosis. Granulomatous infiltration limited to the lip(s) is called *cheilitis granulomatosa*.

**Figure 25-16** Orofacial granulomatosis as part of Melkersson–Rosenthal syndrome. Scrotal tongue.

(IL-2) 2 antibodies (e.g., daclizumab),<sup>110</sup> or extracorporeal photopheresis (ECP).<sup>111–113</sup> Responses in general are poor if initial steroid treatment is not successful, and the risk of infection is high. If at least two second-line treatments fail, alternatives are alemtuzumab (Campath), methotrexate, pentostatin,<sup>114,115</sup> and mesenchymal stem cells.<sup>88,116–119</sup>

Similar regimens have been used to treat cGVHD, although there is no proven standard, with prednisone and calcineurin inhibitors most commonly used for first-line therapy.<sup>92</sup> The mean duration of therapy for patients with cGVHD is 3 years, with about half of the patients able to discontinue therapy 5 years after transplantation. Second-line treatment (steroid-resistant or steroid-sparing) includes one of more of the following: ECP (which gives the best result for skin, oral or liver cGVHD), rituximab,<sup>120</sup> imatinib mesylate (increases range of motion with sclerotic cGVHD),<sup>121–123</sup> mTOR inhibitors, and pentostatin. Third-line treatment includes pulsed high-dose intravenous methylprednisolone, MMF, or methotrexate. Overall, the 5-year survival rate is 50% for those who respond to therapy for GVHD and 30% for those with no or an incomplete response. Mucocutaneous manifestations of GVHD may also benefit from administration of thalidomide, acitretin, application of topical tacrolimus, or treatments with narrowband ultraviolet B (UVB) light, psoralen plus ultraviolet A light, or UVA1 light.<sup>124–128</sup> Supportive intervention for cGVHD includes supplemental nutrition (usually parenteral), scrupulous care of wounds, physical therapy to prevent joint contractures and disability, artificial tears, cutaneous emollients and sunscreens, and prophylaxis against *Pneumocystis* infection with trimethoprim-sulfamethoxazole.

### Orofacial Granulomatosis

Orofacial granulomatosis (OFG; also called *cheilitis granulomatosa* or *granulomatous cheilitis*) (Fig. 25-15) is characterized by face and lip swelling (macrocheilitis). It is the most common manifestation (93% with facial swelling and 66% with lip swelling) of Melkersson–Rosenthal syndrome, which also includes recurrent facial paralysis and a furrowed or “scrotal” tongue (lingua plicata) (Fig. 25-16).<sup>129,130</sup> Furrowing of the tongue and facial palsy have each been reported to occur in approximately 30% of patients. No prodrome warns of attacks, and patients experience no associated erythema, pain, or pruritus. The disorder is more prevalent in males and has a mean age of onset of 11 years.<sup>131</sup> The swelling can increase the size of the lip by twofold to threefold, leading to chapping from exposure of the mucosa. Both lips may be involved, and the swelling may be bilateral or unilateral. In addition to the swelling of the lips and other oral mucosal structures, the eyelids may be swollen. The attacks usually disappear within days or weeks but commonly tend to persist after several recurrences. Facial palsy usually occurs on the side of the facial swelling and tends to resolve spontaneously.<sup>132</sup>

The cause is unknown. Attacks usually start during adolescence with paralysis of a facial nerve, repeated severe headaches, edema of the circumoral tissue of the upper lip or cheeks, and occasionally edema of the gingivae, sublingual area, and lower lip. The edema is

usually asymmetric, but the whole face may be involved. Associated signs include hyperhidrosis, loss of taste, and visual impairment. Biopsy specimens show noncaseating granulomas in an edematous stroma that may be indistinguishable from the granulomas of Crohn disease,<sup>133</sup> and the relationship between Crohn disease and OFG remains controversial. In one systematic review, gastrointestinal signs were present in 26% at time of OFG diagnosis, and 40% of children received a concomitant diagnosis of Crohn disease, with OFG preceding signs of Crohn disease in more than 50%.<sup>131</sup> Concomitant perianal disease and a family history of Crohn disease are associated with a higher risk of Crohn disease.

Intralesional injections of triamcinolone or systemic administration of corticosteroids can control the facial and mucosal swelling; intermittent application of topical clobetasol gel may also lead to improvement. Minocycline, with or without corticosteroids, and sometimes macrolides have also been helpful.<sup>134,135</sup> Other therapies include thalidomide, dapsone, azathioprine, clofazimine, and TNF- $\alpha$  inhibitors, particularly infliximab.<sup>136–138</sup> Wedge resection of the inner lip should be reserved for patients who fail to respond to other options. The recurrent facial palsy tends to be more persistent than recurrent Bell palsy,<sup>139</sup> and transmastoid subtotal facial nerve decompression can lead to improvement in most cases.<sup>140</sup>

### Crohn Disease

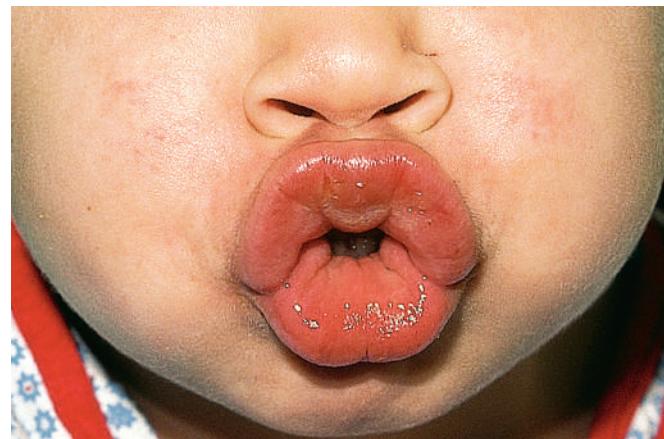

Crohn disease is a granulomatous disorder of the intestinal tract that usually has its onset between 15 and 30 years of age but has been described in young children.<sup>141,142</sup> Approximately one-third of pediatric patients have small intestinal disease, one-third have ileocolitis, and one-third have colitis. Total colitis is more common than segmental or isolated proctitis.<sup>142</sup> Growth failure,<sup>143,144</sup> delayed pubertal development, and osteopenia<sup>145</sup> are important complications of Crohn disease.

The pathogenesis of Crohn disease is complex. The disorder is thought to occur in genetically predisposed individuals when the intestinal mucosal immune function is altered by exogenous agents, such as infectious organisms, or host factors, such as intestinal barrier function, vascular supply, or stress.<sup>146</sup> The disorder occurs twofold to fourfold more often in Ashkenazi Jews and has been linked to certain HLA alleles (DR3, DQ2, DR103), as well as to mutant alleles of NOD2/CARD15. The CARD15 protein senses bacterial peptidoglycan and regulates nuclear factor (NF)- $\kappa$ B signaling.<sup>147,148</sup> Granulomatous colitis is also a feature of a subset of individuals with Hermansky–Pudlak syndrome (see Chapter 11).<sup>149</sup>

Skin manifestations may occur before, concomitantly, or after other evidence of disease.<sup>150</sup> Perianal skin tags are found in 75% to 80% of patients with Crohn disease (Fig. 25-17) and occur before gastrointestinal manifestations in 25% of patients. In addition to tags, skin and mucosal findings have been noted in 22% to 44% of patients (Table 25-4) and occur more often in patients with colonic versus small intestinal disease. Several mucocutaneous manifestations of Crohn disease also are features of ulcerative colitis. Erythema nodosum (see

**Figure 25-17** Crohn disease. Perianal tags are an early manifestation and seen in most affected children.

**Figure 25-19** Crohn disease. Note the infiltration of the lips, which showed noncaseating granulomas in biopsy sections.

**Figure 25-18** Crohn disease. Pyoderma gangrenosum on the vulva of an affected girl. Pyoderma gangrenosum is more commonly seen in individuals with ulcerative colitis than in those with Crohn disease.

**Table 25-4** Mucocutaneous Manifestations of Crohn Disease

	Specific	Nonspecific
Cutaneous	Extraintestinal cutaneous Crohn disease	Erythema nodosum Pyoderma gangrenosum Polyarteritis nodosa Erythema multiforme Vasculitis
Anogenital	Perianal fissures and tags Sinus tracts Labial or scrotal edema	
Oral	Orofacial granulomatosis Cobblestoning Mucosal tags	Aphthous stomatitis Angular cheilitis

Chapter 20) occurs in up to 15% of patients with Crohn disease and has been shown to correlate with the presence of arthritis.<sup>151</sup> Pyoderma gangrenosum occurs less often in Crohn disease<sup>152</sup> (approximately 1% of patients) (Fig. 25-18) than in ulcerative colitis (up to 5% of pediatric patients), occasionally precedes the development of bowel symptoms, and has a course unrelated to the activity of the bowel

disease. Oral aphthous ulcers have been described in greater than 50% of pediatric patients with Crohn disease.<sup>153</sup> Pyostomatitis vegetans, erythematous pustular lesions associated with erosions and ulcerations, is considered a marker for inflammatory bowel disease. Cutaneous changes related to nutritional deficits (particularly acrodermatitis enteropathica caused by zinc deficiency) can occur as well.

Other mucocutaneous manifestations are more specific for Crohn disease.<sup>142</sup> Cobblestoning of the buccal mucosa is seen in up to 20% of affected individuals. Painless swelling of the lips, resembling OFG, may be the initial presentation of Crohn disease in a child or adolescent<sup>154</sup> and may precede the gastrointestinal symptoms by several years (Fig. 25-19).<sup>155-159</sup> Similarly, the vulva may show erythema, swelling, and fissuring,<sup>160,161</sup> and the scrotum and penis may be swollen and erythematous.<sup>162-164</sup> Perianal lesions may extend onto the adjacent perineum, abdomen, or buttocks with fissures, and sinus tracts are common.<sup>165,166</sup> Nasal perforation<sup>167</sup> and chronic granulomatous otitis externa<sup>168</sup> have been described. Abdominal surgical sites may also be loci for cutaneous involvement. Biopsy provides the clue to diagnosis, although the noncaseating granulomas resemble those of Melkersson–Rosenthal/cheilitis granulomatosa and sarcoidosis. Special stains (periodic acid–Schiff, Ziehl–Nielsen and Gram) are important to consider infectious causes of granulomas. These granulomatous lesions of the lips and anogenital area are considered “contiguous” Crohn disease because of their proximity to the gastrointestinal tract. Granulomatous lesions elsewhere are considered extraintestinal (sometimes called *metastatic*) cutaneous Crohn disease.<sup>169,170</sup> These lesions typically are dusky red, swollen/indurated plaques, most commonly found on the genital region of children, lower extremities, abdomen, or trunk; lesions less commonly show no erythema or are ulcerating.<sup>171</sup>

Barium contrast studies are particularly important for investigating small bowel disease, but endoscopy and colonoscopy are important tools for upper and lower bowel disease, respectively. Initial treatment involves administration of systemic corticosteroids and aminosalicylates, with the early addition of azathioprine or 6-mercaptopurine as steroid-sparing alternatives for maintenance therapy.<sup>172</sup> TNF- $\alpha$  inhibitors (etanercept, adalimumab, and infliximab) are very helpful as well, and reduce the need for surgery.<sup>173-177</sup> The development of psoriasisiform dermatitis is common in patients with Crohn disease treated with TNF- $\alpha$  inhibitors and often manifests in periorificial and genital areas, scalp, hands and feet<sup>178-180</sup> (see Chapter 4; Fig. 4-25). The mechanism for the common occurrence of psoriasisiform dermatitis is unclear but has been linked to IL-23 receptor polymorphism.<sup>181</sup> Azathioprine-induced Sweet syndrome has also been described in association with Crohn disease.<sup>182</sup> Oral metronidazole has been used for extraintestinal cutaneous Crohn disease<sup>183,184</sup>; intralesional or topical applications of potent topical corticosteroids or tacrolimus<sup>185</sup> have helped clear the ulcerations of pyoderma gangrenosum. Colectomy in Crohn disease does not prevent recurrence and should be used selectively.<sup>186,187</sup>

## Sarcoidosis

Sarcoidosis is a systemic granulomatous disorder of unknown etiology with CD4+ Th1 cell and monocyte activation, leading to hypergammaglobulinemia, sarcoidal granulomas (predominantly affecting the lungs, eyes, skin, and reticuloendothelial system), and ultimately fibrosis. The condition presents most often in adults between the ages of 20 and 40 years. In pediatric patients, it is most commonly seen in adolescents between 9 and 15 years of age, in which manifestations resemble those of adult patients. In a US series of pediatric sarcoidosis, 72% to 81% among older children were African-Americans (vs. only 7% to 28% in young children).<sup>188</sup>

There is no single reliable test for sarcoidosis. Because the clinical picture may be mimicked by other diseases, histologic confirmation is advisable. In typical lesions, the characteristic histopathologic finding consists of islands of large, pale-staining epithelioid cells containing few if any giant cells intermingled with histiocytes and lymphocytes. Sarcoidosis must also be distinguished from infectious granulomatous conditions, particularly mycobacterial and fungal infections, but cultures and special stains of biopsy sections are negative. Cutaneous anergy is common, but children should be tested for reactivity to tuberculin.

### SARCOIDOSIS IN OLDER CHILDREN AND ADOLESCENTS

Adolescents and older children may have fever and weight loss.<sup>189</sup> Cutaneous involvement occurs in 15% to 25% of pediatric patients and in older children.<sup>190</sup> Several specific and nonspecific lesions have been described, although no lesion is pathognomonic.<sup>191</sup> Most typical are yellow-brown to red flat-topped papules, infiltrated plaques, and nodules that show an apple-jelly color when diascopy (pressure applied with a glass slide) is performed, a characteristic sign of granulomas. Scaling is sometimes associated. These granulomatous lesions are most commonly localized to the face, and an annular configuration of lesions around the nares, lips, and eyelids is highly characteristic, although any site, including the mucosae, palms, and soles, may be involved. Lesions often occur in areas of trauma or scarification. Other cutaneous manifestations of sarcoidosis include subcutaneous, often painful nodules (Darier-Roussy sarcoidosis), ichthyosis (ichthyosiform sarcoidosis, usually most prominent on the lower extremities), generalized erythroderma with scaling, and hypopigmentation. More than 20% of affected children have erythema nodosum (see Chapter 20), which is often manifested at onset and is a good prognostic sign<sup>188</sup> that usually portends clearance of the adenopathy. The combination of erythema nodosum, bilateral hilar adenopathy, uveitis, and fever has been called *Löfgren syndrome*. Lupus pernio is a variant of sarcoidosis in which soft, infiltrated, violaceous plaques are located on the nose, cheeks, ears, forehead, and on the dorsal aspects of the hands, fingers, and toes (Fig. 25-20). This variant can cause significant scarring and deformity and is a marker for upper respiratory involvement, including the larynx.

The lung is the most commonly involved site in older children and adolescents, as in adults. A dry, hacking cough is the most common

**Figure 25-20** Sarcoidosis. The lupus pernio form of sarcoidosis shows infiltrated violaceous plaques on the nose, cheeks, and ears. This girl had hoarseness owing to her laryngeal involvement with sarcoidosis, and was left with severe scarring after treatment.

complaint, but patients may have dyspnea and develop parenchymal lung disease. Lymphadenopathy may be generalized, but typically involves the hilar nodes and is symmetric. More than 90% show an abnormal chest X-ray at onset. Clinical evidence of liver involvement is detected in approximately one-third of patients, although more than half show granulomas when the liver is biopsied. Splenic enlargement has been associated with extensive visceral fibrosis and a poor prognosis. Granulomatous infiltration of the heart may lead to arrhythmias, and infiltration of the lung to congestive heart failure. Some patients with renal involvement will show hypercalciuria, renal stones, and ultimately renal failure from excessive production of 1,25-dihydroxyvitamin D<sub>3</sub>, with or without hypercalcemia; calciphylaxis has also been reported in association with end-stage renal disease, manifesting as painful violaceous plaques, retiform purpura, or subcutaneous nodules, which can progress to nonhealing ulcers and cutaneous gangrene.<sup>192</sup>

Although more common in young children, arthritis is a component of sarcoidosis in older children and can be the presenting feature in more than 10%. Overall, up to 74% of pediatric patients have eye involvement, particularly anterior segment uveitis (Fig. 25-21). Conjunctival granulomas are often seen on biopsy, and lacrimal gland inflammation is not uncommon. Chorioretinitis, keratitis, and glaucoma may occur as well, resulting in blindness. Neurologic manifestations are associated with a poorer prognosis, and overall affect 5% to 10% of older patients, most commonly facial nerve paralysis. The combination of uveitis, facial nerve palsy, parotid gland enlargement, and fever has been called *uveoparotid fever* or *Heerfordt syndrome*. Lytic lesions of the distal bones rarely occur and are asymptomatic.

Thorough evaluation also includes ophthalmologic examination with slit-lamp testing, chest radiographs (with chest computed tomography [CT] scanning if needed), pulmonary function testing, electrocardiogram, and 24-hour urine calcium measurements. Many affected patients have hyperglobulinemia, especially African-Americans. Patients may show hypercalcemia (7% to 24% and usually transient), leukopenia, eosinophilia (>50% of children), and usually an increased ESR. The angiotensin-converting enzyme (ACE) level is often elevated but may be increased in other granulomatous disorders as well and has a 40% false-negative rate.

The natural course of sarcoidosis in childhood is insidious, and the condition often regresses completely after many years, especially in those with an acute onset. Chronic, progressive sarcoidosis has a poorer prognosis and rarely involutes. Features that portend a worse prognosis include chronicity; lupus pernio; symptoms lasting longer than 6 months; black race; involvement of more than three organ systems; and later stage pulmonary disease.<sup>193</sup> The overall mortality rate is 1% to 5%.

Corticosteroids (1 mg/kg per day initially with tapering as possible) can suppress the acute manifestations of the disorder.<sup>194</sup> However, given the hazards of prolonged systemic corticosteroid therapy and

**Figure 25-21** Sarcoidosis. Uveitis in a teenager with sarcoidosis since early childhood. She had ichthyosiform scaling overlying granulomatous papules and arthritis.

**Table 25-5** Common Features of Sarcoidosis in Older Versus Younger Children

Older Children and Adolescents	Preschool-Aged Children
Fever, weight loss	Low-grade fever
Skin lesions	Polyarthritides
Cough, dyspnea	Skin lesions
Lymphadenopathy	Iridocyclitis with uveitis
Hepatomegaly	Parotid gland enlargement
Splenomegaly	Lymphadenopathy, especially peripheral
Arrhythmias	
Congestive heart failure	
Renal stones (hypercalciuria)	
Uveitis	
Facial paralysis	Splenomegaly

the common spontaneous resolution of sarcoidosis, the administration of systemic corticosteroids is best reserved for rapidly progressive and disfiguring skin lesions, ocular disease, and significant visceral abnormalities (persistent hypercalcemia; joint involvement; lesions of the nasal, laryngeal, and bronchial mucosa; severe, debilitating, or rapidly progressing lung disease; central nervous system lesions; persistent facial palsy; myocardial involvement; and hypersplenism). Methotrexate is the most commonly used steroid-sparing systemic agent for pediatric sarcoidosis, and MMF and TNF- $\alpha$  inhibitors (particularly infliximab) have also been used successfully.<sup>195</sup> Ophthalmic steroid preparations may be used adjunctively for eye disease. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used for the arthritis, and hydroxychloroquine and allopurinol have been used successfully for skin lesions.

### SARCOIDOSIS IN PRESCHOOL CHILDREN/BLAU SYNDROME

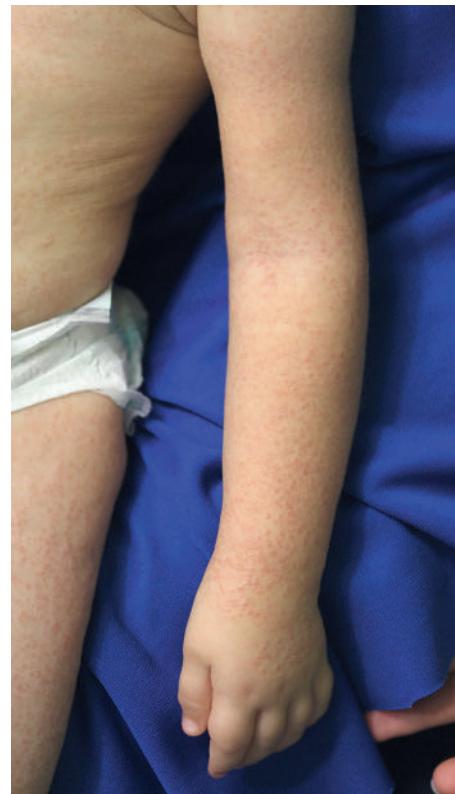

Sarcoidosis in preschool-age children differs from that of older children, adolescents, and adults,<sup>188,196,197</sup> and is characterized by polyarthritis and severe uveitis (commonly suggesting a diagnosis of juvenile idiopathic arthritis [JIA]),<sup>198</sup> cutaneous manifestations, and a conspicuous absence of pulmonary abnormalities (Table 25-5).<sup>199,200</sup> The majority of young children with this presentation (also called *early-onset sarcoidosis* [EOS]) have been found to have heterozygous mutations in *CARD15*. As such, EOS is considered to be the sporadic form of Blau syndrome, an autosomal dominant disorder with the cutaneous granulomas and other features of EOS.<sup>201–203</sup> Blau syndrome/EOS is associated with increased flaring and morbidity and a poorer prognosis than sarcoidosis in older children and adults. The complete classic triad (skin eruption, arthritis, and recurrent uveitis) occurs in 42% of patients with Blau syndrome,<sup>204,205</sup> and cutaneous features are usually the first to appear.<sup>206</sup> Generalized asymptomatic small erythematous papules on the trunk and extremities are most commonly seen (Figs. 25-22 and 25-23), often leaving small pitted scars as sequelae. However, the cutaneous lesions have variably been described as eczematous, ichthyosiform (misdiagnosed as ichthyosis vulgaris), or lichenoid.<sup>207,208</sup> Relapses and remission are common. Erythema nodosum is the second most common skin manifestations of Blau syndrome, and leukocytoclastic vasculitis involving skin has also been described.

Boggy synovitis and tenosynovitis of the wrists, fingers, knees, and ankles are characteristic and show symmetric nonerosive arthritis radiographically.<sup>209</sup> Despite the chronicity, joint destruction is uncommon, and range of motion is usually not reduced, in contrast to the arthritis of JIA. However, the proximal interphalangeal joints disproportionately develop contractures, leading to camptodactyly (usually congenital flexion contracture of a finger).<sup>210</sup> Bone dysplasia can also be seen.

Ocular involvement is extremely common in children,<sup>211</sup> especially an insidious bilateral granulomatous iridocyclitis with uveitis that involves not just the anterior uveitis (as in JIA), but also posterior uveitis. The mean age of onset of ocular disease is 4 years, and it ultimately develops in 80% of patients.<sup>201</sup> Keratitis, retinitis, optic

**Figure 25-22** Blau syndrome. Discrete, erythematous papules were present in a generalized distribution in this young boy with arthralgias. Biopsy showed noncaseating granulomas.

**Figure 25-23** Blau syndrome/early-onset sarcoidosis. Erythematous granulomatous papules on the arm, trunk, and thigh of a 5-year-old boy with a *CARD15* mutation.

atrophy, glaucoma, cataracts, retinal detachment, and involvement of the eyelids and lacrimal glands may also occur. Of those with ocular involvement, 11% show moderate visual impairment and 16% become blind.

Other manifestations are noted in about one-third of patients. In addition to the erythema nodosum, low-grade fever, and sialadenitis with parotid gland enlargement, splenomegaly and lymphadenopathy are relatively common. Other signs are large vessel vasculitis, cranial (but not central) neuropathy, interstitial lung disease, interstitial nephritis, pericarditis, and hepatomegaly without abnormal hepatic function.

The susceptibility gene for Blau syndrome, also known as *familial granulomatous arthritis*, is *CARD15* (also known as *NOD2*).<sup>212</sup> Mutations in *CARD15* lead to constitutive activation of NF-κB signaling. Mutations in *CARD15/NOD2* have also been associated with the development of Crohn disease, but mutations that increase the susceptibility to Crohn disease versus Blau syndrome are in regions.<sup>213,214</sup> The cutaneous granulomatous papules may respond to chronic administration of erythromycin but may leave tiny atrophic macules. Methotrexate and TNF-α inhibitors are most often used for extracutaneous manifestations; thalidomide and IL-1 inhibition have also been reported to be effective.<sup>215,216</sup>

## Auto-Inflammatory Disorders

### HEREDITARY PERIODIC FEVER SYNDROMES

The auto-inflammatory disorders are a group of monogenic inherited disorders characterized by intermittent or fluctuating degrees of inflammation, particularly of the abdomen, skin, and joints, without evidence of high-titer autoantibodies or antigen-specific T cells (Table 25-6).<sup>217-220</sup> One group of auto-inflammatory disorders, inflammasomopathies, results from abnormalities of the inflammasome. The inflammasome is a macromolecular complex that senses microbial products and endogenous “danger signals” to activate caspase-1 and ultimately IL-1β, key steps in the innate immune response. Some of these are intrinsic defects of the inflammasome, such as the cryopyrinopathies (defective cryopyrin leads to familial cold auto-inflammatory syndrome [FCAS], Muckle–Wells syndrome [MWS], and neonatal onset multisystemic inflammatory disorder). Others result from abnormalities or deficits in proteins that interact directly or indirectly with the inflammasome, such as pyrin (hereditary periodic fever syndromes) and PSTPIP1 (pyogenic sterile arthritis, pyoderma gangrenosum, and acne [PAPA] syndrome). The hereditary periodic fever syndromes (familial Mediterranean fever [FMF], mevalonate kinase deficiency, and TNF receptor-associated periodic syndrome) show recurrent episodes of fever, often in association with a cutaneous eruption, serositis (peritonitis, pleuritis), arthritis, and lymphadenopathy. Progressive amyloidosis of the liver and kidneys has been reported in association with several types of periodic fever syndromes and may be life-threatening.

The pyogenic auto-inflammatory disorders include PAPA; periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA); and synovitis, acne, palmoplantar pustulosis and psoriasis, hyperostosis, and osteitis (SAPHO) syndromes (see Chapter 8) and deficiencies of the IL-1 receptor antagonist (DIRA) and interleukin-36 receptor antagonist (DITRA); they feature neutrophilic infiltration, with clinical features that include pyogenic arthritis, aphthous ulcerations, pyoderma gangrenosum-like lesions, and pustular skin eruptions.<sup>221,222</sup> Auto-inflammatory disorders such as Crohn disease and Blau syndrome (see Sarcoidosis section) are related to sequence variations in *NOD2/CARD15*, which plays a central role in the NF-κB activation response to microbial products. Among other disorders considered auto-inflammatory are Behcet syndrome and systemic onset JIA (see Chapter 22).<sup>223-226</sup>

### HEREDITARY PERIODIC FEVER SYNDROMES

#### Familial Mediterranean Fever

Familial Mediterranean fever (FMF; benign paroxysmal peritonitis, familial paroxysmal polyserositis, familial recurrent polyserositis, Armenian disease) is the prototype of the hereditary auto-inflammatory disorders.<sup>227-229</sup> An autosomal recessive disorder, FMF results from loss-of-function mutations in *MEFV* (Mediterranean fever gene), which encodes pyrin (or marenostatin).<sup>230</sup> Pyrin is thought to act as an anti-inflammatory molecule of polymorphonuclear leukocytes and cytokine-activated monocytes. The disorder is most commonly seen in individuals of Arabic, Turkish, or non-Ashkenazi Jewish descent, in which the gene is carried in one of five persons.

The acute attacks of high fever and serositis (peritonitis, pleuritis, and synovitis, with abdominal, chest, and articular pain) begin during the first decade in 67% of cases and by the second decade in 90%. The attacks typically last 1 to 3 days. The erysipelas- or cellulitis-like

**Figure 25-24** Familial Mediterranean fever. Erythematous nodules on the dorsal aspect of the foot and pretibial area of an affected child. (Courtesy of James E. Rasmussen, MD; reprinted from Hurwitz S. The skin and systemic disease in children. Chicago: Year Book Medical Publishers, 1985.)

lesions, the most common cutaneous manifestations, occur in almost 10% of patients (Fig. 25-24).<sup>231</sup> Of importance, these painful, warm, swollen erythematous, well-defined plaques can occur in children without a history of fevers, although acute phase reactants are increased.<sup>232</sup> Both the skin signs and the arthritis may be precipitated by trauma. Other cutaneous manifestations include urticaria, erythematous papules, vesicles, bullae, and subcutaneous nodules histologically resembling periarteritis nodosa or vasculitis. Skin lesions usually appear on the calves, around the ankles, and on the dorsal aspects of the feet.

Usually a single organ is affected during an attack. Attacks last from a few hours to 4 days and recur throughout life with variable periodicity. Asymptomatic intervals may last as long as several years. Although symptoms of the monoarticular joint inflammation persist longer than episodes of peritonitis, sometimes for several months, chronic residual manifestations are rare.

Amyloidosis occurs in about 25% of untreated patients and causes death in 90% of individuals affected with amyloid-induced renal dysfunction before the age of 40. The risk of developing amyloidosis is a function of the duration between disease onset and diagnosis, and of

**Table 25-6** Auto-Inflammatory Disorders

<b>Disorder</b>	<b>Inheritance</b>	<b>Gene Defect</b>	<b>Gene Product</b>	<b>Associated Features</b>
<b>GRANULOMATOUS</b>				
Blau syndrome	AD	<i>NOD2/CARD15</i>	CARD15	Onset usually <5 years old Granulomatous dermatitis, uveitis, synovitis Good response to TNF inhibitors
<b>PERIODIC FEVERS</b>				
Familial Mediterranean fever	AR	<i>MEFV</i>	Pyrin (marenostrin)	Recurrent fever of short duration (24–48 h) Serositis with abdominal pain, pleuritis and chest pain Pericarditis, scrotal swelling, splenomegaly, erysipelas-like eruption in minority of patients High risk of renal amyloidosis if untreated Good response to colchicine, IL-1 blockade
TNF receptor-associated periodic syndrome (TRAPS)	AD	<i>TNFRSF1A</i>	P55 TNF receptor	Recurrent fevers that are prolonged (1–3 weeks) Serositis, rash, conjunctivitis, periorbital edema, arthritis 10% to 25% incidence of renal amyloidosis Response to etanercept and IL-1 blockade
Mevalonate kinase deficiency (MVK)	AR	<i>MVK</i>	Mevalonate kinase	Early onset (usually first year) Periodic fever lasting 4–5 days
Hyper-IgD syndrome (HIDS)				Urticular eruption (>90%), abdominal pain with vomiting and diarrhea, arthritis Headache, hepatosplenomegaly, painful cervical adenopathy, aphthous stomatitis, leukocytosis, high levels of IgD Response to steroids, NSAIDs, simvastatin, IL-1 blockade Often improves by adulthood Amyloidosis rare*
<b>CRYOPYRINOPATHIES</b>				
Familial cold auto-inflammatory syndrome (familial cold urticaria)	AD	<i>CIA1</i>	Cryopyrin	Cold-induced nonpruritic urticaria, arthritis, fever and chills, leukocytosis Responds to IL-1 blockade
Muckle–Wells syndrome	AD	<i>CIA1</i>	Cryopyrin	Recurrent urticaria, sensorineural hearing loss, amyloidosis Responds to IL-1 blockade
Neonatal onset multisystem disease (NOMID) <sup>†</sup>	AD	<i>CIA1</i>	Cryopyrin	Neonatal onset urticaria, chronic aseptic meningitis, arthropathy and bone deformities, fever, ocular changes and hearing loss Responds to IL-1 blockade
<b>PYOGENIC</b>				
Pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome	AD	<i>PSTPIP1/C2BP1</i>	PSTPIP1/C2BP1	Pyogenic (sterile, destructive) arthritis, pyoderma gangrenosum, acne, myositis
Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) syndrome	Unknown	Unknown	Unknown	Periodic fevers, aphthous stomatitis, pharyngitis, and cervical adenitis Malaise, headache
Majeed syndrome	AR	<i>LPIN2</i>	Lipin-2	Multifocal osteomyelitis, congenital dyserythropoietic anemia, inflammatory dermatosis Responds to IL-1 blockade
Deficiency of the IL-1 receptor antagonist (DIRA)	AR	<i>IL1RN</i>	IL-1 receptor antagonist	Fetal distress, joint swelling with periosteal inflammation, severe osteopenia, lytic bone lesions, respiratory involvement, thromboses, aphthae, pyoderma gangrenosum, pustulosis Responds to IL-1 blockade
Deficiency of the IL-36 receptor antagonist (DITRA)	AR	<i>IL36RN</i>	IL-36 receptor antagonist	Usually generalized pustules, fever and malaise May have palmoplantar pustulosis or AGEP-like disorder Nail dystrophy, arthritis, cholangitis
CARD14-mediated pustular psoriasis (see Ch. 4)	AD	<i>CARD14</i>	CARD14	Pityriasis rubra pilaris, plaque psoriasis, erythroderma with pustular psoriasis Usually responds to ustekinumab May respond to methotrexate TNF inhibitor
Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE) syndrome (see Ch. 20)	AR	<i>PSMB8</i>	Proteasome subunit β type	Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (fever), lymphadenopathy, purpuric patches and nodules, arthralgias Same as Nakajo–Nishimura syndrome May respond to JAK inhibitor
STING-associated vasculopathy with onset in infancy (SAVI) syndrome	AD	<i>TMEM173</i>	STING	Acral telangiectatic vasculopathy with soft tissue loss, sometimes large pustules Fevers, adenopathy, interstitial lung fibrosis May respond to JAK inhibitor

AD, Autosomal dominant; AGEP, acute generalized exanthematous pustulosis; AR, autosomal recessive; Ig, immunoglobulin; IL, interleukin; NSAID, nonsteroidal anti-inflammatory drug; STING, stimulator of interferon genes; TNF, tumor necrosis factor.

\*Amyloidosis is unusual in Blau, HIDS, PAPA and PFAPA syndromes.

<sup>†</sup>Also called chronic infantile neurologic cutaneous and articular (CINCA) syndrome.

the frequency of episodes of chest pain, arthritis, and erysipelas-like erythema.<sup>233</sup>

The diagnosis of FMF is dependent on clinical features and, as needed, genetic testing. Colchicine (1 to 2.5 mg/kg per day) prevents the recurrence of attacks and the amyloidosis<sup>234,235</sup>; once daily usage may be as effective and safe as two to three divided daily doses.<sup>236</sup> Anakinra (directed against IL-1), interferon- $\alpha$ , corticosteroids, and cyclophosphamide have been used in rare patients who are unresponsive to colchicine.<sup>237,238</sup> FMF patients carrying a *CARD15/NOD2* mutation have a higher rate of erysipelas-like erythema and acute scrotum attacks, a trend for a higher rate of colchicine resistance, and a more severe disease as compared with patients without mutations.<sup>239</sup>

### TNF Receptor-Associated Periodic Syndrome

TNF receptor-associated periodic syndrome (TRAPS) is an autosomal dominant disorder caused by mutations in the p55 TNF receptor (*TNFR1*), encoded by *TNFRSF1A*,<sup>240</sup> or defects in shedding of the receptor.<sup>241-244</sup> The febrile attacks tend to last longer than those of FMF, at least 5 days and sometimes up to 3 weeks (mean, 11 days with 70 symptomatic days per year).<sup>245</sup> They usually have no periodicity, despite the name, but are recurrent rather than continuous with flares in almost 90% of affected individuals.<sup>244</sup> Fever always occurs in children but is sometimes absent in adults. Only 25% of patients can identify triggers, and a minority have prodromal symptoms (periorbital edema, malaise, headache). Manifestations usually begin during childhood in more than 90% of patients (median age of symptom onset of 3 to 4 years old), and more than 75% of patients have cutaneous involvement.<sup>246</sup> Most typical is the erythematous swollen plaque with indistinct margins that is warm and tender to palpation. It is most commonly located on the extremities, where it may begin distally and migrate proximally during the attack. The eruption is described as maculopapular or urticarial, each in approximately 25% of patients. Localized or generalized serpiginous erythematous patches and plaques and pseudofolliculitis have also been described. Painful myalgias accompany the eruption in 70% of patients and may precede the appearance of cutaneous signs. Severe abdominal pain and arthralgias or occasionally arthritis occur in most patients, but thoracic and scrotal pain, orbital edema, and conjunctivitis are also common complaints. Amyloid deposition, especially in the kidneys and liver, is described in 10% to 25% of individuals with TRAPS at a median age of 43 years.

The diagnosis of TRAPS can be confirmed by gene testing. Corticosteroids are the most effective treatment, but daily administration has been required; NSAIDs provide symptomatic relief. TNF- $\alpha$  inhibitors (etanercept),<sup>247</sup> anakinra,<sup>248</sup> and tofacitinib have been efficacious in some patients, but infliximab and adalimumab may induce paradoxical inflammatory reactions,<sup>249,250</sup> which may be mutation dependent.

### Periodic Fever Associated with Mevalonate Kinase Deficiency (Hyperimmunoglobulin D Syndrome)

Periodic fever associated with mevalonate kinase deficiency (MKD, or hyper-IgD syndrome [HIDS]) is an autosomal recessive disorder that presents during the first 6 months of life in 60% of patients and by 5 years of age in 92%.<sup>251</sup> More than 90% of patients show the cutaneous eruption of erythematous maculopapules or papules. Fever is also often associated with lymphadenopathy (71%), diarrhea (69%), joint pain (67%), abdominal pain (63%), and splenomegaly (63%). The high serum level of IgD distinguishes this periodic fever from FMF.<sup>252</sup> Inflammatory attacks typically last approximately 1 week and recur every 4 to 8 weeks. Renal deposition of amyloid is rare.<sup>253</sup>

Mutations in MVK lead to deficient mevalonate kinase,<sup>254,255</sup> disruption of cholesterol biosynthesis, and a shortage of isoprenoid end products, leading to inflammasome activation and IL-1 mediated inflammation.<sup>256,257</sup> Complete deficiency of mevalonate kinase (vs. the 1% to 8% residual activity in MKD) results in mevalonic aciduria, which is associated with growth and mental retardation and morphologic abnormalities, in addition to recurrent fevers, rash, lymphadenopathy, and inflammation of the joints and gastrointestinal tract. Definitive diagnosis of HIDS cannot rely on the demonstration of high levels of IgD, because this has now been shown in some patients with

FMF and TRAPS, but rather depends on finding evidence of MKD or mevalonic aciduria.

Fevers respond dramatically to steroids, but the frequent recurrence of fevers makes steroid therapy untenable. IL-1 inhibitors are the treatment of choice.<sup>258</sup> However, other cytokines are activated as well,<sup>259</sup> and in patients in whom IL-1 inhibition is insufficient, TNF inhibitors<sup>260,261</sup> and tofacitinib may decrease the inflammation. Administration of simvastatin improves inflammatory attacks; simvastatin inhibits 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, which precedes mevalonate kinase in the isoprenoid pathway.<sup>262</sup>

### THE CRYOPYRINOPATHIES: FAMILIAL COLD AUTO-INFLAMMATORY, MUCKLE-WELLS, AND CINCA/NOMID SYNDROMES

Although originally described as separate disorders, these three autosomal dominant syndromes are now known to be caused by mutations in the gene *NLRP3/CIA1* (cold-induced auto-inflammatory syndrome).<sup>263,264</sup> This gene encodes cryopyrin (or NALP3), which forms a complex that activates caspase 1. Caspase 1 cleaves the inactive IL-1 $\beta$  to the active form of IL-1 $\beta$ . The recent demonstration of IL-17-associated neutrophil recruitment suggests IL-1-induced activation of Th 17 cells and that IL-17/IL-17RA inhibitors may be new therapeutic targets.<sup>265</sup> The mutations that result in the different syndromes are largely distinct.

Recurrent urticarial-like eruptions are common to all three syndromes. In FCAS (familial cold urticaria), the mildest condition of the group, the urticaria is delayed in its onset, usually a few hours after exposure to cold, and persists for less than 24 hours. Fever, conjunctivitis, and arthritis are also seen in association.<sup>266</sup> FCAS must be distinguished from FCAS2, a newly described autosomal dominant disorder caused by mutations in *NLRP12* and responsive to IL-1 inhibition. FCAS2 is characterized by recurrent cold-induced episodes of fever, urticarial eruption, aphthous stomatitis, adenopathy, and abdominal discomfort. Dominant missense mutations in *PLCG2*, encoding phospholipase Cy2, lead to phospholipase Cy2-associated antibody deficiency and immune dysregulation (PLAID) syndrome, characterized by evaporative cold urticaria (see Chapter 20). The onset may be as early as the neonatal period with vesiculopustules and recurrent erythematous granulomatous plaques.<sup>266,267</sup> Other features may include interstitial pneumonitis and bronchiolitis, arthralgia, enterocolitis, ocular issues, and mild immunodeficiency.

MWS is an autosomal dominant auto-inflammatory disorder characterized by recurrent urticarial eruption, arthralgias, conjunctivitis, sensorineural hearing loss, and risk of reactive AA amyloidosis resulting from the progressive visceral accumulation of amyloid fibrils. Proteinuria or renal insufficiency from renal amyloidosis can be observed in up to 25% of patients. Female sex and hearing loss are risk factors for more severe disease.<sup>268</sup>

Chronic infantile neurologic cutaneous and articular (CINCA), or neonatal onset multisystemic inflammatory disease (NOMID), syndrome typically presents as fever and nonpruritic urticarial erythema during the first week of life.<sup>269,270</sup> The urticarial rash usually begins on the extremities and tends to migrate, even during examination. It has a waxing and waning course but never tends to resolve entirely.<sup>271</sup> Arthralgias and arthritis develop early during the first weeks of life and are thereafter persistent, leading to disabling destructive arthropathy during infancy. Bony deformities, especially of the knees, are characteristic, with distinctive radiographic findings of patellar and long bone ossification with overgrowth. Chronic aseptic meningitis has been associated with headaches in older children, and patients may have seizures, spasticity, and motor defects. Some affected children have developed brain atrophy during the neonatal period, which has been linked to developmental delay and retardation. Papillitis with optic atrophy and anterior uveitis are the most common ocular manifestations, with a mean age of onset of 4.5 years; severe visual loss occurs in 26% of patients with ocular disease.<sup>272</sup> Bilateral sensorineural progressive hearing loss is commonly associated as well. Most patients show a typical angelic facies with frontal bossing, a saddleback nose, and midfacial hypoplasia. Lymphadenopathy, splenomegaly, premature atherosclerosis,<sup>273</sup> increased ESR, eosinophilia,

leukocytosis, and hyperglobulinemia are features of chronic inflammation. Early death has been linked to infection, vasculitis, and amyloidosis.

IL-1 inhibitors such as anakinra and canakinumab usually lead to rapid resolution of inflammation in cryopyrin-associated autoinflammatory syndromes (CAPS).<sup>274–277</sup> Canakinumab administration every 8 weeks is well tolerated and leads to a complete response in 78% of treated individuals within 1 week and virtually all patients by 3 weeks of after administration.<sup>278,279</sup> Canakinumab has also been shown to improve kidney function in MWS with overt renal amyloidosis.<sup>280</sup> TNF inhibitors and stem-cell transplantation have been used for severely affected patients who fail to respond to IL-1 inhibition. MCC950, a small molecule inhibitor of NLRP3, reduced IL-1 $\beta$  and showed promise in a mouse model and *ex vivo* samples from individuals with MWS.<sup>281</sup>

### PERIODIC FEVER, APHTHOUS STOMATITIS, PHARYNGITIS, AND CERVICAL ADENITIS SYNDROME

Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) syndrome (or Marshall syndrome) is the most common periodic fever syndrome and occurs primarily in children under 5 years of age.<sup>282</sup> Affected children have a mean of 4 to 5 days of fever greater than 39°C, which recurs regularly every 3 to 8 weeks. Pharyngitis has been described in almost 90% of patients, cervical adenitis in 78%, and stomatitis in 38% to 71%.<sup>283,284</sup> Attacks of mild abdominal pain, vomiting, headache, and malaise are common; arthralgias, genital ulceration,<sup>285,286</sup> erythematous cutaneous eruptions and neurologic signs are uncommon.

Familial cases are often described, but it is unclear if these cases reflect a genetic or environmental predisposition.<sup>282,287–289</sup> Approximately 20% of affected individuals have NLRP3 variants, suggesting that inflammasome-related genes might be involved.<sup>290</sup> IL-1 $\beta$  monocyte production is dysregulated in patients with PFAPA syndrome, with elevation in IP-10/CXCL10 chemokines.

Other inflammatory disorders with fever, including infectious disorders, must be considered. The fever tends to be poorly responsive to acetaminophen or ibuprofen. Short courses (one or two doses) of corticosteroids can be highly effective in controlling symptoms but may shorten the duration of remission.<sup>291</sup> Patients have been shown to respond to IL-1 inhibition.<sup>292</sup> Tonsillectomy has also been associated with improvement.<sup>293,294</sup> Tonsils of patients with PFAPA syndrome have shown significant increases in *Candida albicans* and biofilm formation compared with controls, but less *S. aureus*, *Varicella zoster*, and herpes simplex virus, and no difference in group A  $\beta$ -hemolytic *Streptococcus*.<sup>295</sup> In most patients, episodes tend to occur less often or disappear with advancing age, without any long-term sequelae.<sup>296</sup>

### Deficiency of the Interleukin-1 Receptor Antagonist

Deficiency of the IL-1 receptor antagonist (DIRA) is a recently described autosomal recessive disorder<sup>297,298</sup> in which IL-1 activity is markedly increased because of deficiency of an antagonist that also binds to the IL-1 receptor and prevents IL-1 activity.<sup>299</sup> Affected infants and young children show fetal distress, joint swelling with periosteal inflammation, severe osteopenia with lytic bone lesions, respiratory involvement, thrombotic episodes, oral mucosal and cutaneous pyoderma gangrenosum-like ulcerations, and a localized to generalized pustular eruption that resembles pustular psoriasis (Fig. 25-25). Fever occurs occasionally (not periodically) and only in a few patients. DIRA must be also be distinguished from Majeed syndrome, an autosomal recessive disorder that also features chronic recurrent multifocal osteomyelitis and an inflammatory dermatosis that can vary from a Sweet syndrome-like eruption to chronic pustulosis; Majeed syndrome features congenital dyserythropoietic anemia, results from mutations in *LPIN2*, encoding lipin-2, and responds well to IL-1 inhibition.<sup>300</sup> Administration of anakinra (2 mg/kg per day) dramatically reverses the inflammatory manifestations, whereas other systemic immunomodulators have largely failed to cause improvement.

### Deficiency of the Interleukin-36 Receptor Antagonist

Another rare autosomal recessive auto-inflammatory disorder associated with a pustular psoriasis-like eruption is deficiency of the IL-36

**Figure 25-25** Deficiency of IL-1 receptor antagonist. This Puerto Rican boy with failure to thrive and multifocal lytic lesions of bone showed numerous plaques of erythematous pustules.

**Figure 25-26** Stimulator of interferon genes (STING)-associated vasculopathy with onset in infancy (SAVI) syndrome. These two unrelated boys both show the acral telangiectatic vasculopathy of SAVI syndrome. One of these boys died at 14 years of age because of his pulmonary disease.

receptor antagonist (DITRA), caused by mutations in *IL36RN*, encoding the IL-36 receptor antagonist.<sup>217,301,302</sup> The IL-36 receptor antagonist inhibits NF- $\kappa$ B activation by IL-36 $\alpha$ ,  $\beta$ , and  $\gamma$ . The disorder may have its onset during infancy or childhood, or less commonly during adulthood, and should be considered in adult patients with generalized pustular psoriasis without a history of plaque psoriasis.<sup>303</sup> Rather than generalized pustules with high fevers and malaise, affected individuals may have pustules localized to the palms and soles that may even resemble acute generalized eruptive pustulosis (AGEP) (see Chapter 20). Nail dystrophy, arthritis, and/or cholangitis have been noted in the minority of patients.<sup>302</sup> Bacterial or viral infections and menstruation may be triggers. Patients often respond to systemic retinoids, but steroids, methotrexate, cyclosporine, and anakinra have also been used. DIRA and DITRA need to be distinguished from *CARD14*-mediated pustular psoriasis, an autosomal dominant disorder in which affected children may manifest symptoms of pityriasis rubra pilaris, plaque psoriasis, erythrodermic psoriasis, pustular psoriasis, or an overlap disorder (see Chapter 4).

### STING-Associated Vasculopathy with Onset in Infancy (SAVI) Syndrome

Stimulator of interferon genes (STING)-associated vasculopathy with onset in infancy (SAVI) syndrome is a recently described disorder characterized by the onset by 6 months of telangiectatic vasculopathy (Fig. 25-26)<sup>304</sup> with pustules and residual scarring and soft-tissue loss. Lesions are characteristically localized to the hands, feet, nose, cheeks, and ears with exacerbations in cold weather. Patients have systemic inflammation (increased ESR and C-reactive protein) with

intermittent low-grade fevers, hilar or paratracheal adenopathy, and interstitial lung fibrosis. The disorder results from heterozygous mutations in *TMEM173*, encoding STING.

## Pyoderma Gangrenosum

Pyoderma gangrenosum is a severe, chronic, inflammatory disorder of the skin characterized by a painful sloughing ulceration with purulent or vegetative base and an elevated dusky blue or reddish purple undermined border surrounded by a rim of inflammation (Fig. 25-27; see Fig. 25-18).<sup>305</sup> The lesion usually begins as a tender papulopustule or erythematous nodule that undergoes necrosis and ulcerates. The ulceration heals with cribriform scarring (Fig. 25-28). Lesions in older children and adolescents (as in adults) are most often found on the lower extremities (especially the anterior tibial surface) but can be seen anywhere on the body, including mucosal and peristomal sites.<sup>306</sup> The head, airway, and anogenital areas are more common sites of involvement in neonates, infants, and younger children.<sup>307–310</sup> Pustular, bullous, and superficial<sup>311</sup> variants have been described. The

**Figure 25-27** Pyoderma gangrenosum. Painful leg ulceration with an inflamed, undermined border. Note the pustule distal to the ulceration, often the earliest sign of a new site of involvement. The most common underlying condition in affected children is inflammatory bowel disease, although no underlying abnormality may be discovered.

**Figure 25-28** Pyoderma gangrenosum. Partial response to treatment with cyclosporine. Note the persistent inflammation and evidence of healing ulcerations with residual cribriform scarring. The pyoderma gangrenosum healed fully and remained quiescent while the child was given etanercept, but this young boy developed Takayasu disease several years after onset of the pyoderma gangrenosum despite ongoing inhibition of TNF- $\alpha$  activity.

bullous form may be difficult to distinguish from bullous Sweet syndrome (see Chapter 20). Pulmonary and splenic lesions have been described.<sup>312</sup> The diagnosis is based on clinical features. Biopsy findings are nonspecific, but special stains and cultures of biopsy specimens may help to distinguish pyoderma gangrenosum from other disorders, including vasculitis and infectious causes of ulceration.

Although virtually always described in adults, 4% of cases have occurred in infants and children.<sup>313,314</sup> Pathergy (the development of lesions at sites of minor trauma), which occurs in 20% of patients with this disorder, may be more common in childhood cases; in a recent report, an abused child developed pyoderma gangrenosum at multiple sites of physical abuse.<sup>315</sup> Although the disorder may occur without associated disease, including in siblings,<sup>316</sup> it usually develops in pediatric patients with any of a variety of systemic disorders. Most common in children is inflammatory bowel disease (especially ulcerative colitis; see Crohn Disease section), but immunodeficiency (especially HIV infection, leukocyte adhesion defect,<sup>317,318</sup> SCID,<sup>319</sup> CVID<sup>320</sup>), hematologic disorders (especially leukemia),<sup>321,322</sup> Takayasu disease with or without airway or pulmonary disease,<sup>323–325</sup> and rheumatic disorders (especially JIA, systemic lupus erythematosus, Henoch-Schönlein purpura, and in association with antiphospholipid antibodies)<sup>326,327</sup> have all been reported. Pyoderma gangrenosum can also be seen during adolescence in patients with PAPA syndrome, chronic recurrent multifocal osteomyelitis,<sup>328</sup> and SAPHO syndrome.<sup>329</sup> In children with the onset during infancy, Takayasu disease is the most common association and may occur years after the onset of the pyoderma gangrenosum.

Treatment of pyoderma gangrenosum involves use of systemic and topical anti-inflammatory medications to promote wound healing and decrease pain, as well as a vigorous attempt to control the underlying disease. Debridement and other mechanical trauma may worsen the ulcerations and should be avoided. Systemic corticosteroids are usually the initial drug of choice. Cyclosporine or systemic tacrolimus,<sup>330</sup> TNF- $\alpha$  inhibitors (etanercept, adalimumab, infliximab),<sup>331–336</sup> dapsone, clofazimine, MMF, and intravenous Ig<sup>337</sup> have been used successfully as steroid-sparing agents. Topical tacrolimus ointment applied a few times daily has improved ulcer healing<sup>338</sup>; intralesional steroid injections may be appropriate for adolescents.

## PYOGENIC STERILE ARTHRITIS, PYODERMA GANGRENOSUM, ACNE SYNDROME

This autosomal dominant disorder is characterized by pyoderma gangrenosum-like ulcerative lesions, usually in the second decade of life; severe cystic acne; and episodes of inflammatory arthritis that lead to significant joint destruction.<sup>339,340</sup> Pyoderma gangrenosum lesions are usually seen on the leg but may occur at acne sites (Fig. 25-29). Sterile abscesses have been described at sites of parenteral injections. Affected family members may show variable expressivity. Mutations occur in *PSTPIP1/CD2BP1*, which encodes CD2-binding protein 1, a protein that interacts with pyrin.<sup>341</sup> PAPA syndrome is treated with oral corticosteroids, and marked improvement has been noted with TNF inhibitors and anti-IL-1 treatment.<sup>225,342</sup> The acne can be controlled with isotretinoin administration.<sup>343</sup> Pyoderma gangrenosum and acne have also been associated with suppurative hidradenitis, comprising PASH syndrome.<sup>344–346</sup>

## Behçet Syndrome

Behçet syndrome is a chronic multisystemic auto-inflammatory disease characterized by recurrent oral and genital ulcerations and inflammatory disease of the eye.<sup>347</sup> Although even neonatal onset without maternal Behçet syndrome has been noted,<sup>348</sup> Behçet syndrome usually begins in patients between 10 and 45 years of age, with approximately 17% of cases beginning before 17 years of age.<sup>349</sup> Neonatal Behçet syndrome usually occurs in infants born to mothers with the disease and generally disappears spontaneously by the time the infants reach the age of 6 months. Characterized by aphthous stomatitis and skin lesions, affected neonates rarely have severe, life-threatening complications.<sup>350,351</sup> Although most studies have suggested that Behçet syndrome has a predilection for males,<sup>352</sup> including

**Figure 25-29** Pyogenic sterile arthritis, pyoderma gangrenosum, acne (PAPA) syndrome. This 11-year-old boy had small inflammatory papules of acne, which rapidly became purulent plaques (as shown) and then ulcerated to form pyoderma gangrenosum, leaving residual scars. He also had arthritis. His disease was brought under control with golimumab (TNF inhibitor) and isotretinoin.

**Figure 25-30** Behçet syndrome. Major and minor aphthae on the tongue. Note the scalloping of the tongue border from past scarring lesions.

in pediatric patients, a recent international registry enrolled equal numbers of boys and girls.<sup>353</sup> In general, the disease is less severe and more delayed in its full manifestation in pediatric patients.<sup>354</sup>

The pathomechanism for Behçet disease is not understood, although the majority of patients in several studies carry HLA-B51 alleles, the strongest known risk factor.<sup>355,356</sup> Some 15% to 45% of children have an affected family member, in contrast to 8% of adults.<sup>349,357</sup> The demonstrated activation of inflammatory cytokines TNF- $\alpha$ , IL-1 $\beta$ , and IL-6 has lead to new therapeutic approaches.

Cutaneous and oral lesions are the most common clinical features of pediatric Behçet disease.<sup>357-359</sup> Oral lesions, noted at some point in the course of virtually every affected child, are the initial manifestation in 83% of pediatric patients<sup>358</sup> and occur approximately 8 years before other signs.<sup>360</sup> The ulcerations begin as erythema, and within 1 to 2 days become superficial erosions that range from smaller ulcerations, indistinguishable from aphthous stomatitis, to deeply punched-out necrotic ulcers on the lips, buccal mucosa, tongue (Fig. 25-30), and less commonly, the gingivae. They have regular sharp edges and vary from a few millimeters to a centimeter in diameter. Minor aphthae have a diameter of less than 1 cm, resolve in 7 to 10 days, do not scar, and are most common, whereas major aphthae are larger, deep, more painful, and tend to scar. Sometimes aphthae are grouped (herpetiform aphthae). The ulcer base is covered with a yellowish-gray exudate, and the margin is surrounded by a red halo. Oral lesions in recur at intervals varying from weeks to months; by definition, aphthae

**Figure 25-31** Behçet syndrome. Vulvar ulcerations.

**Figure 25-32** Behçet syndrome. Genital region ulcers on the glans penis and foreskin, in a boy with a positive family history of Behçet syndrome and HLA-B51 positivity.

must recur at least 3 times yearly. Features of Behçet syndrome and relapsing polychondritis have also been described as the mouth and genital ulcers with inflamed cartilage (MAGIC) syndrome.

Genital ulcerations are seen in 60% of children with Behçet syndrome, and occur more often in girls than in boys. They are found on the vulva and vagina of females (Fig. 25-31) and the scrotum or base of the penis in males. They are similar in appearance to the oral ulcerations but less painful and may be overlooked. Perianal ulcerations are less common but have been noted more often in children than in adults (up to 30%). Genital ulcerations are usually deeper than oral ulcerations (Fig. 25-32) and may scar. As with oral ulcerations, they remit in 1 to 2 weeks and tend to recur.

Cutaneous lesions of Behçet syndrome present a varied picture. Seen in approximately 80% of affected children, they consist of folliculitis, pustules, pyoderma, acneiform lesions, furuncles, abscesses, ulcerations, erythema nodosum-like lesions, and palpable purpura (Fig. 25-33). Pathergy (the formation of an ulceration at an area of trauma, skin prick, or venipuncture) is typical.

Ocular lesions, seen in approximately 50% of boys but only 15% to 20% of affected girls, are less common than in adults, but associated with a worse prognosis. Conjunctivitis and photophobia may be early ocular findings, but bilateral panuveitis is the most common manifestation (more than 80% of children with eye findings)<sup>361</sup>; posterior uveitis is found more often than anterior uveitis. Retinal vasculitis and retinitis occur in the majority of children with ocular features, and cataracts, maculopathy and optic atrophy have been described.

Fever and constitutional symptoms are variable. Musculoskeletal complaints, especially arthralgia and arthritis, are found in up to 75%

**Figure 25-33** Behcet syndrome. Palpable purpura on the inner thighs and glans penis of this boy with Behcet syndrome. Superficial ulcerations were also noted on the penile shaft. Biopsy of affected areas showed leukocytoclastic vasculitis.

### Box 25-3 Proposed Criteria for Diagnosis of Pediatric Behcet Disease

Oral aphthous stomatitis, occurring at least three times yearly  
Plus at least one of the following:

- Genital ulceration
- Erythema nodosum
- Pustular/acneiform lesions
- Folliculitis
- Positive pathergy testing
- Uveitis
- Venous/arterial thrombosis
- Family history of Behcet disease

The diagnosis is usually definite with three or more features.

of affected children. Gastrointestinal complaints are more common in children than in adults<sup>362</sup> and may warrant endoscopic evaluation, especially in children under 10 years of age. They range from vague abdominal pain (up to 50%) and anorexia to diarrhea and hemorrhagic colitis. Central nervous system involvement, often the most severe prognostic feature of this disorder, is seen in 20% to 50% of patients, often manifests as headache, and most commonly involves cerebral venous sinus thrombosis.<sup>352</sup> Arterial or venous thrombosis can also affect the lower extremities and can be recurrent.<sup>363,364</sup> Renal involvement, an uncommon complication, may be seen with a spectrum ranging from asymptomatic abnormalities detected on urinalysis to a rapidly progressive glomerulonephritis and nephrosis. Other unusual findings in children include pericarditis, orchitis, and epididymitis.

The diagnosis of Behcet syndrome in a patient with the full triad of oral and genital ulcers and ocular inflammation is not difficult. Two or more major criteria (oral, genital, ocular, or cutaneous involvement) or a combination of major and minor criteria (vascular, neurologic, musculoskeletal, or intestinal involvement), however, allow diagnosis. Having three or more features of Behcet syndrome is highly associated with definitive diagnosis but is only present in 31% of children<sup>360</sup> (Box 25-3). Biopsy is usually not helpful, but having HLA-B51 positivity can be useful supporting evidence of the diagnosis. Although pathergy is common and a helpful criterion to the diagnosis, it may also be seen in children with pyoderma gangrenosum, leukemia, and bowel bypass syndrome (see Chapter 20); a negative pathergy test does not rule out the diagnosis.

Treatment of the aphthous ulcers with potent topical or intralesional corticosteroids, topical application of tacrolimus, oral rinses with elixir of diphenhydramine, or application of 2% viscous lidocaine can give symptomatic relief. For mucocutaneous ulcerations, colchicine is often helpful. Therapy is begun with a dosage of 0.6 mg twice

### Box 25-4 Cutaneous Signs of Anorexia Nervosa and Bulimia Nervosa

- Xerosis
- Generalized pruritus
- Loss of subcutaneous fat
- Carotenemia
- Acne
- Petechiae and purpura
- Edema, especially pretibial and pedal
- Calluses on the dorsum of the hand (Russell sign)
- Other self-inflicted injuries
- Poor wound healing
- Pellagra
- Scurvy
- Acrodermatitis enteropathica
- Seborrheic dermatitis
- Acral changes
  - Periungual erythema
  - Acrocyanosis
  - Acral coldness
  - Perniosis
- Oral changes
  - Cheilitis/perleche
  - Aphthous stomatitis
  - Gum recession
  - Enamel erosion and dental caries
- Hair changes
  - Telogen effluvium
  - Increased lanugo-like body hair
  - Dry hair
- Brittle, dystrophic nails
- Enlarged parotid and salivary glands (full cheeks despite malnutrition)
- Heating pad-induced erythema ab igne

daily for the first week. If the patient has no nausea, vomiting, or diarrhea, the dosage can be increased to three times a day, but colchicine is poorly tolerated by most pediatric patients. Thalidomide 50 to 100 mg once weekly to once daily has also led to improvement, but its use is limited by constipation, fatigue, and peripheral neuropathy, which may be irreversible. Dapsone can also be helpful, especially in children with recurrent oral ulcerations. In severe cases, corticosteroids, alone or in combination with immunosuppressive agents such as methotrexate, azathioprine, or TNF inhibitors,<sup>365–367</sup> are usually successful. For patients who do not respond, inhibitors of IL-1<sup>368</sup> (anakinra, canakinumab) and IL-6 (tocilizumab) activation, as well as rituximab, have been used<sup>369</sup> have also been used successfully. The overall mortality rate of Behcet disease in children is 3%; death usually results from large vessel vasculopathy (aneurysm, thrombosis), intestinal perforation, central nervous system involvement, or as a complication of therapy.

## Anorexia Nervosa and Bulimia

Anorexia nervosa and bulimia nervosa are severe disorders associated with potentially serious medical complications (Box 25-4).<sup>370,371</sup> Anorexia nervosa occurs in up to 3% of pubertal females and less commonly in prepubertal females or males. In both disorders, patients have an intense preoccupation with food and irrational concern about gaining weight. Bulimic patients tend to binge eat and attempt to lose weight by vomiting and abusing laxatives, diuretics, diet pills, or emetics. The cutaneous features, which reflect endocrinologic changes and malnutrition, usually occur when the body mass index drops to less than 16 kg/m<sup>2</sup>.<sup>372,373</sup> Affected individuals often show self-induced lesions as well, particularly the characteristic superficial ulcerations and hyperpigmented calluses or scars on the dorsal aspect of the second and third fingers (Russell sign), the result of repeated abrasion of the skin against the maxillary incisors during forced emesis.<sup>374,375</sup> Other emesis-associated complications include recurrent sore throat, hoarse voice, and dental erosions. Nutritional deficiency, such as zinc deficiency,<sup>376</sup> scurvy, and pellagra<sup>377</sup> have occurred, as has erythema ab igne from chronic use of a heating pad for warmth.<sup>378</sup> Because of

the potential severity of these disorders, it is important that physicians recognize the early signs and symptoms, particularly in view of the fact that patients tend to deny their illness or minimize the severity of their symptoms. The cutaneous manifestations are reversible when weight is gained. Many patients respond well to the combination of antidepressant and cognitive-behavioral therapy.

# 26 Abuse and Factitial Disorders

## Child Abuse

*Child abuse* is a broad term used to describe a spectrum of nonaccidental trauma inflicted upon children. Kempe et al. are generally credited with emphasizing the prevalence and importance of this entity when they coined the term *battered child syndrome* in 1962.<sup>1</sup> This “syndrome” has subsequently been expanded to include an array of childhood abuses including physical abuse, sexual abuse, and neglect. Child abuse continues to be one of the most significant causes of childhood morbidity and mortality in the United States.<sup>2</sup> In one 10-year study of medical records submitted to the National Pediatric Trauma Registry, child abuse accounted for 10.6% of all blunt trauma to patients under 5 years of age.<sup>2</sup> Children who are abused tend to be younger, with the highest incidence seen in those under 3 years of age. High-risk groups include children with a history of prematurity, physical handicap, and behavioral problems. Factors that appear to be associated with an increased risk of abuse are summarized in Table 26-1.<sup>3–5</sup> Up to 75% of abuse may be missed in the acute care setting because of failure of recognition by medical professionals, and this may lead to lost opportunities to intervene.<sup>6</sup>

Various abusive patterns may be evident in families where abuse is an issue. These include parents who were the victims of abuse themselves, parents with emotional disturbances, stressful crises within the family unit (i.e., loss of job or financial distress), and lack of a close support network for the family (see Table 26-1).<sup>7</sup> Recognition of abuse is vital, because the trauma tends to be repeated (an abused child has up to a 50% chance of being abused again), and the risk of future injury or death is high. Instances in which there is a delay in reporting the injury, in which the degree and type of injury are at variance with the history offered, or in which the parents are evasive or vague as to the cause of injury are all suspicious and should lead to consideration for an abuse investigation. In evaluating the child with possible abuse, a detailed history is the most important component of the assessment.<sup>8</sup> Vital details include the alleged mechanism of the injury, developmental history of the child, past medical history (especially of any disorders that may mimic abuse, such as coagulopathy or skin disorders), history of prior injuries, social history, and family history. A complete physical examination should be performed and should include high-quality photography of cutaneous lesions.

Radiographic findings in child physical abuse are often useful in the evaluation and are not discussed in great detail here. Findings that may increase suspicion for abuse include the classic metaphyseal lesion (also known as “corner fracture” or “bucket-handle fracture”), skull and femur fractures, and healing fractures, although each of these findings must be considered in the appropriate context of the medical history and physical examination findings.<sup>9,10</sup>

Although abused children may exhibit multiple abnormalities on physical and radiographic examination, this section will focus primarily on the cutaneous stigmata.

### PHYSICAL ABUSE

Nonaccidental injuries in children may take many forms, and often the skin reveals pathologic findings. Cutaneous trauma may be seen in the form of ecchymoses, burns, lacerations, bite marks, abrasions, underlying hematomas, pigmentary changes, and scars.

Ecchymoses (bruises) are the most common type of skin injury seen in children who have been abused. Lesions on the hands and face, adult human bites, and lesions on the cheeks, mouth, lips, lower back, buttocks, or inner thighs are particularly suspect. Ecchymoses in

various different stages of healing are more suggestive of abuse. Ecchymoses on padded areas such as the buttocks, torso, face, and genitalia (Fig. 26-1, A) or uncommonly injured areas (earlobe, neck, lip, philtrum) are more concerning for possible abuse.<sup>3</sup> In a study of discriminating bruising characteristics in children who have been abused, characteristics that were more predictive of abuse included bruising on the torso, ear (Fig. 26-1, B), or neck (in a child ≤4 years of age, termed the *TEN region*) and bruising in any region in an infant younger than 4 months of age.<sup>6</sup> Abuse-associated bruising should be differentiated from accidental bruising, which is more common in ambulatory children and occurs most commonly over bony prominences such as the forehead and shins.<sup>3</sup> Any bruising in the noncruising infant under 9 months of age should raise significant suspicion for abuse. There are many potential mimics and non-abuse-related causes of ecchymoses, including Mongolian spots, hypersensitivity vasculitis (i.e., Henoch–Schönlein purpura or acute hemorrhagic edema of infancy), Ehlers–Danlos syndrome, vascular malformations, infantile hemangiomas, inks or dyes, and bleeding disorders.

The configurations of lesions in battered children are morphologically similar to the items or methods used to inflict the trauma and may be useful in the abuse investigation. Multiple evenly spaced markings (Fig. 26-2) or curvilinear loops and arcuate lesions (Figs. 26-3 and 26-4) such as those that may be induced by lashing with a doubled-over belt or electric cord are typical of these trauma-induced lesions. They are usually ecchymotic, but they may also present as abrasions, lacerations, or hyperpigmentation.

Belt-buckle imprints (ecchymotic or hyperpigmented) may result from intentional trauma with these items. Adjacent, small ecchymotic macules (Fig. 26-5) are typical of pinch marks. Shackles on the wrists, ankles, or neck leave easily identifiable rings that are red if fresh and hyperpigmented if longstanding. Ligature marks on the neck or extremities and grab or slap marks (fingertip bruises; Fig. 26-6) on the shoulders, hands, or legs are particularly suspicious and highly suggestive of deliberate trauma. Slapping injuries result in linear bruising that outlines the blunt objects (fingers) because of the breakage of superficial skin capillaries. *Çao gio* (“coining”) and cupping, Asian customs believed to treat a variety of ailments, may be confused with ecchymotic lesions of abuse and must be appropriately recognized (see below in *Cutaneous Mimickers of Abuse and Factitial Disorders* section).

Burns are a very common type of injury seen in abused children and result from thermal injury to the skin and subcutaneous tissues. Burns can also be electrical, chemical, or radiant in nature. Thermal burns may be inflicted with cigarettes, matches, scalding liquid, or other heated objects (Fig. 26-7) and are often mistaken for lesions of impetigo. Cigarette burns present as 8- to 10-mm, deep, round crusted ulcers that heal with scars and pigmentary changes (Figs. 26-8 and 26-9). Although they may be accidental, multiple lesions with deeper involvement and significant scarring are highly indicative of abuse, because this pattern is usually suggestive of prolonged contact. The differential diagnosis of cigarette burns includes ecthyma, cellulitis, herpes, and bullous impetigo.

Branding injuries occur after prolonged contact with a heated object, and they may take on the shape of the object used to inflict them. Burns inflicted with a hot iron (Figs. 26-10 and 26-11) reveal differing pigmentary changes between the heated metal surface and the steam vent openings. Figures 26-12 and 26-13 demonstrate burns inflicted by a heated metal spoon, with the shape of the spoon readily visible in the resultant skin markings. Dunking scald injuries are most commonly seen in infants and toddlers and present with a characteristic “stocking and glove” distribution on the extremities or

**Table 26-1** Factors Associated with an Increased Risk of Child Abuse

Child	Parent	Both
Prematurity	Partner violence within the family	Neighborhood factors
Mental retardation	History of past abuse or neglect	Crime
Disability	Substance abuse	Poor recreational activities
Congenital anomalies	Mental illness	Poverty
Clinging	Unemployment	Poor parent-child relationships
Excessive or inconsolable crying	Lack of external support	Substandard housing
Expectations inconsistent with normal child development	African-American child in single-parent household	Poor impulse control
Toilet training or toilet accidents (preschoolers)	Adolescent in age	Rely on children for emotional support

Modified from Swerdlin A, Berkowitz C, Craft N. Cutaneous signs of child abuse. *J Am Acad Dermatol* 2007;57:371–92; Peck MD, Priolo-Kapel D. Child abuse by burning: a review of the literature and an algorithm for medical investigations. *J Trauma* 2002;53:1013–22; and Dubowitz H, Bennett S. Physical abuse and neglect of children. *Lancet* 2007;369:1891–9.

(A)

(B)

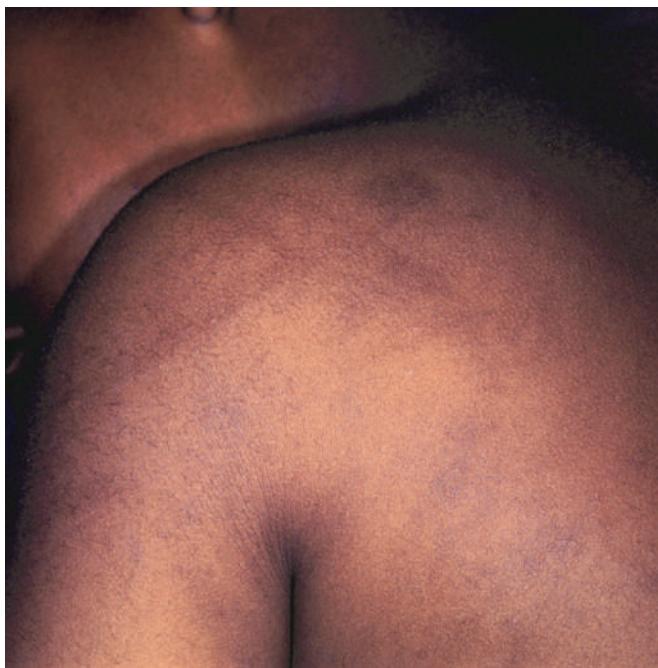

**Figure 26-1** Child abuse. Ecchymoses in certain locations such as these lesions noted on the genitalia (A) and superior ear (B) are more suggestive of nonaccidental trauma. Of ear ecchymoses, the most concerning location for abuse-associated bruising is the earlobe.

**Figure 26-2** Child abuse. The evenly spaced nature of these markings should arouse suspicion for an outside source of these skin findings.

with “doughnut-type sparing” that occurs when the child’s buttocks are held against the cooler tub or basin.<sup>7</sup> These patients have erythema and blistering indicative of a second-degree burn. It should be remembered that children will not stay in contact with a hot surface or scalding hot water. They normally test the heat of the water and step into the bath with one foot at a time. Accordingly, symmetrical burns on the feet, the buttocks, or the hands require careful investigation and evaluation. Stun-gun injuries have been observed in the setting of physical abuse and present as evenly spaced (4 to 5 cm apart), erythematous to hypopigmented papules and macules, usually occurring in multiples.<sup>11</sup>

Bite marks are another pathognomonic sign of nonaccidental trauma. The human bite is differentiated easily from the dog bite by the contusing and crushing characteristics of the latter; dog bites rip and tear the flesh. It is important to distinguish adult from child bite marks, since the former is more likely to be seen in an abusive setting. Adult bites are characterized by a dental arch width greater than 4 cm<sup>3</sup>, whereas the markings of a child’s bite tend to be significantly narrower (Fig. 26-14). The discovery of one bite mark necessitates a thorough examination of the child’s entire body for further evidence of bites or other findings of abuse.<sup>12</sup> Traumatic alopecia may occur when the parent pulls the child’s hair, since the hair provides a readily accessible “handle” that can be used to grab or jerk at the child. The resultant alopecia is an irregularly bordered area that may reveal hemorrhage, hair breakage, and scalp tenderness.

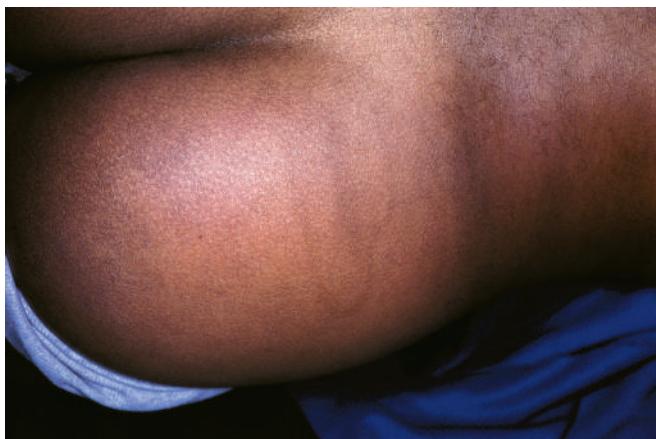

**Figure 26-3** Child abuse. These multiple, overlapping, linear and hyperpigmented patches were the result of postinflammatory changes at sites of whipping.

**Figure 26-4** Child abuse. These burns, the result of intentional contact with a hot wire, presented as curvilinear erosions.

**Figure 26-5** Child abuse. Adjacent, ecchymotic macules are typical of pinch marks.

**Figure 26-6** Child abuse. Fingertip bruises present as hyperpigmented patches in the shape of fingers at sites of excessive slapping or spanking.

**Figure 26-7** Child abuse. This geographically shaped burn was believed to have been inflicted with the heated metal end of a disposable cigarette lighter.

Oral injuries are another common feature in abused children. Findings may include tears of the labial or lingual frenulum caused by a blow to the mouth, forced feeding, or forced oral sex.<sup>12</sup> Other manifestations include burns or lacerations of the gingivae, tongue, or palate from overly hot food or utensils. Teeth may also be involved, including fracture, displacement, or avulsion.

A difficult situation arises when the physician observes recent skin injuries in the child who does not seek treatment for trauma. In one large series, 76% of children between 9 months and 17 years of age seen in a clinic for a reason other than trauma were found to have at least one recent skin injury. Injuries were more prevalent in the summer (in regions with a temperate climate) and were most commonly observed on the shins and knees.<sup>13</sup> The authors offered certain unusual characteristics that may suggest a greater risk of physical abuse (or bleeding disorder), and these include uncommon location, more than 15 injuries, bruises in a child younger than 9 months of age, numerous injuries elsewhere than the lower limbs, numerous injuries in cold seasons in a temperate climate, and injuries other than bruises, abrasions, or scratches.<sup>13</sup> In another series of infants aged 6 to 12 months, bruises were noted to be generally limited to the face, head, or shins, and there was a direct correlation between the number of bruises and increases in mobility.<sup>14</sup> In this group, the prevalence rate of bruises was 12%, and they were most often solitary.

**Figure 26-8** Cigarette burns. This patient has evidence of fresh lesions (erythematous eroded plaque) and older lesions in the forms of hyperpigmentation and scars.

**Figure 26-9** Cigarette burns. These burns demonstrate the classic abuse finding of lesions in various stages of healing.

**Figure 26-10** Iron burn. This hyperpigmented patch is studded with evenly spaced, normally pigmented regions that correlate with sites of steam vent openings.

## SEXUAL ABUSE

Sexual abuse has been defined in many ways, including “any exploitative sexual activity between a child and an adult”; “any sexual activity that a child cannot comprehend or give consent to, or that violates the law”; or “when a child is engaged in sexual activities that he/she cannot comprehend, for which he/she is developmentally unprepared

**Figure 26-11** Iron burn. This child's hand reveals the classic hyperpigmentation with evenly spaced macules of sparing that occur at sites of steam vent openings.

**Figure 26-12** Child abuse. This infant had burns inflicted with a heated metal spoon. Note the overlapping oval-shaped patches of pigmentation and crusting.

and cannot give consent, and/or that violates the law or social taboos of society.”<sup>7,15,16</sup> Some studies have suggested that 1% of children experience some form of sexual abuse each year.<sup>16</sup> It is important to realize that boys may be the victims of sexual abuse as well as girls, although the former tend to be less likely to disclose abuse, and thus it is likely underreported, underrecognized, and undertreated.<sup>17</sup> Adolescents are the perpetrators in up to 20% of reported cases of sexual abuse, and although women may be perpetrators, these allegations are significantly less likely than those involving males.<sup>16</sup> Up to one fifth of adolescents who regularly use the Internet have been solicited by strangers for sex through the Internet. Childhood sexual abuse may lead to a variety of physical and mental symptoms and disorders, including depression, suicidal ideation, eating disorders, low self-esteem, and posttraumatic stress disorder.<sup>18</sup>

The perpetrator of childhood sexual abuse is often well known, or related, to the victim. Activities involved in sexual abuse may include

**Figure 26-13** Child abuse. The same infant as that shown in **Figure 26-12** had these blistering burns on the plantar surfaces. They were inflicted with a heated metal spoon.

**Figure 26-14** Bite marks. These erythematous, petechial macules and papules revealed a dental arch width of 2.5 cm, more consistent with a child's bite. There were no other clinical features of (or concerns for) child abuse in this 2-year-old female.

oral-genital, genital, or anal contact by or to the child, as well as nonphysical abuses such as voyeurism, exhibitionism, or involvement of the child in pornography.<sup>16</sup> Sexual abuse should be differentiated from "sexual play" or age-appropriate exploratory behavior. The child who has been sexually abused may exhibit a variety of features including behavioral changes, school difficulties, regression, depression, eating disturbance, sexual acting-out, symptoms referable to the genitourinary or gastrointestinal tracts, pregnancy, various somatic complaints, or a sexually transmitted disease (STD).<sup>15</sup>

Mucocutaneous findings suggestive of sexual abuse are listed in **Table 26-2**. However, it should be noted that many children who have been sexually abused in the past may have a relatively normal physical examination. Many prepubescent patients seen in emergency departments for a sexual-abuse evaluation have not experienced recent abuse, in distinction to adolescents, who often come after the acute

**Table 26-2** Mucocutaneous Findings in Childhood Sexual Abuse

Finding	Comment
Hymenal changes	Attenuated hymenal tissue, disruption of hymenal contour; acute laceration or ecchymosis
Anal area changes	Boys and girls; changes in anal tone, hematomas, abrasions, lacerations; scarring, skin tags; dilation
Fossa navicularis scarring	
Posterior fourchette scarring	
Inner thigh changes	Abrasions, ecchymosis (concerning but not diagnostic)
Labia minora changes	Scarring or tears (concerning but not diagnostic)
Other genital injuries	Circumferential injuries to penile shaft or glans penis
Oral injuries or diseases	Unexplained erythema or petechiae of the palate; oral or perioral gonorrhea or syphilis (pathognomonic for sexual abuse in the prepubertal child)

**Table 26-3** Implications of Sexually Transmitted Diseases and Clinical Findings for the Diagnosis of Childhood Sexual Abuse

STD or Finding	Implication for Abuse	Suggested Action
Gonorrhea*	Diagnostic	Report
Syphilis*	Diagnostic	Report

Presence of sperm, semen, or acid phosphatase	Diagnostic	Report
Pregnancy	Diagnostic	Report

Modified from Swerdlin A, Berkowitz C, Craft N. Cutaneous signs of child abuse. *J Am Acad Dermatol* 2007;57:371–92, and Kellogg N, American Academy of Pediatrics Committee on Child Abuse and Neglect. The evaluation of sexual abuse in children. *Pediatrics* 2005;116(2):506–12. HIV, Human immunodeficiency virus; STD, sexually transmitted disease.

\*If not perinatally acquired.

<sup>‡</sup>If not transfusion acquired.

<sup>§</sup>Not uncommonly transmitted via benign mode; see discussion in Chapter 15.

Unless caused by autoinoculation.

assault.<sup>19</sup> A normal anogenital examination, therefore, does not preclude prior sexual abuse. The physical examination should be most focused on areas involved in sexual activity, including the mouth, breasts, genitals, perineum, buttocks, and anus. In females, a more thorough examination of the medial thighs, labia majora and minora, clitoris, urethra, hymen and hymenal opening, fossa navicularis, and posterior fourchette should be included.<sup>16</sup> In males, the thighs, penis, and scrotum should be closely examined.

Examinations for STDs should be performed when indicated. Factors to be considered include the possibility of oral, genital, or rectal contact and the child's symptomatology. **Table 26-3** summarizes the implications of various STDs and clinical findings for reporting

**Figure 26-15** Neglect. This toddler came to the clinic for a routine follow-up examination for eczema and was noted to have this blistering sunburn.

**Figure 26-16** Neglect. Dental neglect in this young boy presented as dental caries, periodontal disease, and aphthous ulcerations of the labial surfaces. This lesion was also culture-positive for herpes simplex virus.

childhood sexual abuse. Anogenital warts, which may be sexually transmitted in children, are often the result of benign, nonsexual transmission, especially in infants and young toddlers (see Chapter 15). Nonsexual modes of transmission include perinatal transmission, autoinoculation (child with common warts spreads them via skin-to-skin contact to his or her own anogenital region), heteroinoculation (caregiver with common warts spreads them via skin-to-skin contact to anogenital region of child), and possibly indirect spread from fomites. Importantly, molluscum contagiosum lesions involving the anogenital region in children are nearly always a result of benign transmission or autoinoculation and should not be considered as indicative of childhood sexual abuse. The details of the evaluation, treatment, and reporting of childhood sexual abuse are beyond the scope of this chapter but are well documented elsewhere. Importantly, however, when the diagnosis of childhood sexual abuse is being considered, review of the case with an expert in such evaluations (such as a child-abuse pediatrician) is advisable. Recent data suggest that five or more examinations per month may be required for ongoing competency in the interpretation of medical and laboratory findings in children in whom sexual abuse is suspected.<sup>20</sup>

## NEGLECT

Neglect may be either physical, emotional, or both. The former results when a parent or caretaker fails to provide necessities of life such as food, appropriate supervision shelter, clothing, or medical care.<sup>7</sup> General findings in the neglected child may include lack of immunizations, poor nutrition and growth, and developmental or behavioral problems. Potential cutaneous findings include poor hygiene, untreated injuries, infections, and infestations. Severe or extensive sunburns (Fig. 26-15) may be a sign of parental neglect, although several conditions and medications may make children more sensitive to ultraviolet light. It is important to bear these in mind whenever the possibility of neglect or abuse is being considered.

Physical neglect may also present as dental neglect, which is defined as the "willful failure of parent or guardian to seek and follow through with treatment necessary to ensure a level of oral health essential for adequate function and freedom from pain and infection."<sup>21</sup> Findings may include dental caries, periodontal disease (Fig. 26-16), and other oral conditions. When left untreated, these conditions can lead to significant pain, infection, and loss of function.<sup>21</sup>

## Factitious Skin Disorders

Factitious skin disorders (also called *self-inflicted skin lesions*) are a group of disorders characterized by self-inflicted lesions or artifacts on the skin. The individual cases vary in terms of the visible lesions and the

underlying motive that causes the patient to act. These disorders may be associated with a variety of psychopathologic conditions, and comanagement with a psychologist or psychiatrist is often necessary. Factitious skin disorders fall under the rubric of psychodermatologic conditions or psychocutaneous disorders, although these two classifications also include dermatologic conditions with secondary psychiatric sequelae (i.e., alopecia areata or albinism) and dermatologic conditions that may be aggravated by psychologic factors (i.e., acne, atopic dermatitis, psoriasis).<sup>22</sup> Diagnosis of factitious skin disorders is often delayed, and management is challenging, requiring the development of a therapeutic alliance between the physician and patient and treatment of any underlying psychiatric comorbid conditions. The diagnosis of factitious skin disorders largely remains a diagnosis of exclusion.<sup>23</sup> Treatment often requires a multidisciplinary approach that may include the pediatrician, dermatologist, psychologist, and/or psychiatrist.

## FACTITIOUS DERMATITIS/DERMATITIS ARTEFACTA

Factitious dermatitis is one type of factitious disorder that is caused by a conscious or subconscious behavior driven in response to internal psychologic stressors and not associated with secondary gain.<sup>23</sup> *Dermatitis artefacta* (DA) is often the terminology used to describe a disorder in which the skin is the purposeful target of self-inflicted injuries. In DA, the patient creates the lesions on the skin in order to satisfy a psychological need (of which he or she is often not consciously aware) and in the pursuit of secondary gain.<sup>23,24</sup> There appears to be the need to satisfy an internal emotional necessity—the need to be cared for.<sup>25,26</sup> The desired gain may be obvious or may not be readily evident. DA occurs predominantly among women, with a wide range in the quoted ratios of women to men, from 3 : 1 to 20 : 1.<sup>25</sup> It may have its onset at any time, although it most commonly occurs in teenagers and young adults. When it occurs in children, DA may be related to various stressors including school examinations, bullying, and discord in the home.<sup>27</sup> Several comorbid conditions may be present, including borderline personality disorder, disorders of impulse control, depression, anxiety, obsessive-compulsive disorder (OCD), and psychotic disorders.<sup>22,24,26,28</sup> It may also result from a transient maladaptive response to a recent psychosocial stressor(s). A past and/or current history of sexual abuse is common.<sup>25,29</sup> Patients with DA often have a close connection (either personally or through a close family member) with the healthcare field, and many have an "encyclopedic" grasp of medical knowledge and/or terminology. Some have suggested abandoning the terms *factitious dermatitis* and *DA* in favor of the terminology *factitious disorders in dermatology*.<sup>30</sup>

DA has a variety of presentation patterns. Importantly, the cutaneous features are often only one facet of the entire picture, because these patients often have involvement of other organ systems and have

**Figure 26-17** Suction purpura. This well-demarcated, petechial patch over the upper lip and philtrum area arose after this young girl repeatedly sucked air from a cup placed over her lips and upper chin.

visited numerous medical specialists for other bizarre or unexplained symptoms. The skin lesions themselves may consist of purpura, excoriations, abrasions, crusting, necrosis, blisters, ulcers, erythema, nodules, or scarring. When blisters are present (bullous DA), modes of injury often include thermal, electrical, or chemical injury.<sup>31</sup> The lesions of DA usually lack features of recognizable dermatoses. Notable features often include linearity, geometric arrangements, and sharp demarcation from the surrounding normal skin. The face, upper trunk, and upper extremities are the sites most often involved, and there is notable sparing of areas outside of the patients' reach (i.e., the middle back). There is often a prominence on one side, depending on the handedness of the patient. The lips may also be involved, presenting usually as persistent bleeding and crusting.<sup>32</sup> The lesions are often fully formed and are all in a similar stage of development. This inability of the patient to give details of evolutionary change has been termed *hollow history* and is quite typical of DA.<sup>24,25,33</sup>

Reported modes of injury include rubbing; scratching; picking; cutting; gouging; pinching; puncturing; biting; sucking; applying suction; applying heat, dye, or caustic substances; and injecting caustic materials or bodily secretions.<sup>22,24</sup> The differential diagnosis may be broad and depends on the nature of the inflicted injury. A clue to the diagnosis of DA is indifference or lack of concern on the part of the patient, who will often deny pain or discomfort despite the impressive physical findings.<sup>33</sup> Bullous DA caused by thermal injury may result after the “salt and ice challenge,” a trending dare contest in which participants sprinkle salt on the skin followed by compression with an ice cube.<sup>34</sup>

Factitious purpura, which is a form of mechanical purpura, may result in a detailed, lengthy investigation for other medical causes before the diagnosis is entertained. Patients may be entirely unaware that they are causing the skin lesions. A common form of factitious purpura is that caused by sucking air from a drinking glass placed over the chin and lower lip, resulting in a well-demarcated, circular area of purpura (Fig. 26-17).<sup>35</sup> Other forms may be caused by a variety of instruments or objects, with the purpuric lesions corresponding to the patterns of those objects. Figures 26-18 through 26-30 depict some various presentations of DA.

Malingering may present with lesions similar to DA, but in this setting the patient self-inflicts injury consciously, often with a secondary gain. These patients may exhibit “*la belle indifference*,” which refers to an apparent lack of frustration, despite the recurrent nature of their symptomatology.

Neurotic (psychogenic) excoriations are lesions self-inflicted by patients who have an irresistible urge to manipulate their skin.<sup>26</sup> It is often related to mood disorders, anxiety disorder, drug abuse, or OCD.<sup>36</sup> The cycle of neurotic excoriations may begin with a true physical stimulus such as pruritus or a skin lesion or irregularity such as an acne papule. The latter is referred to as *acne excoriée des jeunes filles*

**Figure 26-18** Dermatitis artefacta. Well-demarcated abrasions and hyperpigmentation in a 10-year-old male.

**Figure 26-19** Dermatitis artefacta. Sharply demarcated, eroded, erythematous plaques from chronic rubbing.

**Figure 26-20** Dermatitis artefacta. This localized discoloration of the hand had been caused by intentional exposure to fabric dye.

and occurs when even mild acne lesions (especially those on the forehead) are squeezed or excoriated (Fig. 26-31). This behavior may result in permanent scarring, and although some patients may fulfill diagnostic criteria for OCD, many do not. Patients with neurotic excoriations usually acknowledge the behavior and may have any of several comorbid conditions, including OCD, a personality disorder, anxiety, or depression. The picking activity is performed most often with the fingernails, although some patients may use an auxiliary tool

**Figure 26-21** Dermatitis artefacta. These evenly spaced, linear, hemorrhagic markings were self-induced.

**Figure 26-24** Dermatitis artefacta. Linear purpura is a common finding in factitious skin disease.

**Figure 26-25** Dermatitis artefacta. These linear and stellate purpuric patches were present in the same patient shown in [Figure 26-24](#). Note the associated resolving purpuric areas located on the arm.

**Figure 26-22** Dermatitis artefacta. This patient with underlying atopic dermatitis had acute worsening in these areas, which ultimately was found to be self-inflicted.

**Figure 26-26** Dermatitis artefacta. Linear purpura was present on both arms of this school-age boy.

**Figure 26-23** Dermatitis artefacta. These well-demarcated erosions are notable for their even spacing and sharp, linear borders.

such as the point of a knife.<sup>24</sup> The resultant skin lesions reveal erythema, erosions, weeping, crusting ([Fig. 26-32](#)), pigmentation, or scarring. There is often a notable sparing of the upper lateral back areas.

Prurigo nodularis (PN) is a condition characterized by firm papules and nodules with pruritus. It most typically presents with discrete, 2- to 10-mm, firm, lichenified hyperkeratotic papules that may reveal some central excoriation or crusting ([Figs. 26-33](#) and [26-34](#)). Common locations include the extremities and the upper and lower back, often with a zone of sparing noted in the middle back, which is a difficult location for the patient to reach. The cause of PN is unknown. It has been seen in a variety of settings, including bite reactions, atopic dermatitis (see [Fig. 3-16](#)), allergic contact dermatitis, folliculitis,

**Figure 26-27** Dermatitis artefacta. Irregularly shaped purpuric patches of the neck and face.

**Figure 26-28** Dermatitis artefacta. Purpuric patches with geometric and linear borders in the same patient shown in [Figure 26-27](#).

psychosocial disorders, thyroid disease, malignancy, iron-deficiency anemia, kidney failure, gluten sensitivity, obstructive biliary disease, and infections (including hepatitis, human immunodeficiency virus [HIV], and mycobacteria).<sup>37,38</sup> If generalized pruritis is reported by the patient, a laboratory investigation (including blood counts, kidney and liver function tests, and thyroid and parathyroid screening) may be warranted.<sup>38</sup> Skin biopsy may be useful if infection is included in the differential diagnosis. Treatment for PN is notoriously difficult and may include topical corticosteroids or calcineurin inhibitors (i.e., tacrolimus and pimecrolimus), topical capsaicin, ultraviolet phototherapy, and antihistamines. In severe cases, systemic agents such as cyclosporine, thalidomide, naltrexone, and etretinate have been used.<sup>37,38</sup> Psychological intervention is often necessary.

**Figure 26-29** Dermatitis artefacta. Well-demarcated linear purpuric macules.

**Figure 26-30** Dermatitis artefacta. These eroded and scarred plaques reveal irregular borders consistent with self-manipulation.

**Figure 26-31** Acne excoriée. Acne papules with erosions, scarring, and hyperpigmentation are typical of this condition.

## DELUSIONS OF PARASITOSIS

A delusional disorder is characterized by adherence to a possible yet implausible belief for which there is no supportive objective evidence.<sup>39</sup> Monosymptomatic hypochondriacal psychosis (MHP) is characterized by a delusional ideation that revolves around one concern, in contrast

**Figure 26-32** Neurotic excoriation. This adolescent female acknowledged her repeated picking and scratching, which resulted in these erythematous eroded and crusted papules on her bilateral breasts.

**Figure 26-34** Prurigo nodularis. Firm, lichenified, hyperpigmented papules were present on the arms and legs of this 9-year-old girl.

**Figure 26-33** Prurigo nodularis. This boy had numerous, discrete, lichenified firm papules on his upper and lower back, forearms, and lower extremities. Note the zone of sparing over the middle back, an area that was difficult for him to reach.

to schizophrenia, in which case patients have multifunctional deficits in mental functioning.<sup>40</sup> The most common type of MHP with dermatologic relevance is delusions of parasitosis. This disorder, also known as *delusional infestation*, is characterized by the conviction of an individual that he or she is infested with parasites in the absence of any objective evidence. Patients with delusions of parasitosis, most often older adult females, complain of having the sensation of crawling, burrowing, and biting insects or worms on their skin. They may resort to self-mutilation in an attempt to remove the offending arthropods. A history of psychiatric illness can be elicited in most patients with this disorder.<sup>41</sup> This discussion is focused on primary delusions of parasitosis; a secondary form may arise from certain medical conditions such as stroke, cardiovascular disease, vitamin (especially B<sub>12</sub>) deficiency, diabetes, or psychiatric diagnoses such as schizophrenia or depression.<sup>42</sup>

Patients with delusions of parasitosis often attend the clinic with spurious samples of the “parasite” that when microscopically examined turns out to be lint, skin cells, scabs, or other debris. Skin findings may include excoriations, lichenification, pigmentary alteration, and

scarring. Treatment of the disorder is challenging, with the anti-psychotic medication pimozide being the most often utilized pharmacologic agent. Other utilized agents have included aripiprazole, olanzapine, and risperidone.<sup>42,43</sup> Before therapy, however, exclusion of true skin disorders (i.e., scabies, dermatitis herpetiformis, or insect-bite reactions) should be considered.<sup>44</sup>

*Morgellons disease* is a term that initially began to surface in 2002 and whose name was taken from the label, given in 1674 in France by Sir Thomas Browne, to children who had hair-like skin extrusions and sensations of movement.<sup>45</sup> This terminology provides an alternative to the decades-old nomenclature of *delusions of parasitosis*, although many consider the two disorders to be part of the same spectrum.<sup>46–50</sup> Patients with Morgellons disease complain of cutaneous dysesthesias, resulting in skin manipulations in an effort to extract the “organisms,” thin fibers, or foreign materials. They may experience itching or crawling sensations, and many report the sense that bugs or worms are stinging or biting them. The examination findings may include excoriations, ulcers, lichenification, and prurigo nodules. Patients with Morgellons disease, much like those with delusions of parasitosis, may bring samples or debris in bottles, jars, or bags to the appointment. Examination of these contents often reveals lint, hair, debris, fuzz, dead skin, material fibers, or bugs.<sup>47</sup> Management of the condition is difficult and includes establishing good rapport, excluding skin or other organic conditions, consideration for the use of psychotropic medications, and treatment of secondary skin infection when necessary. Long-term antibiotic therapy has reportedly been useful.<sup>48,51</sup> Collaborative care with a psychiatrist or a psychodermatology clinic is strongly encouraged for both Morgellons disease and patients with delusions of parasitosis.

## OBSESSIVE-COMPULSIVE DISORDERS

Obsessive-compulsive disorder (OCD) is characterized by the presence of obsessions (recurrent thoughts or images experienced as intrusive or senseless) or compulsions (repetitive, intentional behaviors performed to diminish discomfort or future harm and felt to be unreasonable or excessive).<sup>52</sup> The essential features required for diagnosis in the *Diagnostic and Statistical Manual of Mental Disorders (DSM)* 5 is that the obsessions or compulsions are severe enough to significantly impact the daily routine and social or work functioning and the patient does not realize that they are excessive or unreasonable.

The expression of OCD may take the form of a dermatologic disorder. Entities that may fall into this spectrum are listed in Table 26-4. Clinical features that may suggest an OCD-related spectrum disorder include a heightened concern for cleanliness, fear of contamination, excessive worry about life-threatening illnesses or STDs, inappropriate concerns about body odor, and worries regarding an unattractive appearance or hair loss.<sup>22,53</sup>

OCD often begins in childhood or early adulthood, and most patients have a waxing and waning course. Comorbid conditions are common,

**Figure 26-35** Obsessive-compulsive disorder. This 6-year-old boy has features of onychophagia (nail biting; note shaggy, uneven, and short distal nail plates) and onychotillomania (nail picking; note damage to cuticles). The associated nail pitting was felt to be related to underlying twenty-nail dystrophy of childhood.

**Table 26-4** Obsessive-Compulsive Disorder and Some Possibly Associated Dermatologic Conditions

Disorder	See Chapter Number for Details
Acne excoriée	8
Body dysmorphic disorder	Current
Irritant dermatitis (hand-washing)	3
Lichen simplex chronicus	3
Lip-licker dermatitis	3
Neurotic (psychogenic) excoriations	Current
Onychophagia/onychotillomania	Current
Rhinotillexomania (pathologic nose-picking)	Current
Prurigo nodularis	3
Trichotillomania	7

including depression and anxiety disorders. Childhood OCD may be associated with Tourette syndrome, tics, family history of OCD, developmental delay, and hyperactivity.<sup>54</sup> The most common cutaneous presentations are trichotillomania (see Chapter 7), onychophagia, onychotillomania (Fig. 26-35), and acne excoriée (see Chapter 8).<sup>53,55</sup> *Onychophagia* refers to the compulsive habit of nail biting, which becomes pathological when excessively time consuming or associated with social avoidance.<sup>50</sup> *Onychotillomania* refers to picking of the cuticle or removal of the nail. More recently, *rhinotillexomania* (compulsive nose picking) has been recognized as a potential manifestation of OCD when it becomes socially compromising or physically harmful. Nasal-septum perforation has been reported in some patients. Importantly, patients with pediatric OCD experience chronicity and intractability of the disorder despite multiple interventions.<sup>56</sup>

*Body dysmorphic disorder (BDD)* is defined as preoccupation with an imagined defect in appearance. BDD, which falls into the OCD spectrum of disorders, may present with dermatologic symptoms or concerns. These include concerns about an unattractive appearance, acne scarring, hair thinning, early skin aging, hirsutism, greasy skin, body odor, large nose, small genitalia, or blushing.<sup>53,55,57</sup> Patients with BDD may spend many hours a day worrying about their obsession and visually inspecting the “abnormality,” which may impact on social and professional functioning. BDD occurs at high rates in patients with eating disorders. Tanning addiction has been classified as one subtype of BDD.<sup>58</sup>

Treatment of OCD spectrum disorders includes both behavioral and pharmacologic therapies, most notably the tricyclic antidepressants and selective serotonin reuptake inhibitors.

**Figure 26-36** Psychogenic purpura. This young female with a history of anxiety disorder complained of recurrent, spontaneous ecchymoses. Examination revealed ecchymotic patches with superimposed abrasions.

### PSYCHOGENIC PURPURA/GARDNER-DIAMOND SYNDROME

Psychogenic purpura (autoerythrocyte sensitization syndrome, Gardner–Diamond syndrome) is a rare disorder characterized by recurrent episodes of painful ecchymoses (Fig. 26-36) in various locations. The patients are most often young adult females with emotional disturbances, and the lesions commonly occur after trauma, surgery, or severe emotional stress.<sup>59,60</sup> The individual lesions resolve over 2 weeks. Psychiatric associations include depression, OCD, hypochondriasis, hysterical and borderline personality disorders, and anxiety.<sup>59–61</sup> Gardner and Diamond, in 1955, suggested that the disorder was associated with autoreactivation of patients to their own blood.<sup>62</sup> Traditionally the diagnosis was confirmed by intradermal injection of the patient’s own erythrocytes, which may result in reproduction of the clinical lesions.

The skin lesions of Gardner–Diamond syndrome are often consistent with a factitious dermatosis given their purpuric nature, irregular distribution, peculiar morphology, and erratic onset. However, confirmation of a self-inflicted process is often difficult, if not impossible. During the prodromal stage, nonspecific symptoms such as malaise and fatigue may be reported. The skin lesions develop rapidly after sensations of burning and stinging and evolve over 1 or 2 days from erythematous to ecchymotic. They resolve over 7 to 10 days. Associated findings such as hematuria, epistaxis, or menorrhagia are occasionally noted. Histologic evaluation of skin-biopsy samples reveals nonspecific features including perivascular inflammation (without frank vasculitis), erythrocyte extravasation, and pigment deposition.<sup>63</sup> Avoidance of confrontation with the patient, establishment of rapport, and psychiatric evaluation and therapy are indicated. Psychotropic medications and hypnotherapy have occasionally been utilized.<sup>63</sup>

### CAREGIVER-FABRICATED ILLNESS

Caregiver-fabricated illness (also known as *Munchausen syndrome by proxy*, *pediatric condition falsification*, *fictitious disorder by proxy*, *child abuse in the medical setting*, and *medical child abuse*) is a form of child maltreatment caused by a caregiver who falsifies and/or induces a child’s illness, leading to unnecessary and potentially harmful medical

investigations and/or treatment.<sup>64</sup> Munchausen syndrome is the traditional designation for a form of factitious disorder characterized by dramatic presentations with factitious complaints, exaggerated lying, and “physician shopping.” Patients have recurrent feigned symptoms and often have borderline or antisocial personality types. Caregiver-fabricated illness occurs when a parent or caregiver creates an illness in a child and is a form of child abuse inflicted most often by the mother. The stereotype of a mother involved in caregiver-fabricated illness is one who works in the healthcare field, is estranged from the child’s father, is quite friendly with the medical staff, and seems relatively unconcerned when the physician is unable to render a diagnosis.<sup>65</sup> The perpetrators are often quite familiar with medical terminology and diseases and usually have pathologic attachments to their children.<sup>66</sup> A history of working in a daycare setting is also common.<sup>65</sup>

The classic four criteria set forth for caregiver-fabricated illness are medical illness in a child that is fabricated by a parent; the child is brought for repeated medical evaluation or treatment and often undergoes multiple medical procedures; the perpetrator denies the actions; and acute symptoms and signs resolve when the child and caregiver are separated.<sup>33</sup> Two circumstances should be present for this diagnosis to be confirmed: harm or potential harm to the child involving medical care, and a caregiver who is causing it to happen.<sup>67</sup> Features of the clinical scenario usually include persistent symptoms that defy medical explanation, involvement of an adult caregiver (usually the biologic mother), and an involved physician who is eager to piece together the presentation and ameliorate the patient’s confusing symptoms.<sup>68</sup> Potential indicators of caregiver-fabricated illness in a child are listed in Box 26-1.

There are a variety of clinical symptoms or features that may be seen in the child victim of caregiver-fabricated illness. These include infant or sleep apnea, factitious coagulopathy, bruising, failure to thrive, hypoglycemia, abnormal urinalysis, seizures and other neurologic symptoms, cyanosis, vomiting and diarrhea, recurrent infections, sepsis, lethargy, behavior problems, fever, melena or hematochezia, electrolyte abnormalities, and bone and joint problems.<sup>33,64–67,69</sup> The dermatologic aspects of this disorder may invariably be referred to as *factitious dermatitis by proxy* or *DA by proxy*. Skin findings have been reported in 3% to 9% of cases of caregiver-fabricated illness.<sup>69</sup> These lesions may present with any of the morphologies discussed earlier for factitious dermatitis/DA, including erythema, blistering, burns, lacerations, puncture wounds, and dermatitis.

The diagnosis of caregiver-fabricated illness can be very challenging. The three forms of presenting signs or symptoms include covert injury induced in secret by the caregiver, fabrication of symptoms by the perpetrator, and symptoms neither induced nor fabricated but exaggerated by the caregiver.<sup>70</sup> The former is rendered when there is unquestionable evidence of commission such as capturing the act during covert videotape surveillance (CVS) in the hospital setting.<sup>71</sup> Some experts believe that such CVS is required in order to make a definitive and timely diagnosis in most cases of caregiver-fabricated illness.<sup>65</sup> When used, adequate safeguards including continuous surveillance and an agreed-upon plan of action must exist in order to

#### Box 26-1 Potential Red Flags for Caregiver-Fabricated Illness in a Child

- Persistent symptoms that defy medical explanation
- Unusual signs or symptoms (case often considered “atypical”)
- Symptoms out of proportion to physical findings
- Caregiver is neither satisfied or reassured when informed of positive progress
- History is inconsistent
- Caregiver encourages additional investigations or consultations
- Signs and symptoms consistently occur in presence of same caregiver
- Lack of response (or unusual response) to established therapies
- Caregiver with history of somatization disorders

Modified from Flaherty EG, MacMillan HL. Caregiver-fabricated illness in a child: a manifestation of child maltreatment. Pediatrics 2013;132:590–7, and Squires JE, Squires RH. A review of Munchausen syndrome by proxy. Pediatr Ann 2013;42(4):e67–71.

prevent further injury to the child.<sup>67</sup> The use of CVS remains controversial, with some arguing that it is an invasion of a parent’s right to privacy or constitutes entrapment. If utilized, hospital-implemented protocols that guide its use are encouraged.<sup>64</sup> A diagnosis of exclusion is occasionally rendered when all other possible explanations for the child’s condition have been considered and excluded.<sup>71</sup> Consultation with all colleagues who have cared for the child and a “separation test,” in which the child is demonstrated to be free of disease outside the care of the mother, are useful.<sup>72</sup> Child protective services should be involved and the perpetrator referred to a professional with significant experience in caregiver-fabricated illness. Long-term morbidity or permanent disability is common in survivors.

#### Cutaneous Mimickers of Abuse and Factitious Disorders

Although child abuse or factitious disorders should always be considered in the child with unusual skin marks or injuries, there are several potential mimickers that must be kept in mind. These are summarized in Table 26-5.<sup>73,74</sup> Although they are not each discussed in detail here, it is important to recognize potential cutaneous mimickers in order to reduce the erroneous diagnosis of child abuse.<sup>75</sup>

There are a number of cultural practices that may be confused with abuse, given the trauma-induced skin lesions that result from these practices. With the increasing influx of Asian immigrants entering the United States, such traditional East Asian medicine methods are being practiced with increasing incidence. The philosophy of East Asian medicine is to achieve a state of balance and equilibrium, including proper flow of energies within “channels” or “meridians.”<sup>76</sup> The goal of traditional folk remedies is to facilitate this energy balance. It is important for the pediatric practitioner to be familiar with these culturally based therapies, which include coining/spooning, cupping, moxibustion, gridding, blood letting, and warm-needle acupuncture.<sup>76–78</sup> The former three entities will be briefly discussed here.

Coining is also known as spooning, coin rubbing, skin scraping, or *cao gio*. It is an ancient Vietnamese folk remedy performed by applying heated, mentholated oil to the back, chest, and shoulders and then vigorously rubbing a coin on selected parts of the body in order to produce linear petechiae or ecchymoses (Fig. 26-37).<sup>79</sup> Other items that may be used include a ceramic Chinese soup spoon, water-buffalo horn, piece of jade or ginger root, or edge of a jar cap. Whereas a coin is traditionally used by the Vietnamese, a spoon is commonly the instrument used by the Chinese, in which case the practice is referred to as *quat sha*.<sup>80</sup> Those who utilize coining believe it to be useful for a variety of complaints including headache, fever, pain,

**Figure 26-37** Coining. These linear and stellate purpuric patches were caused by the vigorous rubbing of a coin on the skin, termed *coining*, or *cao gio*. (Courtesy of Jean Hlady, MD.)

**Table 26-5** Potential Mimickers of Abuse or Factitial Disorders

Disorder	Chapter/Comment
Accidental burns	Various, including enuresis blanket, acetic acid, objects heated by sun (i.e., bike seats, car upholstery)
Allergic contact dermatitis	Ch. 3; may be confused with abuse, especially when vesicular or bullous
Anal fissures	Most commonly associated with constipation, passage of hard stools; however, occasionally associated with sexual abuse
Autoimmune bullous disease	Ch. 13; vulvar pemphigoid, linear IgA bullous disease of childhood
Behçet syndrome	Ch. 25
Berloque dermatitis	Ch. 19; phototoxic reaction to fragrance products
Bullous impetigo	Ch. 14; may be confused with cigarette burns
Crohn disease	Ch. 25; may present with perianal erythema, fissures, skin tags, bleeding, scarring, swelling
Ecthyma	Ch. 14; confused with cigarette burns; usually caused by GABHS
Ehlers–Danlos syndrome	Ch. 6; may have poor wound healing, scarring, easy bruising
Enlarged hymenal opening	Important reassuring features include intact hymenal tissue at posterior rim, lack of laceration/deep notching/bruising/bleeding <sup>73</sup>
Epidermal nevus	Ch. 9; perianal lesions may be confused with anogenital condylomata <sup>74</sup>
Epidermolysis bullosa	Ch. 13; especially dominant dystrophic or simplex varieties
Fixed drug eruption	Ch. 20
Folk remedies	Current chapter; see text
Hematologic disorders	Various, including hemophilia, von Willebrand disease, leukemia, ITP, vasculitis
Herpes zoster	Ch. 15; may be confused with abuse when involves genital (S2, S3) dermatomes
Incontinentia pigmenti	Ch. 11; vesicular and pigmentary lesions with bizarre patterning
Labial adhesions	
Lichen sclerosus et atrophicus	Ch. 22; genital variant confused with sexual abuse; may be bullous
Mongolian spots	Ch. 11
Netherton syndrome	Ch. 5; dermatitis, ichthyosis, failure to thrive, and alopecia may be confused for abuse
Nevus of Ota or Ito	Ch. 11
Normal bruising	Most commonly children 2–5 years of age; consider distribution, developmental status, history
Osteogenesis imperfecta	Ch. 6; frequent fractures, osteoporosis, short stature, frontal bossing, blue sclerae
Perianal pyramidal protrusion	Ch. 15
Perianal streptococcal dermatitis	Ch. 14
Phytophotodermatitis	Ch. 19; phototoxic reaction to psoralens (lemons, limes, celery, parsley, dill)
Vaginal foreign body	May result in vaginal discharge, bleeding
Xeroderma pigmentosum	Ch. 19; severe sunburn may be confused with neglect

GABHS, Group A β-hemolytic streptococci; IgA, immunoglobulin A; ITP, idiopathic thrombocytopenic purpura.

and inflammation. Although serious injury is rare, minor and even major burns (resulting from ignition of the oil in the skin) have been reported.<sup>79</sup>

Cupping is an ancient technique dating back to the fourth century BC in Egypt.<sup>81</sup> It is practiced in the United States most often by Russian immigrants but is also utilized within Asian and Mexican-American cultures (where it is referred to as *ventosas*).<sup>80</sup> It is used to relieve such symptoms as abdominal pain, abscesses, stroke paralysis, lower back pain, indigestion, menstrual irregularities, fever, congestion, and poor appetite. With this remedy, a cup or jar is immediately placed on the skin after a cotton-ball soaked with alcohol has been ignited within the cup to create a suction vacuum. The procedure results in circular ecchymotic lesions (Figs. 26-38 and 26-39) with eventual hyperpigmentation. In Middle-Eastern cultures, the skin may be initially lanced, with some blood drawn into the cup during the procedure. This has been referred to as *wet cupping*.

Moxibustion is another folk remedy utilized primarily in Asian cultures for a variety of complaints including enuresis, behavioral disorders, asthma, and pain.<sup>76,80</sup> It has also been utilized for correction of breech presentation<sup>82</sup> and for treatment of tennis elbow.<sup>83</sup> In moxibustion, the moxa herb (mugwort herb, *Artemisia vulgaris*) is rolled into a cone or cigar, ignited, and placed on the appropriate body part (either directly or indirectly with a medium separating the moxa from the skin). It is allowed to burn to the point of pain, and the resulting skin

**Figure 26-38** Cupping. This 7-year-old girl (right) who was brought to the clinic for an unrelated skin complaint was noted to have this round, ecchymotic lesion on her back. Examination of her mother (left) revealed multiple such lesions that were being induced by cupping in hopes of treating her rheumatoid arthritis. The family performed the procedure on the girl at her request.

**Figure 26-39** Cupping. Close-up image of the ecchymotic lesion seen in the female patient in [Figure 26-38](#).

lesions vary from transient redness to second-degree burns that resemble cigarette burns on acupuncture sites and may scar. As with all folk remedies, these lesions may be confused with intentional child abuse. Indirect moxibustion, in which the lit moxa stick is held near (not on) the skin until it turns red, is less painful and less often results in scarring.<sup>84</sup>
